concordance for dichorionic twins (Davis, Phelps, and Bracha 1995); though this work has not yet been replicated in ASD twins, in principle it opens the door to non-genetic interpretations of any concordance figures that have generally been assumed to be indicators of heritable genetics. The authors of this study interpreted their findings as consistent with data on viral infection as a contributor to schizophrenia risk (a possibility also entertained in ASDs (Patterson 2012; Teixeira and Barichello 2012; Atladottir et al. 2012, 2012; Hornig et al. 1999), but one could also consider the possibility of differences in the dichorionic cases in the integrity of the placental barrier.

All of this calls into question the idea that genetics can be presumed to be the 'cause' of autism simply based upon heritability calculations, and upgrades the importance of looking not only at the environment and environmentally vulnerable physiology, but also at acquired mutations. There is certainly progress being made through genetic research to the identification of networks of genes and mechanisms on which genes converge (Voineagu et al. 2011), but environmental mechanisms converge on these mechanisms too (Stamou et al. 2012), and the mechanisms are what drive the impacts.

Genotoxicity

One route through which environmental impacts may influence an organism's status is by changing genes through mutation – that is, by genotoxicity. This has been proposed as a mechanism for the generation of 'de novo' mutations (found in children but not their parents) being found in ASDs (Kinney et al. 2010) and increasingly in other settings as well, making mutations something that needs to be accounted for rather than simply assuming tey are associated with normal, stable variation. Reviews and published scientific papers on genotoxicity and EMF report that both ELF-EMF and RFR exposures can be considered genotoxic – i.e., damaging to DNA – under certain conditions of exposure, including under conditions of intermittent and/or chronic ELF and RFR exposure that are of low-intensity and below current world safety standards (Ruediger 2009; Ivancsits et al. 2005; Diem et al. 2005; Blank and Goodman 2011; Phillips, Singh, and Lai 2009; REFLEX 31 May 2004; Sage and Carpenter 2009; Lai and Singh 2004). Types of genetic damage reported have included DNA fragmentation and single- and double-strand DNA breaks, micronucleation and chromosome aberrations, all of which indicate genetic instability. Genotoxic impacts of EMF/RFR are further reviewed in the BioInitiative Working Group 2007 contribution by Lai as well as in Section 6 of the present Bioinitiative Report {Lai, 2007; Lai, 2012).

The European research program REFLEX (Risk Evaluation of Potential Environmental Hazards From Low-Energy Electromagnetic Field Exposure Using Sensitive in vitro Methods – a 5FP EU project) documented many changes in normal biological functioning in tests on DNA at exposure levels below existing public safety standards(REFLEX 31 May 2004). Some of the key findings included:

- Gene mutations, cell proliferation and apoptosis which are caused by or result in altered gene and protein expression profiles. The convergence of these events is required for the development of all chronic diseases.
- Genotoxic effects and a modified expression of numerous genes and proteins after EMF exposure could be demonstrated with great certainty.
- Genotoxic effects produced by RF-EMF in fibroblasts, HL- 60 cells, granulosa cells of rats and neural progenitor cells derived from mouse embryonic stem cells.
- Response of cells to RF exposure between SAR levels of 0.3 and 2 W/Kg with a significant increase in single- and double-strand DNA breaks and in micronuclei frequency.
- A clear demonstration of increase in intracellular generation of free radicals in HL-60 cells accompanying RF-EMF exposure.
- The observation that the induced DNA damage was not based on thermal effects, which raises concerns about the thermal-based environmental safety limits for ELF-EMF exposure.

These impacts could be contributors to a role for genetics in ASDs that does not derive from only inheritance but also from environmental and epigenetic influences. Moreover, in the light of the great heterogeneity of genetic findings in ASD alongside the documented impacts of EMF/RFR upon many other levels of pathophysiology than simply genetics, it becomes worth reflecting whether genetics might not be the primary problem but instead, in many cases at least, just one of many levels of collateral damage from environmental impacts. Whatever genetic variants a person carries may bias their system toward specific vulnerability, or may contribute more generically by increasing entropy and molecular disorder; in either capacity they may aggravate the situation but may not be part of the main cause.

Contributors to Genotoxicity

Oxidative stress and free radical damage to DNA

Oxidative stress and excessive free radical production are very well known to be potentially genotoxic. They can be a consequence of myriad environmental factors, including but by no means limited to EMF/RFR. The DNA damage that can result could very well be one cause of 'de novo' mutations. Although there is not a consensus at this time about the rates or causes of *de novo* mutations in ASDs, and using present methods of detection are only found in a small percentage of individuals with ASDs, given the potential contribution of environmentally triggered oxidative stress and free radical damage that we know is present in at least large numbers of people with ASDs, a serious investigation of the potential contribution of EMF and RFR to de novo mutations in ASD seems warranted, given the large increase in exposure to these phenomena accompanying the massively increased non-ionizing radiation exposures in daily life due to

electrification and the global saturation of RFR from wireless technologies (BioInitiative 2012 Report, Section 24, Public Health Implications, Sage and Carpenter, 2012).

Challenge to DNA repair mechanisms

Reduced DNA repair may contribute to increased risk of cancers, but it may also contribute to a variety of other diseases and disturbances of growth and development. When the rate of damage to DNA exceeds the rate at which DNA can be repaired, there is the possibility of retaining mutations and initiating pathology. Failure to trigger DNA damage repair mechanisms, or incomplete or failed repair, may be a consequence of a variety of commonplace stressors, including EMF/RFR exposure. A decrease in DNA repair efficiency has been reported to result from exposure to low-intensity RFR in human stem cells, and other cells. Mobile phone frequency GSM exposure at the frequency of 915 MHz consistently inhibited DNA repair foci in lymphocytes (Markova et al. 2005; Belyaev et al. 2005; Belyaev, Markova, and Malmgren 2009). Belyaev, Markova and colleagues (2005) and Markova et al. (2009) reported that very low-intensity microwave radiation from mobile phones inhibits DNA repair processes in human stem cells. A significant reduction in 53BP1 ((tumor suppressor p53 binding protein 1) foci was found in cells exposed to microwave radiofrequency radiation within one hour of exposure. Fibroblast cells were impacted in this fashion but adapted over time, whereas stem cells were similarly affected (inhibited 53BP1 foci) but did not adapt to microwave radiation during chronic exposure (Markova et al. 2005; Belyaev et al. 2005). Additional challenges to DNA repair mechanisms include not only toxicants and other damaging inputs but also nutritional insufficiencies of substances important to the proper functioning of DNA repair mechanisms, including Vitamin D, essential fatty acids, and minerals such as selenium and molybdenum (Christophersen and Haug 2011). The high possibility that various such contributors may combine supports an 'allostatic load' model of environmental injury and genotoxicity. Also note the overlap between nutritional risk factors for oxidative stress and for impaired DNA repair mechanisms. This supports a vicious circle model where the more oxidative damage to the genome, the less the cells will be prepared to deal with it successfully. It can also work the other way around – nutrients can attenuate the degree of damage; instances of this will be discussed in the Melatonin section below.

Chromatin condensation

Chromatin condensation is another hallmark of damage from EMF and RFR. Orderly chromatin condensation is a normal part of cell division, but it can also be provoked pathologically. The work of Markova, Belyaev and others has repeatedly shown that RFR exposure can cause chromatin condensation. Belyaev (1997) reported that super-low intensity RFR resulted in changes in genes, and chromatin condensation of DNA at intensities comparable to exposures from cell towers (typically at RFR levels of 0.1 to 1.0 uW/cm2) (Belyaev, Alipov, and Harms-Ringdahl 1997). Significant microwave-induced

changes in chromatin conformation were observed when rat thymocytes were analyzed in-between 30-60 min after exposure to MW (Belyaev and Kravchenko 1994). This effect nearly disappeared if the cells were incubated more than 80 min between exposure and analysis.

In recent studies, human lymphocytes from peripheral blood of healthy and hypersensitive to EMF persons were exposed to non-thermal microwave radiation NT MW) from the GSM mobile phones (Belyaev et al. 2005; Markova et al. 2005). NT MW induced changes in chromatin conformation similar to those induced by heat shock, which remained up to 24 h after exposure. The same group has reported that contrary to human fibroblast cells, which were able to adapt during chronic exposure to GSM/UMTS low intensity RFR exposure, human stem cells did not adapt (Belyaev, Markova, and Malmgren 2009).

Researchers have recently identified large numbers of "spontaneous genetic glitches," or de novo mutations, more likely to be transmitted by fathers than by mothers to their children (Neale et al. 2012; O'Roak et al. 2012; Sanders et al. 2012). These glitches are widely distributed across the genome, with their location rather than their size conferring risk. The Eichler team at the University of Washington found that 39% of the 126 most severe or disruptive mutations map to a network associated with chromatin remodeling that has already been ranked as significant amongst autism candidate genes (O'Roak et al. 2012). Whether the prominence of chromatin-related gene mutations can be related in any meaningful way to the impacts of EMF/RFR on chromatin condensation is not possible to say at this point in time and this apparent parallel between ASDs and EMF/RFR may be a pure coincidence, though an intriguing one worth looking into further, including regarding how these mutations and the chromatin-remodeling impacts of EMF/RFR exposure may interact.

Gonadal and germline impacts

De novo mutations have been shown to be more of a problem related to paternal age (O'Roak et al. 2012; Paul, Nagano, and Robaire 2011; Iossifov et al. 2012; Cantor et al. 2007; Alter et al. 2011), and this may be related to the impact of environmental factors such as EMF/RFR on the stem cell genome, particularly in sperm which have no DNA repair capacity. Vulnerability of testes and ova, and of sperm and egg cells, relates to the tissue milieu in which damage to the germline can take place, as well as on the greater vulnerability of stem cells. Several international laboratories have replicated studies showing adverse effects on sperm quality, motility and pathology in men who use and particularly those who wear a cell phone, PDA or pager on their belt or in a pocket (Agarwal et al. 2008; Agarwal et al. 2009; Wdowiak, Wdowiak, and Wiktor 2007; De Iuliis et al. 2009; Fejes et al. 2005; Aitken et al. 2005) Kumar, 2012). Other studies conclude that usage of cell phones, exposure to cell phone radiation, or storage of a

mobile phone close to the testes of human males affect sperm counts, motility, viability and structure (Aitken et al. 2004; Agarwal et al. 2007; Erogul et al. 2006). Animal studies have demonstrated oxidative and DNA damage, pathological changes in the testes of animals, decreased sperm mobility and viability, and other measures of deleterious damage to the male germ line (Dasdag et al. 1999; Yan et al. 2007; Otitoloju et al. 2010; Salama et al. 2009) Behari et al. 2006; Kumar et al. 2012). Of note, altered fatty acids consistent with oxidative stress have been found in sperm cells in male infertility (Zalata et al. 1998; Zalata, Hafez, and Comhaire 1995).

There are fewer animal studies that have studied effects of cell phone radiation on female fertility parameters. Panagopoulous et al. 2012 report decreased ovarian development and size of ovaries, and premature cell death of ovarian follicles and nurse cells in *Drosophila melanogaster* (Panagopoulos 2012). Gul et al (2009) report rats exposed to stand-by level RFR (phones on but not transmitting calls) caused decrease in the number of ovarian follicles in pups born to these exposed dams (Gul, Celebi, and Ugras 2009). Magras and Xenos (1997) reported irreversible infertility in mice after five (5) generations of exposure to RFR at cell phone tower exposure levels of less than one microwatt per centimeter squared (μW/cm2) (Magras and Xenos 1997).

Implications of genotoxicity

The issue of genotoxicity puts the contribution of genetic variation into a different light – as something that needs to be accounted for, not necessarily assumed as the starting point. In this regard it has been speculated that the apparent higher rates of autism in Silicon Valley, discussed in the past as related to 'geek genes' (Silberman 2001), might be conditioned by higher levels of exposure to EMF/RFR. The relationship between the greater vulnerability of male sperm than of female eggs to adverse effects of EMF/RFR exposure and the marked (4:1) predominance of paternal origin of de novo point mutations (4:1 bias), also deserves further careful attention (O'Roak et al. 2012).

5. Implications of Damage

We have reviewed parallels between ASD and EMF/RFR in molecular, cellular and tissue damage, including cellular stress (oxidative stress, the heat shock response and protein misfolding), injury of membranes, aberrant calcium signaling, and compromise of junctions and barriers. The genotoxicity of EMF/RFR was reviewed in relation to issues of environmental contributions to autism and of the phenomenon of de novo mutations. The compromise of the tissue substrate appears to have many commonalities in ASDs and in EMF/RFR exposures. Also notable was the possibility of attenuating some of the damage through increasing antioxidant status.

These commonalities come to mind in considering the implications of a recent study documenting arrest of symptomatology in a mouse model of Rett syndrome through a

bone marrow transplant of wild-type microglia (Derecki et al. 2012; Derecki, Cronk, and Kipnis 2012). The introduction of these competent microglia cells did not directly target the neuronal defect associated with the MECP2 gene mutation; instead the benefits of the transplant were diminished through inhibition of phagocytosis. Phagocytosis involves removing debris. This suggests that while research has focused on how specific molecular defects, particularly in the synapse, may contribute to Rett pathophysiology, there may also be an important contribution from cellular debris, misfolded proteins and other disordered cellular structure and function. Such disorder could be accumulating in cells under the conditions of pathophysiological disarray reviewed above. This has potentially broad implications for other genetic disorders, as well as for conditions like ASDs which are for the most part idiopathic. Based on this study as well as on the levels of damage just reviewed, problems in cells that are pertinent to ASDs most likely go beyond any specific defect introduced by a mutation. Additionally it is conceivable that many of the mutations may be not part of normal background variation but instead collateral damage from the same environmental factors that are also driving the damage to the pathophysiology. It is also encouraging that at least some of the damage and dysfunction was reversible by a generic cellular mechanism (phagocytosis), and this could have broad significance for idiopathic ASDs as well, along with other conditions involving related pathophysiological challenges.

B. Degradation of System Integrity

In the setting of molecular, cellular and tissue damage, one would predict that the organization and efficiency of a variety of organelles, organs and systems would also be degraded. EMF/RFR exposures yield a stressful situation of chronically interrupted homeostasis. Here we will review disturbances from EMF/RFR in systems (including include oxidative and bioenergetics metabolism, immune function and electrophysiological oscillations) that include molecular and cellular components subject to the kinds of damage discussed in the previous section. We will review disturbances that have been associated with EMF/RFR, and consider the parallel disturbances that have been documented in ASDs.

1. Mitochondrial dysfunction

Mitochondria are broadly vulnerable, in part because the integrity of their membranes is vital to their optimal functioning – including channels and electrical gradients, and their membranes can be damaged by free radicals which can be generated in myriad ways. Moreover, just about every step in their metabolic pathway can be targeted by environmental agents, including toxicants and drugs, as well as mutations (Wallace and Starkov 2000). This supports an allostatic load model for conditions in which mitochondrial dysfunction is an issue, which includes ASDs as well as myriad other chronic conditions.

Mitochondria are commonly discussed in terms of the biochemical pathways and cascades of events by which they metabolize glucose and generate energy. But in parallel with this level of function there also appears to be a dimension of electromagnetic radiation that is part of the activity of these organelles. For example, electromagnetic radiation can be propagated through the mitochondrial reticulum, which along with the mitochondria has a higher refractive index than the surrounding cell and can serve to propagate electromagnetic radiation within the network (Thar and Kuhl 2004). It is also the case that *"The physiological domain is characterized by small-amplitude oscillations in mitochondrial membrane potential (delta psi(m)) showing correlated behavior over a wide range of frequencies…. Under metabolic stress, when the balance between ROS [reactive oxygen species, or free radicals] generation and ROS scavenging [as by antioxidants] is perturbed, the mitochondrial network throughout the cell locks to one main low-frequency, high-amplitude oscillatory mode. This behavior has major pathological implications because the energy dissipation and cellular redox changes that occur during delta psi(m) depolarization result in suppression of electrical excitability and Ca2+ handling…"* (Aon, Cortassa, and O'Rourke 2008). These electromagnetic aspects of mitochondrial physiology and pathophysiology could very well be impacted by EMF/RFR.

There are also a variety of types of mitochondrial damage that have been documented in at least some of the studies that have examined the impacts of EMF/RFR upon mitochondria. These include reduced or absent mitochondrial cristae (Khaki et al. 2006; Lahijani, Tehrani, and Sabouri 2009; Esmekaya et al. 2011), mitochondrial DNA damage (Xu et al. 2010), swelling and crystallization (Lahijani, Tehrani, and Sabouri 2009), alterations and decreases in various lipids suggesting an increase in their use in cellular energetics (Chernysheva 1987), damage to mitochondrial DNA (Xu et al. 2010), and altered mobility and lipid peroxidation after exposures (Wang et al. 2002). Also noted has been enhancement of brain mitochondrial function in Alzheimer's transgenic mice and normal mice (Dragicevic et al. 2011). The existent of positive as well as negative effects gives an indication of the high context dependence of exposure impacts, including physical factors such as frequency, duration, and tissue characteristics; these are

intensively reviewed in Belyaev's contribution to BioInitiative 2012 in Section 15 (Belyaev 2012).

The idea that mitochondrial dysfunction might be common in ASDs met with a fair bit of consternation, and many professionals have preferred to limit their consideration to mitochondrial disorders with proven genetic mutations. However the concept of mitochondrial dysfunction is better established in other areas of medicine, with thousands of papers and hundreds of reviews carrying "mitochondrial dysfunction" in their titles. By now there is a large amount of evidence for biochemical and other abnormalities in a large portion of children with autism that are consistent with mitochondrial dysfunction (Giulivi et al. 2010; Palmieri et al. 2010; Pastural et al. 2009). Recently published postmortem brain tissue studies that have added a new dimension of evidence for mitochondrial abnormalities in ASDs will be reviewed in the section on alteration of brain cells below.

Some have called the mitochondrial issues most commonly seen in ASDs 'secondary mitochondrial dysfunction' (Zecavati and Spence 2009; Rossignol and Frye 2011) to indicate that it results from environment insults and/or other pathophysiological dysfunction rather than directly from genetics (Hadjixenofontos et al. 2012); the already discussed potential for EMF/RFR to damage channels, membranes and mitochondria themselves could contribute in a number of ways to degrading mitochondrial function without a basis in genetic mutation, as could toxicant exposures and immune challenges. In a meta-analysis of studies of children with ASD and mitochondrial disorder, the spectrum of severity varied, and 79% of the cases were identified by laboratory not associated with genetic abnormalities (Rossignol and Frye 2011). "*Substantial percentages of autistic patients display peripheral markers of mitochondrial energy metabolism dysfunction, such as (a) elevated lactate, pyruvate, and alanine levels in blood, urine and/or cerebrospinal fluid, (b) serum carnitine deficiency, and/or (c) enhanced oxidative stress……In some patients, these abnormalities have been successfully explained by the presence of specific mutations or rearrangements in their mitochondrial or nuclear DNA. However, in the majority of cases, abnormal energy metabolism cannot be immediately linked to specific genetic or genomic defects."* (Palmieri and Persico 2010)

2. Melatonin dysregulation

Melatonin, mitochondria, glutathione, oxidative stress

Melatonin is well-known for its role in regulation of circadian rhythms, but it also plays important metabolic and regulatory roles in relation to cellular protection, mitochondrial malfunction and glutathione synthesis. (Leon et al. 2005; Luchetti et al. 2010; Limon-Pacheco and Gonsebatt 2010) *"It is known that melatonin scavenges oxygen and*

nitrogen-based reactants generated in mitochondria. This limits the loss of the intramitochondrial glutathione and lowers mitochondrial protein damage, improving electron transport chain (ETC) activity and reducing mtDNA damage. Melatonin also increases the activity of the complex I and complex IV of the ETC, thereby improving mitochondrial respiration and increasing ATP synthesis under normal and stressful conditions." (Leon et al. 2005) It also helps prevent the breakdown of the mitochondrial membrane potential, decrease electron leakage, and thereby reduce the formation of superoxide anions. (Hardeland 2005) Pharmacological doses of melatonin not only scavenge reactive oxygen and nitrogen species, but enhance levels of glutathione and the expression and activities of some glutathione-related enzymes. (Limon-Pacheco and Gonsebatt 2010; Gupta, Gupta, and Kohli 2003)

Melatonin can attenuate or prevent some EMF/RFR effects

Melatonin may have a protective effect in the setting of some EMF/RFR exposures, apparently in relation to these functions just described. EMF/RFR can impact melatonin; one example is exposure to 900-MHz microwave radiation promoted oxidation, which reduced levels of melatonin and increased creatine kinase and caspase-3 in exposed as compared to sham exposed rats (Kesari, Kumar, and Behari 2011).

Further types of adverse impacts can be seen in the next set of examples, but what is interesting is that melatonin can attenuate or prevent them. In an experiment exposing rats to MW from a GSM900 mobile phone with and without melatonin treatment to study renal impacts (Oktem et al. 2005), the untreated exposed rats showed increases of lipid peroxidation markers as reduction of the activities of superoxide dismutase, catalase and glutathione peroxidase indicating decrement in antioxidant status. However these negative effects were inhibited in the exposed rats treated with melatonin. Melatonin also inhibited the emergence of preneoplastic liver lesions in rats exposed to EMFs (Imaida et al. 2000). The development of DNA strand breaks was observed in RFR exposed rats; this DNA damage was blocked by melatonin (Lai and Singh 1997). Exposure of cultured cortical neurons to EMF led to an increase in 8-hydroxyguanine in neuronal mitochondria, a common biomarker of DNA oxidative damage, along with a reduction in the copy number of mitochondrial DNA and the levels of mitochondrial RNA transcripts; but these effects could all be prevented by pretreatment with melatonin (Xu et al. 2010). In a study of skin lesion induced by exposure to cell phone radiation, the skin changes in the irradiated group (which included thicker stratum corneum, epidermal atrophy, papillamatosis, basil cell proliferation, increased epidermal granular cell layer and capillary proliferation, impaired collagen tissue distribution and separation of collagen bundles in dermis) were prevented (except for hypergranulosis) by melatonin treatment (Ozguner et al. 2004). Melatonin as well as caffeic acid phenyethyl ester (an antioxidant) both protected against retinal oxidative stress in rates exposed long-term to mobile phone irradiation (Ozguner, Bardak, and Comlekci 2006). Nitric oxide (NO) was increased in

nasal and sinus mucosa in rats after EMF exposure, with this NO possibly acting as a defense mechanism suggesting tissue damage; but this was prevented by pretreatment with melatonin (Yariktas et al. 2005). Melatonin treatment significantly prevented the increase in the MDA (malondyaldehyde, a marker of lipid peroxidation) content and XO (xanthine oxidase) activity in rat brain tissue after 40 days of exposure, but it was unable to prevent the decrease of CAT activity and increase of carbonyl group contents (Sokolovic et al. 2008).

Of note, the melatonin production of infants in isolettes in neonatal intensive care units appears to be impacted by the high ELF-EMF environment, in that when infants were removed from those exposures they showed an increase in melatonin levels (Bellieni, Tei, et al. 2012). There is an increased prevalence of ASDs in children who were born prematurely (Indredavik et al. 2010; Indredavik et al. 2008; Johnson et al. 2011; Johnson et al. 2010; Johnson and Marlow 2011; Lampi et al. 2012; Limperopoulos 2009, 2010; Limperopoulos et al. 2008; Matson, Matson, and Beighley 2011; Pinto-Martin et al. 2011). There are many potential prematurity-associated factors that could contribute to increased risk for ASDs, but electromagnetic exposure might be one of them worthy of further consideration, as it could be modified; conversely, such exposures in vulnerable infants are likely to have much broader impacts beyond reducing melatonin synthesis.

Melatonin and autism

Based on the commonality of both sleep disorders and low melatonin levels, Bourgeron (2007) proposed that synaptic and clock genes are important in ASDs, and that future studies should investigate the circadian modulation of synaptic function (Bourgeron 2007). A number of melatonin-related genetic variants have been identified as associated with ASDs. Polymorphisms, deletions and polymorphisms in the ASMT gene, which encodes the last enzyme of melatonin synthesis, have been found (Pagan et al. 2011; Jonsson et al. 2010; Melke et al. 2008), and variations have been found as well for melatonin receptor genes (Chaste et al. 2010; Pagan et al. 2011; Jonsson et al. 2010). CYP1A2 polymorphisms have been found in slow melatonin metabolisers, in whom melatonin levels are aberrant and initial response to melatonin for sleep disappeared in a few weeks (Braam et al. 2012).

Regarding melatonin status in people with ASDs, a recent meta-analysis summarized the current findings as indicating that *"1) Physiological levels of melatonin and/or melatonin derivatives are commonly below average in ASD and correlate with autistic behavior, 2) Abnormalities in melatonin-related genes may be a cause of low melatonin levels in ASD, and 3) … treatment with melatonin significantly improves sleep duration and sleep onset latency in ASD."* (Rossignol and Frye 2011) The meta-analysis also showed that polymorphisms in melatonin-related genes in ASD could contribute to lower melatonin

concentrations or an altered response to melatonin, but only in a small percentage of individuals, since pertinent genes were found in only a small minority of those screened.

Autism AND Melatonin AND Glutathione

Whereas PubMed searches for "autism AND melatonin" and "autism AND glutathione" each coincidentally yielded 72 citations, and "melatonin AND glutathione" yielded 803 citations, the search for "autism AND melatonin AND glutathione" yielded zero citations. This is interesting given the strong connection of melatonin and glutathione metabolically, as discussed above, alongside of the strongly established interest in both glutathione and melatonin in ASD research and increasingly in clinical practice. Hopefully one contribution of an investigation of EMF/RFR links to ASDs will be to help bring attention to this relationship, which may help identify potential environmental and physiological causes for low melatonin in those without pertinent mutations. Of pertinence, tryptophan hydroxylase (TPH2) – the rate limiting enzyme in the synthesis of serotonin, from which melatonin is derived – is extremely vulnerable to oxidation, and tends to misfold when its cysteine residues are oxidized, with the enzyme being converted to a redox-cycling quinoprotein (Kuhn and Arthur 1999; Kuhn and Geddes 1999; Kuhn et al. 2011; Kuhn and Arthur 1997).

3. Disturbed immune function

There is by now a broad appreciation of the presence of immune disturbances in ASDs, to the point where there is an emerging discussion of ASDs as neuroimmune disorders (Bilbo, Jones, and Parker 2012; Persico, Van de Water, and Pardo 2012). Research identifying immune features in ASDs spans from genetics where risk genes have been identified to epigenetics where altered expression of immune genes is being reported as prominent in ASD epigenetics (Kong et al. 2012; Waly et al. 2012; Lintas, Sacco, and Persico 2012), and also includes prenatal infectious and immune disturbances as risk factors for autism as well as other neurodevelopmental and neuropsychiatric diseases as well as other conditions such as asthma (Patterson 2011; Smith et al. 2007; Fox, Amaral, and Van de Water 2012). Immune disturbances in infants and children with ASD are heterogeneous, with some but not all manifesting autoimmunity (Soumiya, Fukumitsu, and Furukawa 2011; Martin et al. 2008). Anecdotally, recurrent infection is common while on the other hand some get sick less often than their peers. It is common for people with autism to have family members with immune or autoimmune diseases (Croen et al. 2005). The immune system is turning out to have an important role in brain development (Bilbo and Schwarz 2012; Schwarz and Bilbo 2012; Boksa 2010). As mentioned, glial activation associated with brain immune response has been identified in a growing number of studies. Whether or not EMF/RFR contributes to these features of ASDs causally, based on the evidence below regarding immune impacts of EMF/RFR exposure (which is also reviewed much more thoroughly by Johansson in Section 8 of the present

Bioinitiative Report) (Blank 2012), it is certainly plausible that such exposures could serve as aggravating factors.

Low-intensity exposures

It is clear that the body's immune defense system responds to very low-intensity exposures. Chronic exposure to factors that increase allergic and inflammatory responses on a continuing basis is likely to be harmful to health, since the resultant chronic inflammatory responses can lead to cellular, tissue and organ damage over time. We are increasingly appreciating the extent to which many chronic diseases are related to chronic immune system dysfunction. Disturbance of the immune system by very low-intensity electromagnetic field exposure is discussed as a potential underlying cause for cellular damage and impaired healing (tissue repair), which could lead to disease and physiological impairment (Johansson 2009; Johannson 2007).

Both human and animal studies report that exposures to EMF and RFR at environmental levels associated with new technologies can be associated with large immunohistological changes in mast cells as well as other measures of immune dysfunction and dysregulation. Mast cells not only can degranulate and release irritating chemicals leading to allergic symptoms; they are also widely distributed in the body, including in the brain and the heart, which might relate to some of the symptoms commonly reported in relation to EMF/RFR exposure (such as headache, painful light sensitivity, and cardiac rhythm and palpitation problems).

Consequences of immune challenges during pregnancy

As mentioned, infection in pregnancy can also increase the risk of autism and other neurodevelopmental and neuropsychiatric disorders via maternal immune activation (MIA). Viral, bacterial and parasitic infections during pregnancy are thought to contribute to at least 30% of cases of schizophrenia (Brown and Derkits 2010). The connection of maternal infection to autism is supported epidemiologically, including in a Kaiser study where risk was associated with psoriasis and with asthma and allergy in the second trimester (Croen et al. 2005), and in a large study of autism cases in the Danish Medical registry (Atladottir et al. 2010) with infection at any point in pregnancy yielding an adjusted hazard ration of 1.14 (CI: 0.96-1.34) and when infection occurred during second trimester the odds ratio was 2.98 (CI: 1.29-7.15). In animal models, while there is much variation in study design, mediators of the immune impact appear to include oxidative stress, interleukin-6 and increased placental cytokines (Smith et al. 2007; Patterson 2009; Boksa 2010). Garbett et al. (2012) commented on several mouse models of the effects of MIA on the fetal brain that *"The overall gene expression changes suggest that the response to MIA is a neuroprotective attempt by the developing brain to counteract environmental stress, but at a cost of disrupting typical neuronal differentiation and axonal growth."* (Garbett et al. 2012). Maternal fetal brain-reactive

autoantibodies have also been identified in some cases (Braunschweig et al. 2012; Braunschweig and Van de Water 2012; Fox, Amaral, and Van de Water 2012; Goines et al. 2011; Wills et al. 2009; Wills et al. 2011; Zimmerman et al. 2007).

Although we have evidence of immune impacts of EMF/RFR, the impact of repeated or chronic exposure to EMF and RFR during pregnancy is poorly studied; could this trigger similar immune responses (cytokine production) and stress protein responses, which in turn would have effects on the fetus? Although this has been poorly studied, we do have data that very low cell phone radiation exposures during both human and mouse pregnancies have resulted in altered fetal brain development leading to memory, learning, and attention problems and behavioral problems (Aldad et al. 2012).

Potential immune contributions to reactivity and variability in ASDs

Immune changes in ASDs appear to be associated with behavioral change (Shi et al. 2003; Ashwood et al. 2008; Ashwood et al. 2011; Breece et al. 2012; Heuer et al. 2008), but the mechanisms are complex and to date poorly understood (Careaga and Ashwood 2012) and likely will need to be elucidated through systems biology methods that capture multisystem influences on the interactions across behavior, brain and immune regulation (Broderick and Craddock 2012), including electrophysiology.

Two of the particularly difficult parts of ASDs are the intense reactivity and the variability in assorted symptoms such as tantrums and other difficult behaviors. Children with ASDs who also have gastrointestinal symptoms and marked fluctuation of behavioral symptoms have been shown to exhibit distinct innate immune abnormalities and transcriptional profiles of peripheral blood monocytes (Jyonouchi et al. 2011). It is worth considering EMF/RFR exposures could be operating through related mechanisms so as to add to allostatic loading in ways that exacerbate behavior. In Johansson 2006 and 2007 a foundation is provided for understanding how chronic EMF/RFR exposure can compromise immune function and sensitize a person to even small exposures in the future (Johannson 2007; Johansson et al. 2006). Johansson discusses alterations of immune function at environmental levels resulting in loss of memory and concentration, skin redness and inflammation, eczema, headache, and fatigue. Mast cells that degranulate under EMF and RFR exposures and substances secreted by them (histamine, heparin and serotonin) may contribute to features of this sensitivity to electromagnetic fields (Johansson et al. 2006). Theoharides and colleagues have argued that environmental and stress related triggers might activate mast cells, causing inflammatory compromise and leading to gut-blood-brain barrier compromise, seizures and other ASD symptoms (Theoharides et al. 2012, 2010), and that this cascade of immune response and its consequences might also be triggered in the absence of infection by mitochondrial fragments that can be released from cells in response to stimulation by IgE/anti-IgE or by the proinflammatory peptide substance P (Zhang, Asadi, et al. 2012).

Seitz et al. (2005) reviewed an extensive literature on electromagnetic hypersensitivity conditions reported to include sleep quality, dizziness, headache, skin rashes, memory and concentration impairments related to EMF and RFR (Seitz, 2005). Some of these symptoms are common in ASDs, whether or not they are due to EMF/RFR exposure, and the experience of discomfort may be hard to document due to difficulties with self-reporting in many people with ASDs.

Johansson (2007, 2009) also reports that benchmark indicators of immune system allergic and inflammatory reactions occur under exposure conditions of low-intensity non-ionizing radiation (immune cell alterations, mast cell degranulation histamine-positive mast cells in biopsies and immunoreactive dendritic immune cells) (Johannson 2007; Johansson 2009). In facial skin samples of electro- hypersensitive persons, the most common finding is a profound increase in mast cells as monitored by various mast cell markers, such as histamine, chymase and tryptase (Johansson et al. 2001). In ASDs, infant and childhood rashes, eczema and psoriasis are common, and they are common in family members as well (Bakkaloglu et al. 2008).

4. Alteration of and damage to cells in the brain

Brain cells have a variety of ways of reacting to environmental stressors, such as shape changes, metabolic alterations, upregulation or downregulation of neurotransmitters and receptors, other altered functionality, structural damage, production of un-metabolizable misfolded proteins and other cellular debris, and apoptosis; these range along a spectrum from adaptation to damage and cell death. These types of alterations can be looked at in animals under controlled conditions, but in human beings direct cellular examination can only be done on surgical biopsy tissue – which is hardly ever available in people with ASDs – or after death, at which point there has been a whole lifetime of exposures that are generally impossible to tease apart if there were even motivation to do so. This complicates the comparison of brain cell and tissue-related pathophysiology between what is seen in ASDs and what is associated with EMF/RFR exposures.

Brain cells

Impact of EMF/RFR on cells in the brain has been documented by some of the studies that have examined brain tissue after exposure, although the interpretation of inconsistencies across studies is complicated by sometimes major differences in impact attributable to differences in frequencies and duration of exposure, as well as to differences in resonance properties of tissues and other poorly understood constraints on cellular response. These studies and methodological considerations have been reviewed in depth in Belyaev, 2012 in section 15 of the 2012 BioInitiatve Report (Belyaev 2012), as well as by Salford et al. (2012) in Section 10 (Salford, Nittby, and Persson 2012). A few examples of observations after exposure have included dark neurons (an indicator of neuronal damage), as well as alteration of neuronal firing rate (Bolshakov and Alekseev

1992), and upregulation of genes related to cell death pathways in both neurons and astrocytes (Zhao, Zou, and Knapp 2007). Astrocytic changes included increased GFAP and increased glial reactivity (Chan et al. 1999; Ammari et al. 2008; Ammari et al. 2010; Brillaud, Piotrowski, and de Seze 2007), as well as astrocyte-pertinent protein expression changes detected by Fragopoulou et al, 2012 as mentioned above. Also observed has been a marked protein downregulation of the nerve growth factor glial maturation factor beta (GMF) which is considered as an intracellular signal transduction regulator in astrocytes, which could have significant impact on neuronal-glial interactions as well as brain cell differentiation and tumor development. Diminution of Purkinje cell number and density has also been observed, (Ragbetli et al. 2010) including in two studies of the impacts of perinatal exposure (Albert, 1981; Albert, 1981). Promotion of pro-inflammatory responses in EMF-stimulated microglial cells has also been documented (Yang et al. 2010).

Neuropathology findings in ASDs have been varied and have been interpreted according to various frameworks ranging from a regionalized approach oriented to identifying potential brain relationships to ASD's behavioral features (Amaral, Schumann, and Nordahl 2008) to identifying receptor, neurotransmitter and interneuron abnormalities that could account for an increased excitation/inhibition ratio (Levitt 2009; Geschwind 2007; Anney 2010; Casanova 2006; Rubenstein 2003). Studies have documented a range of abnormalities in neurons, including altered cellular packing in the limbic system, reduced dendritic arborization, and reductions in limbic GABAergic systems. Over the past decade a shift has occurred from presuming that all pertinent brain changes occurred prior to birth, to an acknowledgement that ongoing cellular processes appear to be occurring not only after birth but well into adulthood (Bauman and Kemper 2005). One of the reasons for this shift was the observation that head size (as well as brain weight and size) was on average larger in children with autism, and the head sizes of children who became diagnosed with autism increased in percentile after birth (Herbert 2005).

Neuroinflammation, glial activation and excitotoxicity

Although much attention has been paid in ASD brain literature to specific regions manifesting differences in size and activity in comparison to those without ASDs, there are other observations that are not strictly regional in nature, such as more widely distributed scaling differences (e.g. larger brains, wider brains, increased white matter volume, along with altered functional connectivity and coherence to be discussed below). Recently more studies have appeared identifying pathophysiological abnormalities such as neuroinflammation, mitochondrial dysfunction and glutathione depletion in brain tissue. Neuroinflammation was first identified in a study of postmortem samples from eleven individuals aged 5-44 who had died carrying an ASD diagnosis, in which activated astrocytes and microglial cells as well as abnormal cytokines and chemokines were found. Other research has identified further astrocyte abnormalities include, altered

expression of astrocyte markers GFAP abnormalities including elevation, antibodies, and altered signaling (Laurence 2005; Singh 1997; Fatemi et al. 2008). Increased microglia activation and density as well as increased myeloid dendritic cell frequencies have also been documented. (Vargas et al. 2005; Breece et al. 2012; Tetreault et al. 2012), as has abnormal microglial-neuronal interactions (Morgan et al. 2012). Recently through use of the PET ligand PK11105 microglial activation was found to be significantly higher in multiple brain regions in young adults with ASDs (Suzuki et al. 2013). Genes associated with glial activation have been documented as upregulated. Garbett et al measured increased transcript levels of many immune genes, as well as changes in transcripts related to cell communication, differentiation, cell cycle regulation and chaperone systems (Garbett et al. 2008). Voineaugu and colleagues performed transcriptomic analysis of autistic brain and found a neuronal module of co-expressed genes which was enriched with genetically associated variants, and an immune-glial module showing no such enrichment for autism GWAS signals (Voineagu et al. 2011).

Neuroinflammation also does not appear to be strictly localized in a function-specific fashion, and it may contribute both to more broadly distributed and more focal features for tissue-based reasons. It may be that brain regions with particular prominence in ASDs may have distinctive cellular characteristics – e.g. the amygdala (Baron-Cohen et al. 2000; Dziobek et al. 2010; Hall et al. 2010; Mercadante et al. 2008; Nordahl et al. 2012; Otsuka et al. 1999; Schulkin 2007; Schumann and Amaral 2006; Schumann et al. 2009; Truitt et al. 2007; Zirlinger and Anderson 2003), which may have a larger or more reactive population of astrocytes (Johnson, Breedlove, and Jordan 2010) or the basal ganglia which may have greater sensitivity to even subtle hypoxia or perfusion abnormalities. In this case it may be the histology of these areas that makes them vulnerable to environmental irritants, and this may contribute to how environmental factors such as EMF/RFR might trigger or aggravate some of ASD's features. More widely distributed brain tissue pathology be part of what leads to differences in ASDs in brain connectivity. However these types of tissue-function relationships have been poorly investigated. The contribution of tissue differences is one of the physical considerations covered by Belyaev (2012) in Section 15 of the 2012 BioInitiative Report (Belyaev, 2012).

Various signs of mitochondrial dysfunction and oxidative stress have also been identified in the brain. Findings include downregulation of expression of mitochondrial electron transport genes (Anitha, Nakamura, Thanseem, Matsuzaki, et al. 2012) or deficit of mitochondrial electron transport chain complexes (Chauhan et al. 2011), brain region specific glutathione redox imbalance (Chauhan, Audhya, and Chauhan 2012), and evidence of oxidative damage and inflammation associated with low glutathione redox status (Rose, Melnyk, Pavliv, et al. 2012). Oxidative stress markers were measured as increased in cerebellum (Sajdel-Sulkowska, Xu, and Koibuchi 2009).

Additional support for the presence of tissue pathophysiology-based changes in brains of people with ASDs comes from the various studies documenting reduction in Purkinje cell numbers (Whitney et al. 2009; Whitney et al. 2008; Bauman and Kemper 2005; Shi et al. 2009; Blatt and Fatemi 2011; Fatemi et al. 2002; Fatemi et al. 2012), possibly due to oxidative stress and an increased excitation/inhibition ratio that could potentially be acquired (Fatemi et al. 2012). Also of note are changes in the glutamatergic and GABAergic systems, which when imbalanced can disturb the excitation/inhibition ratio and contribute to seizure disorders; reductions in GABA receptors as well as in GAD 65 and 67 proteins that catalyse the conversion of glutamate into GABA have been measured. (Yip, Soghomonian, and Blatt 2007, 2008, 2009) A consensus statement on the cerebellum in ASDs stated that, *"Points of consensus include presence of abnormal cerebellar anatomy, abnormal neurotransmitter systems, oxidative stress, cerebellar motor and cognitive deficits, and neuroinflammation in subjects with autism."* (Fatemi et al. 2012)

Some indirect corroboration for these findings has come from neuroimaging, where the initial hypothesis regarding the tissue basis of the larger size of brains in so many people with autism – that it was due to a higher density of neurons and more tightly packed axons – came under question with the emergence of contradictory findings, well reviewed a few years ago by Dager and colleagues (Dager et al. 2008). These include reduced rather than increased density of NAA (n-acetylaspartate, a marker of neuronal integrity and density that is produced in the mitochondria), reduced rather than increased fractional anisotropy suggesting less tightly packed axonal bundles (Bode et al. 2011; Cascio et al. 2012; Mak-Fan et al. 2012; Travers et al. 2012; Walker et al. 2012; Wolff et al. 2012); Sundaram, 2008) and greater rather than lower diffusivity, all of which may be more consistent with lower density of tissue and tissue metabolites and more fluid, which could be consistent with neuroinflammation and/or oxidative stress. The early postnatal development of such lower fractional anisotropy and increased diffusivity was measured in the process of occurring recently, in the first large prospective longitudinal imaging study of infants, who trended from 6 months to 2 years in the direction of these findings becoming more pronounced – but still with substantial overlap with those infants who did not develop autism (Wolff et al. 2012). This trend was consistent with prior studies showing increase in head size after birth, and added some information about what was happening in the brain to drive this size increase, although due to its methods it could only indirectly address the possibilty that emergence during the first few years of life of tissue pathophysiology disturbances such as neuroinflammation might be contributing to these trends (Herbert 2012).

There is also substantial variability across many different types of brain findings. Of interest is that a number of functional brain imaging and electrophysiology studies have identified greater heterogeneity in response to stimuli between individuals in the ASD

group than individuals in the neurotypical control group (Muller et al. 2003; Dinstein et al. 2012). This may make more sense from the point of view of non-linear response – i.e. a disproportionality between output and input (as well as state and context sensitivity), in a pathophysiologically perturbed brain system. Nonlinearity has also been a significant methodological issue in EMF/RFR research because linear methods of study design and data analysis have often been insensitive to effects, whereas nonlinear methods have been argued to show greater sensitivity (Carrubba and Marino 2008; Marino, Wolcott, Chervenak, Jourd'heuil, Nilsen, Frilot, et al. 2001; Marino and Frilot 2003; Carrubba et al. 2006; Carrubba et al. 2012; Marino, Nilsen, and Frilot 2003; Marino, Wolcott, et al. 2001, 2001; Carrubba et al. 2007; Marino et al. 2000; Bachmann, 2005).

The presence of various types of tissue pathophysiology both in findings in postmortem tissue from individuals with ASDs and in documented impacts of EMF/RFR exposure are intriguing and suggest overlap in processes involved. But it is not really possible to infer any specific agent of injury from cellular responses since for the most part these are not specific but rather are stress or repair responses generic to a variety of triggers. It is important to entertain how environmental agents could contribute to brain changes in ASDs, and how these changes may develop over progress over time after the earliest periods in brain development. EMF/RFR exposures could be preconceptional, prenatal or postnatal – or all of the above; it is conceivable that this could be the case in ASDs as well.

Altered development

There is some evidence for altered brain and organism development in relation to EMF/RFR exposure. Aldad et al. 2012 exposed mice in utero to cellular telephone radiation, with resultant aberrant miniature excitatory postsynaptic currents, dose-responsive impaired glutamatergic synaptic transmission onto layer V pyramidal neurons of the prefrontal cortex (Aldad et al. 2012). Lahijani exposed preincubated chicken embryos to 50 Hz EMFs, and made the following morphological observations: *"exencephalic embryos, embryos with asymmetrical faces, crossed beak, shorter upper beak, deformed hind limbs, gastroschesis, anophthalmia, and microphthalmia. H&E and reticulin stainings, TEMS, and SEMs studies indicated EMFs would create hepatocytes with fibrotic bands, severe steatohepatitis, vacuolizations, swollen and extremely electron-dense mitochondria, reduced invisible cristae, crystalized mitochondria with degenerated cristae, myelin-like figures, macrophages engulfing adjacent cells, dentated nuclei, nuclei with irregular envelopes, degenerated hepatocytes, abnormal lipid accumulations, lipid droplets pushing hepatocytes' nuclei to the corner of the cells, abundant cellular infiltrations cellular infiltrations inside sinusoid and around central veins, disrupted reticulin plexus, and release of chromatin into cytosol,, with partially regular water layers,"* and attributed cell damage to elevated free radical induced cell membrane disruptions (Lahijani, Tehrani, and Sabouri 2009).

Although it is of great interest to characterize the changes in development associated with ASDs, it is also difficult to do in human beings because at present diagnosis is not possible until at least 2-3 years after birth. By now there have been a lot of prospective studies of infants at high risk for autism, but the in vivo brain imaging and electrophysiology data from these studies is only starting to be published, and so the for now the main sources of information are still inference backwards from post-mortem or imaging data, and animal models, both of which have clear limitations. Thus it is impossible to seek precise parallels here between what we know about the development of ASDs compared with the impacts of EMF/RFR exposures.

Nevertheless it is of real concern that such exposures have elicited some of the brain tissue changes that have been documented, both in early development and subsequently. Already noted above is the question of whether high exposures of neonates to monitoring equipment may affect the melatonin levels of neonates (Bellieni, Tei, et al. 2012); these exposures also impact heartrate variability . There are no studies yet on infants exposed to baby surveillance monitors or DECT wireless phones. However there are good laboratory testing studies yielding actual measurements of these devices that conclude: "*Maximum incident field exposures at 1m can significantly exceed those of base stations (typically 0.1 - 1 V/m). At very close distances the derived or reference exposure limits are violated" for baby surveillance monitors and DECT phones.* Further, the authors conclude that, based on very strictly controlled laboratory testing of everyday devices like baby monitors and some cordless phones *"(W)orse case peak spatial SAR values are close to the limit for the public or uncontrolled environments, e.g., IEEE802.11b and Bluetooth Class I".*(Kuhn et al. 2012) Even exposure of the fetus to laptop computer wireless emissions through the pregnant mother's use of them may on her lap involve induction of strong intracorporeal electric current densities from the power supply possibly even more than the device itself (Bellieni, Pinto, et al. 2012).

Brain blood flow and metabolism

Cerebral perfusion and metabolism abnormalities have been identified in close to 2 dozen papers studying autistic cohorts. Cerebral perfusion refers to the quantity of blood flow in the brain. Abnormal regulation of cerebral perfusion is found in a range of severe medical conditions including tumors, vascular disease and epilepsy. Cerebral hypoperfusion has also been found in a range of psychiatric disorders (Theberge 2008). Neurocognitive hypotheses and conclusions, as well as localization of perfusion changes, have been heterogeneous across these papers. Hypoperfusion or diminished metabolism has been identified in frontal regions (George, 1992; Gupta, 2009; Degirmenci, 2008; Wilcox, 2002; Galuska, 2002; Ohnishi, 2000; temporal lobes (Boddaert, 2002 ; Burroni, 2008 ; Degirmenci, 2008, Galuska, 2002, George, 1992 ; Hashimoto, 2000, Ohnishi, 2000, Ryu, 1999, Starkstein, 2000, Zilbovicius, 2000), as well as a variety of subcortical regions including basal ganglia (Degirmenci, 2008; Ryu, 1999; Starkstein, 2000),

cerebellum (Ryu, 1999), limbic structures (Ito, 2005, Ohnishi, 2000) and thalamus (Ito, 2005, Ryu, 1999, Starkstein, 2000) – i.e., in a widely distributed set of brain regions. It is interesting to note that even with this regional variation in localization, most of these publications showed that cerebral perfusion was *reduced*; in the only one of those studies reporting some areas of localized hyperfusion, these areas were found in the middle of areas in the frontal pole and temporal lobe that were hypoperfused (McKelvey 1995), Only one study showed no difference in perfusion between autistic and control subjects (Herold 1988). Possibly because virtually all of these studies were oriented toward testing neuropsychological rather than pathophysiological hypotheses, there were no probes or tests reported to unearth the tissue level alterations that might be underlying these reductions in blood flow in these brains.

While a large number of animal studies have documented BBB abnormalities from EMF/RFR exposures, only a few PET studies have been performed evaluating EMF exposure effects upon brain glucose metabolism. Volkow et al. performed PET scans both with and without EMF exposure (50 min of GSM-900 with maximum SAR of 0.901 W/kg), and the participants were blinded to the exposure situation (Volkow et al. 2011). A 7% increase in metabolism in the exposure situation compared to controls was identified regionally on the same side of the head as where the mobile phone was placed, in the right orbitofrontal cortex and in the lower part of the right superior temporal gyrus . The strength of the E-field from the phones correlated positively with the brain activation, which the authors hypothesized was from an increase in brain neuron excitability. . A subsequent smaller study by Kwon et al. demonstrated not increased but decreased brain ^{18}FDG uptake after GSM-900 exposure, this time in the temporoparietal junction (Kwon et al. 2011).

Many possible mechanisms could be involved in the metabolic and perfusion abnormalities identified, ranging from altered neuronal activity that was hypothesized in the Volkow et al. (2011) ^{8}FDG PET study to narrowing of vascular lumen in the setting of reduced perfusion. Underlying tissue pathophysiology-based phenomena could influence the measurable metabolism and perfusion abnormalities, via mechanisms such as excitotoxicity, cell stress response, constriction of capillary lumen by activated astrocytes, volume effects of vascular extravasation, subtle alterations in blood viscosity due to immune or oxidative stress-associated blood chemical changes, with other possibilities as well. Given the types of damage at the cellular level covered in this pathophysiology section so far – including oxidative stress, membrane and barrier function damage and poorly functioning channels, which occur both in ASDs as a consequence of EMF/RFR exposure, and given the heterogeneity of localization of abnormalities in the autism perfusion papers as well as considerations of nonlinearity, it may not be so surprising that the results in the two PET studies of human impacts of EMF exposure were not consistent.

6. Electrophysiology perturbations

At this stage the argument we hit a key pivot point, where we look at how the alterations in molecular, cellular and systems physiological function, which occur in the brain as well as in the body, impact the transduction into the electrical signaling activities of the brain and nervous system. Certainly the cells and tissues whose physiological challenges we have already discussed provide the material substrate for the electrical activity. Although ASD behaviors are influenced by many factors, they must in principle be mediated through nervous system electrophysiology.

If the cells responsible for generating synapses and oscillatory signaling are laboring under cellular and oxidative stress, lipid peroxidation, impaired calcium and other signaling system abnormalities, then mitochondrial metabolism will fall short, all the more so because of the challenges from the immune system which in turn be triggered to a major extent by environment. How well will synapses be generated? How well will immune-activated and thereby distracted glial cells be able to modulate synaptic and network activity? (Tasker et al. 2012; Eroglu and Barres 2010; Bilbo and Schwarz 2009; Fields 2006)

At present we are in the early stages of being able to formulate these questions well enough to address them. We do know that microglial activation can impact excitatory neurotransmission mediated by astrocytes (Pascual et al. 2012). We do know that the cortical innate immune response increases local neuronal excitability and can lead to seizures (Rodgers et al. 2009; Gardoni et al. 2011). We do know that inflammation can play an important role in epilepsy (Vezzani et al. 2011). We know less about lower levels of chronic or acute pathophysiological dysfunction and how they may modulate and alter the brain's electrophysiology.

Seizures and Epilepsy

EEG signals in ASDs are abnormal on a variety of levels. At the most severe level, EEGs show seizure activity. In addition to the association of some severe epilepsy syndromes (e.g. Landau Kleffner, tuberous sclerosis) with autism, the risk of epilepsy is substantially higher in people with ASDs than in the general population, with a large subset of these individuals experiencing seizure onset around puberty, likely in relation to aberrations in the dramatic and brain-impactful hormonal shifts of that phase of life. Although less than 50% of people clearly have seizures or epilepsy, a much larger number have indications of epileptiform activity, and an even larger percent have subclinical features that can be noted by a clinical epileptologist though not necessarily flagged as of clinical concern.

Epileptic seizures can be both caused by and cause oxidative stress and mitochondrial dysfunction. Seizures can cause extravasation of plasma into brain parenchyma (Mihaly

and Bozoky 1984; Librizzi et al. 2012; Marchi et al. 2010; van Vliet et al. 2007; Yan et al. 2005) which can trigger a vicious circle of tissue damage from albumin and greater irritability, as discussed above. Evidence suggests that if a BBB is already disrupted, there will be greater sensitivity to EMF/RFR exposure than if the BBB were intact (Tore et al. 2002; Tore et al. 2001), suggesting that such exposures can further exacerbate vicious circles already underway.

The combination of pathophysiological and electrophysiological vulnerabilities has been explored in relation to the impact of EMF/RFR on people with epilepsy – which, as discussed above, is a lot more common in ASDs than in the general population.. EMF/RFR exposures from mobile phone emissions have been shown to modulate brain excitability and to increase interhemispheric functional coupling (Vecchio et al. 2012; Tombini et al. 2012). In a rat model the combination of picrotoxin and microwave exposure at mobile phone-like intensities led to a progressive increase in neuronal activation and glial reactivity, with regional variability in the fall-off of these responses three days after picrotoxin treatment (Carballo-Quintas et al. 2011), suggesting a potential for interaction between a hyperexcitable brain and EMF/RFR exposure.

One critical issue here is nonlinearity and context and parameter sensitivity of impact. In one study, rat brain slices exposed to EMF/RFR showed reduced synaptic activity and diminution of amplitude of evoked potentials, while whole body exposure to rats led to synaptic facilitation and increased seizure susceptibility in the subsequent analysis of neocortical slices (Varro et al. 2009). Another study unexpectedly identified enhanced rat pup post-seizure mortality after perinatal exposure to a specific frequency and intensity of exposure, and concluded that apparently innocuous exposures during early development might lead to vulnerability to stimuli presented later in development (St-Pierre et al. 2007)

Sleep

Sleep involves a profound change in brain electrophysiological activity, and EEG abnormalities including disrupted sleep architecture figure in sleep challenges in ASD. Sleep symptoms include bedtime resistance, sleep onset delay, sleep duration and night wakings, and sleep architecture can involve significantly less efficient sleep, less total sleep time, prolonged sleep latency, and prolonged REM latency (Buckley et al. 2010; Giannotti et al. 2011), with these sleep problems being worse in children with ASDs who regressed than in those who did not regress into their autism (Giannotti, 2011). EEG abnormalities have also been associated with EMF/RFR exposure, including disrupted sleep architecture as well as changes in sleep spindles and in the coherence and correlation across sleep stages and power bands during sleep (Borbely, 1999; Huber, 2003).

Sleep disturbance symptoms are also common in both situations. Insomnia is commonly reported in people who are chronically exposed to low-level wireless antenna emissions. Mann (1996) reported an 18% reduction in REM sleep, which is key to memory and learning functions in humans. In ASDs sleep difficulties are highly pervasive and disruptive not only to the affected individual but also to their whole family due to the associated problems such as noise and the need for vigilance.

The multileveled interconnections involved in the modulation of sleep exemplify the interconnectedness of the many levels of pathophysiology reviewed here: *"Extracellular ATP associated with neuro- and glio-transmission, acting via purine type 2 receptors, e.g., the P2X7 receptor, has a role in glia release of IL1 and TNF. These substances in turn act on neurons to change their intrinsic membrane properties and sensitivities to neurotransmitters and neuromodulators such as adenosine, glutamate and GABA. These actions change the network input-output properties, i.e., a state shift for the network."* (Clinton et al. 2011) With disturbance simultaneously at so many of these levels, it is not surprising that sleep dysregulation is nearly universal in ASDs, and common in the setting of EMF/RFR exposures.

Quantitative electrophysiology

While clinical reading of EEG studies is done visually, a growing number of studies are examining EEG and MEG data using digital signal processing analysis, and often using data collected in controlled research settings with high density array equipment and carefully designed stimuli paradigms. In these settings a variety of abnormalities have been identified other than epileptic. These include abnormalities in the power spectrum, i.e. the distribution of power over the different frequencies present, with some studies showing impaired or reduced gamma-and activity (Sun et al. 2012; Rojas et al. 2008; Rippon, 2007) and others 8) showing reduction of spectral power across all bands (Tierney et al. 2012) while still others showed increased high-frequency oscillations. (Orekhova et al. 2007) Abnormalities in coherence and synchronization between various parts of the brain have been found (Muller 2008; Muller et al. 2011; Wass 2011), comparable to abnormal functional connectivity measured by fMRI (Just et al. 2004) but measurable using EEG or MEG with higher temporal resolution (Duffy, 2012; Isler, 2010; Murias, 2007; Murias, 2007; Coben, 2008). Several studies have identified reduced complexity and increased randomness in EEGs of people with autism (Lai et al. 2010; Catarino et al. 2011), as well as an increase in power but a reduction in coherence (Isler et al. 2010; Mathewson et al. 2012). Some electrophysiological metrics are emerging as potential discriminators between brain signal from individuals with ASDs and those who are neurotypical, such as a wavelet-chaos-neural network methodology applied to EEG signal (Ahmadlou, Adeli, and Adeli 2010).

EMF/RFR also has impacts at levels of brain function measurable by these techniques. At various frequencies and durations of exposure it has been noted to impact alpha and beta rhythms (Hinrikus et al. 2008), to increase randomness (Marino, Nilsen, and Frilot 2003; Marino and Carrubba 2009), to alter power, to modulate interhemispheric synchronization (Vecchio et al. 2007), to alter electrical activity in brain slices (Tattersall et al. 2001) and to alter the patterns of coordination (spectral power coherence) across the major power bands (Hountala et al. 2008). Bachman et al. (2006) showed statistically significant changes in EEG rhythms and dymanics occurred in between 12% and 20% of healthy volunteers (Bachmann, 2006). In children, exposures to cell phone radiation have resulted in changes in brain oscillatory activity during some memory tasks.

Sensory processing

At the symptomatic level issues with sensory processing are highly prevalent in ASDs. Phenomenology can include hypersensitivity to external stimuli, hyposensitivity to internal sensations and difficulty localizing sensation including pain, and difficulty processing more than one sensory channel at one time. (Robledo, Donnellan, and Strandt-Conroy 2012; Perry et al. 2007; Sacco et al. 2010) There is now electrophysiological evidence of abnormalities at early (brainstem) stages of sensory processing, as well as in later stages of processing that occur in the cortex. Some studies have shown lower and some longer latencies of response to an auditory stimulus. Domains of perception where the performance of people with ASDs is superior to that of neurotypical individuals have been identified. (Marco et al. 2011) *"It is obvious…that sensory processing abnormalities in ASD are distributed rather than localized; sensory abnormalities in ASD obviously span multiple dimensions of latency, adaptation, magnitude and behavior abnormalities, with both enhanced and impaired behavior associated with aberrant cortical responses. Given this diversity in findings, the heterogeneity of ASD, and broad variability seen over and over again in the ASD groups almost irrespective of the study, it is hard to imagine that one single theory could account for all of these observations…. It is therefore probable that several mechanisms and neuronal abnormalities, most likely at multiple levels (from single neurons through to inter-area connections), all contribute to varying degrees to the abnormal sensory processing observed in ASD. It is also likely that no single mechanism is unique to one sensory modality, which is why we see such a widely distributed range of abnormalities across modalities."* (Kenet 2011)

It is also possible that the mechanisms may not simply be neural – they may also be modulated by glial, metabolic, immune, perfusional and other physiological processes and physical properties as well. Yet although there is some consideration of the pathophysiology-sensory function interaction (Kern et al. 2010), it has basically not been fleshed out in studies of ASDs with experimental designs integrating pathophysiological and electrophysiology.

Kenet et al. (2010) demonstrated environmental vulnerability of sensory processing in the brain by the exposure of rat dams to noncoplanar polychlorinated biphenyls (PCBs), during gestation and for three subsequent weeks of nursing (Kenet, 2011). *"Although the hearing sensitivity and brainstem auditory responses of pups were normal, exposure resulted in the abnormal development of the primary auditory cortex (A1). A1 was irregularly shaped and marked by internal nonresponsive zones, its topographic organization was grossly abnormal or reversed in about half of the exposed pups, the balance of neuronal inhibition to excitation for A1 neurons was disturbed, and the critical period plasticity that underlies normal postnatal auditory system development was significantly altered. These findings demonstrate that developmental exposure to this class of environmental contaminant alters cortical development."* (Kenet et al. 2007). This study may be particularly relevant for EMF/RFR exposures, as the noncoplanar PCBs were discussed above as targeting calcium signaling as do EMF/RFR exposures – i.e. they both converge upon a common cellular mechanism (Pessah and Lein 2008; Stamou et al. 2012), justifying exploring the hypothesis that the outcomes one might expect from EMF/RFR could be similar.

Autonomic dysregulation

Although there are a fair number of negative studies regarding the impact of EMF/RFR exposure on the autonomic nervous system, increased HRV and autonomic disturbances have been documented (Andrzejak et al. 2008; Szmigielski et al. 1998; Bortkiewicz et al. 2006; Graham et al. 2000; Saunders and Jefferys 2007). Buchner and Eger (2010), in a study in rural Germany of the health impacts of exposures from a new base station yielding novel exposure to EMF/RFR, saw a significant elevation of the stress hormones adrenaline and noradrenaline during the first six months with a concomitant drop in dopamine, with a failure to restore the prior levels after a year and a half. These impacts were felt by the young, the old and the chronically ill, but not by healthy adults (Buchner and Eger 2011).

Effects on the neonate are also evident. Bellieni et al (2008) found that heart rate variability is adversely affected in infants hospitalized in isolettes or incubators where ELF-EMF levels are in the 0.8 to 0.9 μT range (8 to 9 mG). Infants suffer adverse changes in heart rate variability, similar to adults (Bellieni et al. 2008). This electromagnetic stress may have lifelong developmental impacts, based on a study showing that in utero beta 2 agonist exposure can potentially induce a permanent shift in the balance of sympathetic-to-parasympathetic tone (Witter et al. 2009).

Meanwhile clinical observation and a growing body of literature support a major role for stress in ASDs (Anderson and Colombo 2009; Anderson, Colombo, and Unruh 2012; Daluwatte et al. 2012; Ming et al. 2011), with variability amongst individuals in the severity of the stress response but a tendency to have high tonic sympathetic arousal at

baseline (Hirstein, Iversen, and Ramachandran 2001; Toichi and Kamio 2003; Ming, Julu, et al. 2005; Mathewson et al. 2011; Cheshire 2012; Chang et al. 2012).

The impact of EMF/RFR exposure can also be greatly influenced by the stress system status of the individual being exposed. Tore et al sympathecotomized some of his rats before exposure to GSM, to simulate cell phone exposure (Tore et al. 2002; Tore et al. 2001). Salford et al. (2012) reviewed the results:

> *"Comparing the animals, which had been subjected to ganglionectomy, to the other animals, Töre et al. made an interesting observation: as expected, albumin extravasation was more prominent in the sympathectomised sham-exposed rats as compared to normal exposed rats. This was due to the fact that the sympathectomised rats were in a chronic inflammation-prone state with hyper-development of pro-inflammatory structures, such as the parasympathetic and sensory inputs as well as mast cells, and changes in the structure of the blood vessels. Such an inflammation-prone state has a well-known effect on the BBB leakage. However, when comparing sham-exposed sympathectomised rats to GSM-exposed sympathectomised rats, a remarkable increase in albumin leakage was present in the GSM exposed sympathectomised rats compared to the sham rats.* ***In the GSM-exposed sympathectomised rats, both brain areas and the dura mater showed levels of albumin leakage resembling those observed in positive controls after osmotic shock****.[emphasis added] Indeed, more attention should be paid to this finding, since it implicates that the sensitivity to EMF-induced BBB permeability depends not only on power densities and exposure modulations, but also on the initial state of health of the exposed subject."* (Salford, Nittby, and Persson 2012)

This dramatically greater impact on an autonomically and immunologically vulnerable set of animals raises concerns since the vulnerabilities of these animals bear some resemblance to the pathophysiological challenges of individuals with ASDs.

The interconnection between stress and brain connectivity (or coherence) in ASDs is brought out by Narayanan et al. (2010) n a pilot study testing the impact of the beta blocker propranolol on brain functional connectivity measured using functional MRI (Narayanan et al. 2010). A fairly immediate increase in functional connectivity was noted from propranolol – but not from nadolol which has the same vascular effects but does not cross the BBB. Propranolol decreases the burden of norepinephrine, thereby reducing the impact of stress systems on brain processing, and the authors interpreted these effects as creating an improvement of the brain's signal-to-noise ratio (Hasselmo, 1997), allowing it to utilize and coordinate more remote parts of its networks. This suggests that stressors such as EMF/RFR, by adding non-biologically meaningful noise to the system, might have the opposite effects, degrading coherent integration.

C. De-tuning of the Brain and Organism

1. Electromagnetic signaling, oscillation and synchrony are fundamental, and vulnerable

While electrophysiological activity is an intrinsic property of the nervous system, electromagnetic signaling are vital parts of every cell and of molecular structure.

> *"All life on earth has evolved in a sea of natural low-frequency electromagnetic (EM) fields. They originate in terrestrial and extraterrestrial sources. The ever-growing use of electric power over the last century has sharply modified this natural environment in urban environments. Exposure to power-frequency fields far stronger than the natural environment is now universal in civilized society."* (Adey 1994)

Adey published some of the earliest scientific studies on the "cooperativity" actions of cells in communication. Studies showing us that the flux of calcium in brain tissue and immune cells is sensitive to ELF-modulated radiofrequency fields is actually telling us that some of the most fundamental properties of cells and thus of our existence can be modulated by EMF/RFR.

> *"...in first detection of environmental EM fields in tissues, there appears to be a general consensus that the site of field action is at cell membranes. Strands of protein are strategically located on the surface of cells in tissue, where they act as detectors of electrical and chemical messages arriving at cell surfaces, transducing them and transmitting them to the cell interior. The structural basis for this transductive coupling by these protein strands is well known. Through them, cell membranes perform a triple role, in* ***signal detection, signal amplification, and signal transduction to the cell interior****."* (Adey 1994)

Communication between cells through gap junctions, which is a means of "metabolic cooperation," is also vulnerable to disruption, as discussed earlier.

Oscillation is also a universal phenomenon, and biological systems of the heart, brain and gut are dependent on the cooperative actions of cells that function according to principles of non-linear, coupled biological oscillations for their synchrony, and are dependent on exquisitely timed cues from the environment at vanishingly small levels (Buzsaki 2006; Strogatz 2003). The key to synchronization is the joint actions of cells that co-operate electrically - linking populations of biological oscillators that couple together in large arrays and synchronize spontaneously according to the mathematics described for Josephson junctions (Brian Josephson, the 1993 Nobel prize winner for this concept). This concept has been professionally presented in journal articles and also popularized in a book by Prof. Steven Strogatz, a mathematician at Cornell University who has written

about ‘sync’ as a fundamental organizing principle for biological systems (Strogatz 2001) (Strogatz 2003).

> *“Organisms are biochemically dynamic. They are continuously subjected to time-varying conditions in the form of both extrinsic driving from the environment and intrinsic rhythms generated by specialized cellular clocks within the organism itself. Relevant examples of the latter are the cardiac pacemaker located at the sinoatrial node in mammalian hearts and the circadian clock residing at the suprachiasmatic nuclei in mammalian brains. These rhythm generators are composed of thousands of clock cells that are intrinsically diverse but nevertheless manage to function in a coherent oscillatory state. This is the case, for instance, of the circadian oscillations exhibited by the suprachiasmatic nuclei, the period of which is known to be determined by the mean period of the individual neurons making up the circadian clock. The mechanisms by which this collective behavior arises remain to be understood.”* (Strogatz 2003)

The brain contains a population of oscillators with distributed natural frequencies, which pull one another into synchrony (the circadian pacemaker cells). Strogatz has addressed the unifying mathematics of biological cycles and external factors disrupt these cycles. This also applies to mitochondria:

> *“Organisation of mitochondrial metabolism is a quintessential example of a complex dissipative system which can display dynamic instabilities. Several findings have indicated that the conditions inducing instabilities are within the physiological range and that mild perturbations could elicit oscillations. Different mathematical models have been put forth in order to explain the genesis of oscillations in energy metabolism. One model considers mitochondria as an organised network of oscillators and indicates that communication between mitochondria involves mitochondrial reactive oxygen species (ROS) production acting as synchronisers of the energy status of the whole population of mitochondria. An alternative model proposes that extramitochondrial pH variations could lead to mitochondrial oscillations.”* (Iotti, Borsari, and Bendahan 2010)

The field of bioelectromagnetics has studied exposure to very low levels of electromagnetic frequencies.

These exposures can alter critical properties of chemical reactions. *“In a chemical reaction, the bond breaks and each partner reclaims its electron from the bond, moving away to encounter a new partner. It is now an unattached, highly reactive free radical. Reforming a bond requires a meeting between two radicals with opposite electron spins, the union producing a singlet pair. The lifetime of free radicals is typically short, in the*

range of microseconds to nanoseconds. It is in this brief period that imposed magnetic fields may alter the rate and amount of product of a chemical reaction. Since the effect is only on the kinetics of chemical reactions, they are known as magnetokinetic effects (Steiner and Ulrich, 1989). They occur only in nonthermal states of biomolecular systems, defined as an insensitivity to random thermal interactions during the brief period of their existence (Walleczek, 1994). They are a consequence of a coherent quantum-mechanical step which accompanies free radical formation." (Adey 1994)

Not just chemical reactions but synchronous biological oscillations in cells (pacemaker cells) can be disturbed and disrupted by artificial, exogenous environmental signals, whicn can lead to desynchronization of neural activity that regulates critical functions (including metabolism) in the brain, gut and heart and circadian rhythms governing sleep and hormone cycles (Strogatz, 1987). Buzsaki in his book *Rhythms of the Brain* (2006) says "*rhythms can be altered by a wide variety of agents and that these perturbations must seriously alter brain performance."* (Buzsaki 2006)

Disturbance can get increasingly disruptive as more damage occurs and more systems are thrown out of kilter and out of cooperativity. One can think of the kindling model in which repeated induction of seizures leads to longer and more sever seizures and greater behavioral involvement. The combination of disruptive and stimulatory effects of biologically inappropriate EMF/RFR exposures could contribute to disruption of synchronized oscillation and cooperativity at a myriad of levels but particularly in the brain, and this may contribute to the loss of coherence and complexity in the brain in autism, as well as dysregulation of multiple other bodily systems. Strogatz points out that there are many more ways of being desynchronized than being synchronized (Strogatz, 2003). It has even been suggested that autism itself could be due to brain desynchronization (Welsh, 2005).

2. Behavior as an "emergent property"

Although from a pathophysiological point of view one might hypothesize that a brain with greater indications of oxidative stress along with immune activation and mitochondrial dysfunction might generate different oscillatory activity than a brain in which those pathophysiological features were absent, to date almost no attention has been paid to testing this hypothesis in ASD or neurodevelopmental and neuropsychiatric conditions more generally. From this vantage point it would make sense to propose that the compromised whole body health status of at least many with ASDs would make it harder for them to maintain the resilience of their brain cells and brain activities in the face of potentially disruptive exposures. Yet the investigation of how this might occur remains a largely unexplored frontier. But from the point of view of making sense of the

brain impact of environmental challenges – including but not limited to EMF-RFR – this investigation is crucial.

The pathophysiological perspective that guides this review would suggest a move away from considering the behavioral manifestations of ASDs as core 'traits,' *Instead behaviors may be better understood as 'outputs' or emergent properties – what the brain and body produce – when their physiological attributes are altered* in these fashions for whatever reasons – be they genetic, environmental or many combinations of both (Anderson 2009, 2008; Sieb 2004; Smith and Thelen 2003; Custodio et al. 2007; Herbert 2012). Sleep and consciousness have also been considered 'emergent properties' (Krueger et al. 2008; Krueger and Obal 2003). Brain oscillatory activity is critical for organizing behavior, and it arises from cells and subcellular features that are shaped by the environment and can act differently based on their functional status as well as on account of external sensory or psychosocial stimuli.

In particular, a) brain oscillatory activity is intimately connected with underlying cellular, metabolic and immune status, b) EMF/RFR is capable of perpetrating changes at each of these levels, and c) problems at each of these levels can make other problems worse. And as mentioned earlier, EMF/RFR and various toxicants can co-potentiate damage (Juutilainen and Kumlin 2006; Juutilainen, Kumlin, and Naarala 2006; Verschaeve et al. 2006; Ahlbom et al. 2008; Hoyto et al. 2008; Juutilainen 2008; Luukkonen et al. 2009; Markkanen, Juutilainen, and Naarala 2008), amplifying allostatic load.

Put together, all of this implies that the combination of these EMF/RFR impacts may quite plausibly significantly contribute both to how ASDs happen in individuals and to why there are more reported cases of ASDs than ever before (with studies showing that not all of this increase can be written off as artifact (King and Bearman 2009; Hertz-Picciotto and Delwiche 2009).

The hopeful side of this framing of the problem comes from moving beyond the increasingly anachronistic idea that autism is determined overwhelmingly by genetic code about which we can do little or nothing. An emerging model that explains much more of what we now know frames ASDs as the dynamic, active outcomes of perturbed physiological processes – again, more like a chronic but changeable 'state' than a 'trait.' In the latter model, one is empowered to strongly reduce exposures and to make aggressive constructive environmental changes – particularly in diet and nutrition, given their protective potency discussed above (Herbert and Weintraub 2012). In this way allostatic load can be reduced, physiological damage can be repaired, homeostasis can be restored and resilience and optimal function can be promoted.

III. IMPLICATIONS

A. Summary

In the above review, the case has been made that ASDs involve physiological challenges at multiple levels, and that these challenges are paralleled in the physiological impacts of EMF/RFR exposure. Evidence has also been presented to suggest that the many levels of damage and degradation of physiological and functional integrity are profoundly related to each other. Although autism spectrum disorders (ASDs) are defined by problems with behavior, communication, social interaction and sensory processing, under the surface they also involve a range of disturbances of underlying biology that find striking parallels in the physiological impacts of electromagnetic frequency and radiofrequency exposures (EMF/RFR). At the cellular and molecular level many studies of people with ASDs have identified oxidative stress and evidence of free radical damage, evidence of cellular stress proteins, as well as deficiencies of antioxidants such as glutathione. Elevated intracellular calcium in ASDs can be associated with genetic mutations but more often may be downstream of inflammation or chemical exposures. Cell membrane lipids may be peroxidized, mitochondria may function poorly, and immune system disturbances of various kinds are common. Brain oxidative stress and inflammation as well as measures consistent with blood-brain barrier and brain perfusion compromise have been documented. Changes in brain and autonomic nervous system electrophysiology can be measured and seizures are far more common than in the population at large. Sleep disruption and high levels of stress are close to universal. In parallel, all of these phenomena have also been documented to result from or be modulated by EMF/RFR exposure. Moreover, some people with ASDs have de novo mutations (that their parents do not have), and EMF/RFR exposures could contribute to this due to their potential genotoxicity. EMF/RFR exposure during pregnancy may send spurious signals to developing brain cells during pregnancy, altering brain development during critical periods, and may increase oxidative stress and immune reactivity that can increase risk for later developmental impairments, with further disruption later in development increasing risk, physiological dysregulation and severity of outcome.

All of this does not prove that EMF/RFR exposures cause autism, but it does raise concerns that they could contribute by increasing risk, and by making challenging biological problems and symptoms worse in these vulnerable individuals. Placed alongside the dramatic rise in reported cases of ASDs, that parallels the dramatic rise in deployment of wireless technologies, a strong case can be made for aggressively investigating links between ASDs and EMR/RFR, and minimizing exposures for people with autism as well as families preconceptionally, during pregnancy, and around infants and children at home, at school, and in health care centers and hospitals.

These arguments have implications for how we understand what ASDs 'are' and how they work. These implications call upon us to take the environmental contribution very seriously, which involves on the one hand a sobering appreciation of the vast array of exposures that can contribute to risk via perturbed development and physiological degradation, and on the other hand a sense that there are powerful things we can do to improve the situation.

B. Exposures and their Implications

Several thousand scientific studies over four decades point to serious biological effects and health harm from EMF and RFR as are intensively reviewed in the many detailed sections of this BioInitiative Report. These studies report genotoxicity, single-and double-strand DNA damage, chromatin condensation, loss of DNA repair capacity in human stem cells, reduction in free-radical scavengers (particularly melatonin), abnormal gene transcription, neurotoxicity, carcinogenicity, damage to sperm morphology and function, effects on behavior, and effects on brain development in the fetus of human mothers that use cell phones during pregnancy. Cell phone exposure has been linked to altered fetal brain development and ADHD-like behavior in the offspring of pregnant mice.

1. Exposures have outpaced precautions

There is no question that huge new exposures to EMF/RFRs have occurred over the past few decades. As discussed extensively in other parts of this Bioinitiative 2012 update (Sage, 2012), there is much concern that regulations to date have been based on a very limited sense of the pertinent biology, and particularly that limiting concern to thermal impacts is no longer valid since there is a wealth of evidence by now that non-thermal impacts can be biologically very powerful.

Only in the last two decades have exposures to RFR and wireless technologies become so widespread as to affect virtually every living space, and affect every member of societies around the world. Even as some disease patterns like brain tumors from cell phone use have become 'epidemiologially visible', there are no comprehensive and systematic global health surveillance programs that really keep up to report EMF/RFR health trends (Fragopoulou et al. 2010).

> "*The deployment of new technologies is running ahead of any reasonable estimation of possible health impacts and estimates of probabilities, let alone a solid assessment of risk. However, what has been missing with regard to EMF has been an acknowledgement of the risk that is demonstrated by the scientific studies. There is clear evidence of risk, although the magnitude of the risk is*

uncertain, and the magnitude of doing nothing on the health effects cost to society is similarly uncertain. This situation is very similar to our history of dealing with the hazards of smoking decades ago, where the power of the industry to influence governments and even conflicts of interest within the public health community delayed action for more than a generation, with consequent loss of life and enormous extra health care costs to society." (Sage and Carpenter 2009).

2. The population's exposure has increased

Given the range of physiological impacts described in Part 2, the very rapid global deployment of both old and new forms of emerging wireless technologies in the last two decades needs aggressive evaluation from a public health perspective.

In the United States, the deployment of wireless infrastructure (cell tower sites) to support cell phone use has accelerated greatly in the last decades. The Cellular Telephone Institute of America (CTIA) estimated that in 1997 there were only 36,650 cell sites in the US; but increased rapidly to 131,350 in June 2002; 210,350 in June 2007 and 265,561 in June 2012 (Roche, 2012; Cellular Telephone Industry of America (CTIA) 2012). About 220,500 cell sites existed in 2008 (Reardon, 2007; Cellular Telephone Industry of America (CTIA) 2012; Anonymous, May 2005). These wireless facilities for cellular phone voice and data transmission produce RFR over broad areas in communities and are an involuntary and unavoidable source of radiofrequency radiation exposure. Other new RFR exposures that didn't exist before are from WI-FI access points (hotspots) that radiate 24/7 in cafes, stores, libraries, classrooms, on buses and trains, and from personal WI-FI enabled devices (iPads, tablets, PDAs, etc).

Not surprisingly, the use of cell phones has a parallel growth trend. In the late 1980s and early 1990's, only a few percent of the US population were cell phone users. By 2008, eighty-four percent (84%) of the population of the US owned cell phones [16]. CTIA reports that wireless subscriber connections in the US increased from 49 million in June 1997 to 135 million in June 2002 to 243 million in June 2007 to 322 million in June 2012 (Roche, 2012; Cellular Telephone Industry of America (CTIA), June 2012) This represents more than a 100% penetration rate in the US consumer market, up from just a few percent in the early 1990's. The number of wireless subscribers in June 1997 was 18%; in June 2002 it was 47%; in June 2007 it was 81% and in June 2012 it is 101%.

The annualized use of cell phones in the US was estimated to be 2.23 trillion minutes in 2008 and 2.296 trillion minutes in 2010 (CITA, 2012). There are 6 billion users of cell phones world- wide in 2011 up from 2.2 billion in 2008 and many million more users of cordless phones.

The number of US homes with *only* wireless cell phones has risen from 10.5% in 2007 to 31.6% in June of 2012 (Roche, 2012; Cellular Telephone Industry of America (CTIA),

June 2012). There are no statistics for June 1997 nor for June 2002, since landline (non-wireless) phone use predominated. The shift to wireless communications, more minutes of use, and reliance on cell and cordless phones rather than corded phones is an extremely revealing measure of new EMF and RFR exposures for both adults and children.

3. Infants, children and childbearing families are highly exposed and vulnerable

With regard to children, the spread of cell towers in communities, often placed on pre-school, church day-care, and school campuses, means that young children may have hundreds of thousands of times higher RF exposures in home and school environments than existed even 20-25 years ago. In addition, the nearly universal switch to cordless and cell phones, and away from corded landline phones, means close and repetitive exposures to both EMF and RFR in the home. Wireless laptops and wireless internet in schools, and home offices and for homework mean even more chronic exposures to RFR, a designated IARC 2B Possible Human Carcinogen (International Agency for Research on Cancer of the World Health Organization, May 2011; Baan, 2011) The great utility of handheld devices as communication aids and sources of information and satisfaction for people on the autism spectrum may come with a concerning underbelly.

Exposures prior to conception or during pregnancy and infancy are also important to consider. These exposures can come from faulty wiring, proximity to power lines, or high-frequency transients from a proximate transformer on a utility pole, or internal sources of pulsed RFR in the home (examples include an electronic baby monitor in the crib, a wireless router in the next room, a DECT phone that pulses high emissions of RFR on a continuous basis 24/7, or conversion to all compact fluorescent bulbs that produce significant 'dirty electricity' for occupants due to low-kilohertz frequency fields on electrical wiring and in ambient space. Sick and vulnerable infants in neonatal intensive care units are heavily exposed from being surrounded by equipment, with negative metabolic and autonomic consequences documented and other likely consequences needing further investigation (Bellieni et al. 2008; Bellieni, Tei, et al. 2012).

Wireless phones and laptops exposures produce extremely low frequency pulses from the battery of the wireless device (Sage, 2007; Sage and Carpenter 2009) and the exposures to pulsed radiofrequency microwave radiation when the wireless device is transmitting or receiving calls and emails.

Especially since EMF/RFR exposures are already classified as IARC 2B Possible Human Carcinogens, we should be actively investigating these sources of damage to DNA that could reasonably result in 'de novo mutations' but also be aware that common environmental exposures from EMF and RFR might play a role in the higher rates of concordance for autism (ASD) among twins and siblings.

Researchers also should be aware that common environmental exposures from EMF and RFR might play a role in the higher rates of autism (ASD) among twins and siblings, not solely because of maternal use of wireless devices during pregnancy and paternal sperm exposure to wireless devices peri-conception; but also because such oxidative damage to DNA can occur at levels introduced into the world of the fetus, and young developing infant and child via baby surveillance monitoring devices in the crib and wireless devices in the home. The deployment of technologies poses risks to human fertility and reproduction capacity, to the fetus, to children and adults (Sage and Carpenter 2009).

4. ASD risk and genomic damage to future generations

Barouki and Grandjean (2012) make a persuasive case that public health interventions are critically needed in early childhood development to prevent adult diseases that appear decades later (Barouki et al. 2012). Although they do not include EMF or RFR but only chemicals, they do say that physiological stressors, which EMF and RFR certainly have been established to be, should be reduced during critical development windows. They say: "*The current pandemic of non-communicable diseases and the increased prevalence of important dysfunctions demand an open interrogation of why current interventions appear insufficient. We now know that disease risk can be induced very early in the life course and that it is modifiable by nutrients and environmental chemical exposures (along with drugs. infections, and other types of stresses)".*

Part II of this chapter documents the detailed scientific basis for considering EMF/RFR exposures to be of significance to the ASDs crisis. Public health interventions are warranted now to protect the genetic heritage of humans, as well as the other stocks of genetic material in wildlife and plants in the face of what appears to be on-going impairment of these genomes. The risk of genomic damage for future generations is sufficiently documented to warrant strong preventative action and new public safety limits that observe EMF/RFR levels shown to cause adverse effects.

5. De-tuning the organism

Genetic mutations may lead to cancer and other diseases in the present and future generations, but the exposures that are capable of creating genotoxic impacts also compromise physiological function Even genotoxicity can have not only specific but also non-specific effects due to inefficiencies, misfolded proteins, and cellular debris, as discussed in the section "Implications of Damage" at the end of the first part of Part II, regarding the rescue of a mouse model of Rett syndrome through enabling a probably generic process of microglial phagocytosis, critical to debris removal, rather than through correcting some specific molecular defect of the synapse (Derecki et al. 2012; Derecki, Cronk, and Kipnis 2012).

In the present setting, where the argument about the pertinence of the cascade of physiological and genotoxic compromises to autism includes the degradative impact on oscillatory synchronization, it is also worth considering that oscillation is a property of living and even physical systems much more generally, and not just of brain oscillatory networks (Strogatz 2003). Under certain circumstances, phase transitions occur and synchronization emerges, often rather quickly rather than gradually – more like a state change than a gradual trend. On the other hand, as mentioned, synchronization can be lost, and there are an enormous number of ways for a system to be de-synchronized, which may relate to the heterogeneity amongst people with ASD that so vexes researchers.

In the setting of autism, a baby gestated or developing as a neonate in a milieu with excessively elevated EMF/RFR exposures is bound to have interference with the normal development processes, including the organization of information and experience in the brain. This baby's environment also often nutritional insufficiencies (processed denatured pesticide-laden food low in antioxidants, minerals and essential fatty acids essential to cellular protection). The baby's gestational period may have been complicated by the mother's own health issues such as conditions like obesity and diabetes (Krakowiak, 2012) which converge on inflammation, oxidative stress and other common forms of physiological dysregulation associated with or even just eating nutrient-depleted, pesticide-laden processed food. The exquisite 'tuning up' of the brain and body as it develops will integrate and respond to the environmental inputs it receives, and is particularly sensitive to environmental miscues (whether chemical like endocrine disruptors, EMF/RFR, or other hostile environmental conditions whether hostile or nurturing). To the extent that the baby is burdened with more disorganized or hostile cues than nurturing and organizing cues, that baby may lose resiliency and become more physiologically vulnerable –perhaps approaching a tipping point into decompensation.

From a systems point of view, the phenomenon of 'autistic regression' may occur after an accumulation of multisystem signaling interference leading to a tipping point of loss of some vital systems synchronization and increase in randomization. EMF/RFR exposures could plausibly contribute both to this vulnerability and to the decompensation/desynchronization process – as could other stressors such as infection, toxicity, acute stress. The vulnerability, then, is the 'allostatic load' – the total burden of stressors pressing toward disorganization. The tipping point may come in a variety of ways but upon investigation one is likely to find that unless it is a severe stressor it is not triggered simply by a single source of stress in an otherwise blissfully healthy child, but rather is the "straw that breaks the camel's back' laid atop a prior accumulation of 'allostatic load.'

C. Conclusions and Recommendations

1. Change our deployment of EMF/RFR

The deployment of RFR from wireless technologies has incredible momentum, and it has made many things easier and many other things possible for the first time. On the other hand this momentum can interfere with setting up the technology in a fashion truly respectful of biological tolerances. Other sections in the Bioinitiative 2012 update will address recommendations and guidelines for increasing the safety profile. This will undoubtedly provoke controversy. The problems will not get settled immediately, and transformation to healthier arrangements will take time.

> *"There is no question that global implementation of the safety standards proposed in the Bioinitiative Report, if implemented abruptly and without careful planning, have the potential to not only be very expensive but also disruptive of life and the economy as we know it. Action must be a balance of risk to cost to benefit. The major risk from maintaining the status quo is an increasing number of cancer cases, especially in young people, as well as neurobehavioral problems at increasing frequencies. The benefits of the status quo are expansion and continued development of communication technologies. But we suspect that the true costs of even existing technologies will only become much more apparent with time. Whether the costs of remedial action are worth the societal benefits is a formula that should reward precautionary behavior*." (Sage and Carpenter 2009)

2. Encourage precautions right now based on present knowledge

In the meantime many people have already started taking precautionary measures, and more will wish to do so. Physicians and health care people should raise the visibility of EMF/RFR as a plausible environmental factor in clinical evaluations and treatment protocols. Reducing or removing EMF and wireless RFR stressors from the environment is a reasonable precautionary action given the overall weight of evidence.

- Children with existing neurological problems that include cognitive, learning, attention, memory, or behavioral problems should as much as possible be provided with wired (not wireless) learning, living and sleeping environments,
- Special education classrooms should aim for 'no wireless' conditions to reduce avoidable stressors that may impede social, academic and behavioral progress.
- All children should reasonably be protected from the physiological stressor of significantly elevated EMF/RFR (wireless in classrooms, or home environments).
- School districts that are now considering all-wireless learning environments should be strongly cautioned that wired environments are likely to provide better learning and teaching environments, and prevent possible adverse health consequences for both students and faculty in the long-term.

- Monitoring of the impacts of wireless technology in learning and care environments should be performed with sophisticated measurement and data analysis techniques that are cognizant of the non-linear impacts of EMF/RFR and of data techniques most appropriate for discerning these impacts.
- There is sufficient scientific evidence to warrant the selection of wired internet, wired classrooms and wired learning devices, rather than making an expensive and potentially health-harming commitment to wireless devices that may have to be substituted out later, and
- Wired classrooms should reasonably be provided to all students who opt-out of wireless environments.

Undoubtedly risks and the above recommendations will be dismissed by those poised to benefit from the sale of these new systems. Many people also feel that new possibilities have opened up to themselves and the world through wireless technologies. But the public needs to know that these risks exist, that transition to wireless should not be presumed safe, and that it is very much worth the effort to minimize exposures that still provide the benefits of technology in learning, but without the threat of health risk and development impairments to learning and behavior in the classroom.

Broader recommendations also apply, related to reducing the physiological vulnerability to exposures, reduce allostatic load and build physiological resiliency through high quality nutrition, reducing exposure to toxicants and infectious agents, and reducing stress (Herbert and Weintraub 2012), all of which can be implemented safely based upon presently available knowledge.

3. Build an environmentally physiologically centered research program in ASDs as a platform for investigating the EMR/RFR-ASD linkage

This review has been structured around the physiological parallels between ASDs and the impacts of EMF/RFR. What is missing from the autism research agenda is some cross-study of these two bodies of research evidence. To do this we will need both a recognition of the importance of these risks, and a collaborative multi-site research program centered around a "middle-out" physiological approach that can incorporate the the gene-brain-behavior agenda that has dominated ASD research into a broader framework (Herbert 2013). While the middle-out approach is an emerging framework in systems biology that can incorporate complexity and nonlinear, multileveled modeling (Cristofolini et al. 2008; de Graaf et al. 2009; Majumder and Mukherjee 2011; Vinga et al. 2010; Walker and Southgate 2009), the gene-brain-behavior approach has been based on an expectation of linear mapping across the levels on which it focuses, but instead the systems involved appear to be much more complex, and the physiological levels largely

left out of this linear approach are critically important to helping people with ASDs because they will help not only with understanding how environment impacts function but also with identifying leverage points.

4. Take the evidence as a call to action

Both EMF and RFR exposures are already classified as IARC 2B Possible Human Carcinogens. The substantial scientific literature on EMF and RFR effects on DNA, on immune and blood-brain barrier disruption, on stress proteins, on circadian rhythms and hormone disregulation, and on cognition, sleep, disruption of neural control and altered brainwave activity all argue for reduction of exposures now, and better coordinated research in these areas.

All relevant environmental conditions should be given weight in defining and implementing prudent, precautionary actions to protect public health, including EMF and RFR. Evidence is sufficient to add EMF/RFR prominently to the list of exposures that can degrade the human genome, and impair normal development, health and quality of our physiology. With the rising numbers people with ASDs and other childhood health and developmental disorders, we cannot afford to ignore this component of risk to our children and vulnerable populations. When the risk factors are largely avoidable or preventable, ignoring clear evidence of large-scale health risks to global populations poses unnecessary and unacceptable risks. Taking this evidence as a call to action will be challenging and disruptive in the short term, but constructive in the longer term as we learn to use EMF/RFR in healthier ways.

October 2012

TABLE OF CONTENTS

I. INTRODUCTION

This section highlights some major milestones in documentation of potential health effects of low-intensity electromagnetic fields and radiofrequency radiation, and subsequent national and international actions taken to address the problem. The categories of response are divided into Publications and Health Agency Advisories, Local and National Country Actions, Expert Research Group and Physicians' Advisories and the formal classification by the World Health Organization International Agency for Research on Cancer for RFR as a 2B Possible Human Carcinogen.

II. PUBLICATIONS AND HEALTH AGENCY ADVISORIES (2007 – 2012)

The BioInitiative Report (2007)

The BioInitiative Report (1) is a 650+ page report documenting the evidence for bioeffects and adverse health effects (the science and public health consequences of that body of scientific evidence) from electromagnetic field and radiofrequency (microwave) radiation. It was written by an independent international research group to give an overview of what is known of biological effects that occur at low-intensity EMFs exposures (for both radiofrequency radiation RFR and power-frequency ELF-EMF), and various forms of combined exposures that are now known to be bioactive). The Report examines the research and current standards and finds that these standards are far from adequate to protect public health. The report presents solid science on this issue, and makes recommendations to decision-makers and the public.

The BioInitiative Working Group was composed of scientists, researchers and public health policy professionals. In 2007, the Working Group documented information from over 2000 published scientific studies and reviews reporting bioeffects and adverse health impacts of electromagnetic fields and radiofrequency radiation at exposure levels far below current public safety standards that should be considered in the international debate about the adequacy (or inadequacy) of existing public exposure standards.

Eleven chapters documented key scientific studies and reviews identifying low-intensity effects of electromagnetic fields. Sections 16 and 17 were prepared by public health and policy experts. These sections discuss the standard of evidence which should be applied in public health and environmental planning, how the scientific information should be evaluated in the context of prudent public health policy, and the basis for taking precautionary and preventative actions that are proportionate given this evidence.

European Environment Agency (2007)

European Environmental Agency Executive Director Jacqueline McGlade, PhD provided early support for the BioInitiative Report (2007). The Agency's Head of Communications and Corporate Affairs issued a news release on the publication of the BioInitiative Report, and the EEA contributions to it on September 17, 2007, two weeks after the Report was published on the web. It stated (2):

> *"A new report raising concerns about the effects of electromagnetic fields (EMF) on human health calls for tougher safety standards to regulate radiation from mobile phones, power lines and many other sources of exposure in daily life. The report, 'Bioinitiative: A Rationale for a Biologically-Based Public Exposure Standard for Electromagnetic Fields' was compiled by the BioInitiative Working Group, an international group of scientists, researchers and public health policy professionals. The EEA has contributed to this new report with a chapter drawn from the EEA study 'Late lessons from early warnings: the precautionary principle 1896–2000' published in 2001."*
>
> *"The EEA study reviews the histories of a selection of public and environmental hazards, such as asbestos, benzene and PCBs, from the first scientifically based early warnings about potential harm, to subsequent precautionary and preventive measures. Cases on tobacco smoking and lead in petrol are forthcoming."*
>
> *"Although the EEA does not have specific expertise in EMF, the case studies of public hazards analyzed in the 'Late Lessons from Early Warnings' publication show that harmful exposures can be widespread before there is both 'convincing' evidence of harm from long-term exposures, and biological understanding of how that harm is caused."*
>
> *"There are many examples of the failure to use the precautionary principle in the past, which have resulted in serious and often irreversible damage to health and environments. Appropriate, precautionary and proportionate actions taken now to avoid plausible and potentially serious threats to health from EMF are likely to be seen as prudent and wise from future perspectives. We must remember that precaution is one of the principles of EU environmental policy*."
>
> Professor Jacqueline McGlade, Executive Director, EEA.

In the fall of 2007, the EEA Director responsed to strong media and industry attention to the BioInitiative Report, defending the EEA's position to declare 'early warnings' appropriate with respect to the evidence on mobile phone radiofrequency radiation and possible health hazards. The Director defended EEA recommendations for prudent public health action, based on the scientific evidence presented in the BioInitiative Report. (3)

> *"The BioInitiative report draws attention to some of the emerging evidence of potential harm from the long term effects of non-ionising radiations from electro and magnetic fields (EMF), particularly from the radio frequency (RF) exposures that arise from mobile phone telecommunications."*
>
> *"The Bioinitiative report, however, is only one of several reports reviewing the risks from the*

thermal and non-thermal effects of EMF that have been published over recent years."

"These include reports from the NIEHS, the EU, the WHO, the UK National Radiological Protection Board and others The EEA's contribution to the BioInitiative report was a chapter on the history and general application of the precautionary principle to a number of well known hazards for which there had been, and in some cases still is, much scientific uncertainty. The chapter summarised the main messages from our report, "Late Lessons from Early Warnings: the Precautionary Principle 1896-2000", (EEA 2001)."

"The point of our chapter for the BioInitiative report was to illustrate how past uncertainties had been dealt with so as to provide lessons that may be helpful in dealing with current hazards for which there is both scientific uncertainty and high stakes, both health and economic."

"It is because this accumulating evidence on RF is of increasing scientific concern, and because the exposure of the public, particularly vulnerable groups, is widespread and generally rising, that we judged it was timely to draw wider attention to the possibly serious hazards from EMF".

"In our judgement, the human and experimental evidence, taken together, is "clear" enough to support using the precautionary principle to justify reducing exposures, where feasible, and to review the evidence for the existing exposure limits, which, as you know, are based on thermal effects only."

EEA Director Jacqueline McGlade to Wolfram Konig, Nov 27, 2007

<u>*European Parliament (2007)*</u>

In September 26, 2007 Carolyn Lucas, MEP, introduced the topic of the BioInitiative Report recommendations to the European Parliament (4) and asked the European Commission what action the Commission is taking in response to the report, its conclusions and endorsement by the European Environment Agency.

"As the Commission will be aware, on 31 August 2007 the international BioInitiative Working Group of renowned scientists and public health policy experts published a report called "A Rationale for a Biologically-Based Public Exposure Standard for Electromagnetic Fields (ELF and RF)".

"This report documents evidence that ELFs are a risk factor for both childhood and adult cancers, and sets out how wireless technologies which rely on RF to send emails and voice communications are thousands of times stronger than levels reported to cause sleep disorders, headaches, problems with memory and concentration and other physical symptoms. It notes the unprecedented levels of exposure to ELFs being created by the "explosion of new sources" and raises serious scientific concerns over the health risks posed by long-term and cumulative exposure."

"The report concludes that current safety limits regulating the levels of ELF permitted from power lines, mobile phones and other sources are highly inadequate, and that a much more cautious approach should be taken to further deployment of risky technologies."

"The European Environment Agency (EEA) contributed a chapter to the report, concerning the consequences of previous failures to apply the precautionary principle in the face of public and environmental hazards. Following publication of the study the EEA's Executive Director has publicly stressed the importance of precaution where potentially serious future consequences may be involved, and called for actions to reduce exposures to ELF, particularly where vulnerable groups are concerned."

"What action is the Commission taking in response to this report, its conclusions and endorsement by the EEA? Does the Commission agree that the balance of evidence points to the need to revise public safety standards regulating radiation levels from sources of day-to-day ELF exposure, as well as policies on the testing and deployment of new telecommunications technologies?"

European Parliament 2008

The European Parliament issued advice on the Communication from the Commission to the Council, the European Parliament and the European Economic and Social Committee regarding the mid-term review of the European Environment and Health Action Plan 2004-2010 (COM(2007)0314). See Appendix A for full text, but in part, it stated:

21. Is greatly concerned at the Bio-Initiative international report (8) concerning electromagnetic fields, which summarises over 1500 studies on that topic and which points in its conclusions to the health risks posed by emissions from mobile-telephony devices such as mobile telephones, UMTS, Wifi, Wimax and Bluetooth, and also DECT landline telephones;

22. Notes that the limits on exposure to electromagnetic fields which have been set for the general public are obsolete, since they have not been adjusted in the wake of Council Recommendation 1999/519/EC of 12 July 1999 on the limitation of exposure of the general public to electromagnetic fields (0Hz to 30 GHz) (9, obviously take no account of developments in information and communication technologies, of the recommendations issued by the European Environment Agency or of the stricter emission standards adopted, for example, by Belgium, Italy and Austria, and do not address the issue of vulnerable groups, such as pregnant women, newborn babies and children;

23. Calls, consequently, upon the Council to amend its Recommendation 1999/519/EC in order to take into account the Member States' best practices and thus to set stricter exposure limits for all equipment which emits electromagnetic waves in the frequencies between 0.1 MHz and 300 GHz

Pathophysiology Journal Publication - Special Issue on EMF (2009)

As a direct result of the BioInitiative Report, a special, peer-reviewed issue of Pathophysiology (6) was published in March 2009 and contained most of the BioInitiative content (some chapters updated from 2006 to 2009 published works) including a chapter on public health implications of wireless technologies (7). It also extended the scope of coverage to include RF impacts on the blood-brain barrier, effects of cell towers on wildlife, and reproduction effects in animal studies. It provided assurance of the high scientific quality of the BioInitiative Report analysis and conclusions, and buttressed the need for new EMF safety standards in a respected, peer-reviewed scientific journal.

"Bioelectromagnetics, the study of biological effects of electromagnetic fields (EMF), is an interdisciplinary science with a technical literature that is not easily accessible to the non-specialist. To increase access of the public to the technical literature and to the health implications of the scientific findings, the Bioinitiative Report was organized by an international group of scientists and published online at www.bioinitiative.org on August 31, 2007. The report has been widely read, and was cited in September 2008 by the European Parliament when it voted overwhelmingly that the current EMF safety standards were obsolete and needed to be reviewed. "

"DNA shows biological effects at the sub-cellular level that occur at very low EMF thresholds and across frequency ranges of the EM spectrum. Interactions with DNA may account for many of the effects of EMF, and they raise the possibility that genetic damage due to EMF can lead to cancer."

"The brain is exposed to radiation from mobile phone antennas, and laboratory studies show that the radiation causes leakage of the protective blood–brain barrier, as well as the death of neurons in the brain. Radiation emitted from base stations can affect all who are in the vicinity. Epidemiological studies have shown a relation between exposure to mobile phones, base-stations and the development of brain tumors. Some epidemiological studies have significant flaws in design, and the risk of brain cancer may be greater than reported in the published results."

"In addition to the risk of brain cancer, EMF in the environment may contribute to diseases like Alzheimer's dementia and breast cancer in humans, as well as reproductive and developmental effects in animals in the wild. EMF affects the biochemical pathways and immunological mechanisms that link the different organ systems in our bodies and those of animals. The human body can act as an antenna for RF signals, and a small percentage of the population appears to be so sensitive to EMF that it interferes with their daily lives. In addition to the growing presence of EMF signals in the environment, the complexity of the signals may be important in altering biological responses. These are among the many factors that must be considered in approaching EMF safety issues."

Preface, Pathophysiology, Guest Editor Martin Blank, PhD

Media coverage of the Pathophysiology Journal in 2009 highlighted the everyday problems of EMF and wireless exposures in society. For the typical person on the street, the message of the BioInitiative Report and its subsequent contributions to a scientific journal were broken down into examples more familiar to them (8).

"Public health concerns and scientific evidence for risks from cell phones and other wireless devices is published today in the journal Pathophysiology. International researchers have urged quick precautionary action to address a possible epidemic of brain tumors and many other health risks. Over four billion people around the world now use cell phones. They are rapidly eliminating the use of traditional land-line phones throughout the world. Health researchers from six countries give findings in fifteen (15) chapters covering health risks to humans and wildlife from electromagnetic fields and radiofrequency radiation."

"The global rollout of wireless technologies and devices like cell phones, cordless phones, cell towers (masts) and many other sources greatly increases our EMF exposure in daily life. The enormous popularity of new communication devices that allow email, texting, and access to the Internet from any city street has placed the issue squarely before government agencies like the FDA and the FCC, and also parents and school administrators. Parents must decide whether possible health risks to their children outweigh the convenience of keeping track of them. School officials and teachers care because of disruption and distraction in the classroom from cell phone use. National safety officials in the US face public criticism about highway collisions and road deaths from cell phone use while driving. Federal railway officials are

still coping with the problem of illicit texting by US railroad personnel that lead to the catastrophic collision of two trains in Chatsworth, California in 2008 killing 24 and injuring 135 more."

Reba Goodman, PhD (Columbia University) commented: "*cells in the body react to EMFs as potentially harmful, just like to other environmental toxins including heavy metals and toxic chemicals. The DNA in living cells recognizes electromagnetic fields at very low levels of exposure, and produces a biochemical stress response."*

David O. Carpenter, MD, Co-Editor of the BioInitiative Report and Director of the University of Albany, Institute of Health and the Environment concluded: "*the existing FCC and international limits do not do enough to protect people, especially children, from daily exposures to electromagnetic fields and radiofrequency radiation. The existing safety limits did not anticipate these new kinds of technologies affecting the health of people living with and using wireless devices on a daily basis. These effects are now widely reported to occur at exposure levels significantly below most current national and international limits."*

Brain tumor specialist Dr. Lennart Hardell, MD, PhD works as both an oncologist and a researcher at Orebro University Hospital in Sweden. He is an expert on cell phones and brain tumors.

"The evidence for risks from prolonged cell phone and cordless phone use is quite strong. For people who have used these devices for 10 years or longer, and when they are used mainly on one side of the head, the risk of malignant brain tumor is doubled for adults and is even higher for persons with first use before the age of 20 years."

Swedish researcher Olle Johansson, PhD (Karolinska Institute) said: "*most worrisome to me are the constant and unavoidable EMF exposures (from cell and DECT phones, power lines, new wireless technologies like WIMAX and WI-FI, etc.) everywhere in our daily life that may affect the overall health of this and coming generations. I worry especially about the impacts on the immune system, our only real line of defense against disease."*

Wildlife biologist Alfonso Balmoro, PhD of Valladolid, Spain voiced his concern that: *"electromagnetic radiation is a form of environmental pollution which may hurt wildlife. Phone masts located in their living areas are irradiating continuously some species that could suffer long-term effects, like reduction of their natural defenses, deterioration of their health, problems in reproduction and reduction of their useful territory through habitat deterioration. Therefore microwave and radiofrequency pollution constitutes a potential cause for the decline of animal populations and deterioration of health of plants living near phone masts."*

Co-Editor of the BioInitiative Report Cindy Sage observed: *"Prolonged exposure to radiofrequency and microwave radiation from cell phones, cordless phones, cell towers, WI-FI and other wireless technologies has been linked to interference with short-term memory and concentration, sleep disruption, headache and dizziness, fatigue, immune disruption, skin rashes and changes in cardiac function."*

"*these effects can happen with even very small levels of exposure if they occur on a daily basis. Cell phone use is likely to be more harmful in children whose brain and nervous system development can last into late adolescence*"

"The public health implications of billions of people who are exposed makes this a matter of critical concern to policy-makers around the world."

The European Environment Agency Director's Statement (2009)

Two years following the publication of the BioInitiative Report, and just months after publication of the special issue of Pathophysiology on EMF, the EEA updated its comments on potential health

risks of EMF and concern over the adequacy of public safety limits for emerging wireless technologies. The EEA issued a Statement on Mobile Phones for the September, 2009 conference 'Cell Phones and Health: Science and Public Policy Questinos, Washington DC. In part, the comments read (9):

> *"This event and the related Senate Hearings yesterday, have been, in part, stimulated by the BioIntiative Report, (2007), which helped increase public awareness of the potential hazards of electromagnetic fields, not least from mobile phones. The European Parliament responded to this debate with its resolution earlier this year which, among other things, called for lowering exposure to electromagnetic fields and for new exposure limits that would better protect the public. We fully share these recommendations."*

The EEA provides data, information and knowledge on the environment, including its impacts on public health, to EU institutions (the European Parliament, European Commission, and European Council of Ministers), to the 32 Member Countries of the EEA, and to the general public.

> *"The intention of the EEA to promote the use of mobile telephony in this way increases its responsibility to provide information that can help ensure the safety of the public when using mobile phones, especially vulnerable groups such as children, the elderly, and the immuno- compromised. This is the reason why the EEA issued an early warning about the potential hazards of EMF on 17 September 2007."*
>
> *"In this we drew attention to the BioInitiative report and to the other main references relevant to this debate (from the EU, the WHO, and the UK National Radiological Protection Board) which, taken together, provided the basis for our early warning on EMF."*
>
> *"Specifically, we noted that there are many examples of the failure to use the precautionary principle in the past, which have resulted in serious and often irreversible damage to health and environments. Appropriate, precautionary and proportionate actions taken now to avoid plausible and potentially serious threats to health from EMF are likely to be seen as prudent and wise from future perspectives".*
>
> *"This is the reason why the EEA issued an early warning about the potential hazards of EMF on 17 September 2007."*

EEA Recommendations based on current evidence (2009)
The evidence is now strong enough, using the precautionary principle, to justify the following steps:

1. *For governments, the mobile phone industry, and the public to take all reasonable measures to reduce exposures to EMF, especially to radio frequencies from mobile phones, and particularly the exposures to children and young adults who seem to be most at risk from head tumours. Such measures would include stopping the use of a mobile phone by placing it next to the brain. This can be achieved by the use of texting; hands free sets; and by the use of phones of an improved design which could generate less radiation and make it convenient to use hands free sets.*
2. *To reconsider the scientific basis for the present EMF exposure standards which have serious limitations such as reliance on the contested thermal effects paradigm; and simplistic assumptions about the complexities of radio frequency exposures.*
3. *To provide effective labeling and warnings about potential risks for users of mobile phones.*
4. *To generate the funds needed to finance and organise the urgently needed research into the health effects of phones and associated masts. Such funds could include grants from industry and possibly a small levy on the purchase and or use of mobile phones. This idea of a research levy is*

a practice that we think the US pioneered in the rubber industry with a research levy on rubber industry activities in the 1970s when lung and stomach cancer was an emerging problem for that industry. The research funds would be used by independent bodies.

European Parliament 2009

On April 2, 2009, the European Parliament adopted the "European Parliament resolution of 2 April 2009 on health concerns associated with electromagnetic fields (2008/2211(INI))" (10). The Document was based on the "Report on health concerns associated with electromagnetic fields", Rapporteur: Frederique Ries (11) Committee on the Environment, Public Health and Food Safety. See Appendix B for full text. It part, the resolution says:

H. (W)hereas, however, there are some points that appear to be the subject of general agreement, in particular the idea that reactions to microwave exposure vary from one person to another, the need, as a matter of priority, to conduct exposure tests under actual conditions in order to assess the non-thermal effects associated with radio-frequency (RF) fields, and the fact that children exposed to EMFs are especially vulnerable (9) ,

1. Urges the Commission to review the scientific basis and adequacy of the EMF limits as laid down in Recommendation 1999/519/EC and report to the Parliament; calls for the review to be undertaken by the Scientific Committee on Emerging and Newly Identified Health Risks;

2. Calls for particular consideration of biological effects when assessing the potential health impact of electromagnetic radiation, especially given that some studies have found the most harmful effects at lowest levels; calls for active research to address potential health problems by developing solutions that negate or reduce the pulsating and amplitude modulation of the frequencies used for transmission;

5. Invites the Member States and local and regional authorities to create a one-stop shop for authorisation to install antennas and repeaters, and to include among their urban development plans a regional antenna plan

6. Urges the authorities responsible for authorising the siting of mobile telephony antennas to reach agreement, jointly with the operators in that sector, on the sharing of infrastructure, in order to reduce the volume thereof and the exposure of the public to EMFs;

15. Draws attention in this context to the appeal for caution from the coordinator of the Interphone study, Elisabeth Cardis, who, in the light of existing knowledge, recommends, as far as children are concerned, that mobile phones should not be used beyond reasonable limits and that landlines should be preferred;

21. Calls on the Commission, in recognition of the public concern in many Member States, to work with all relevant stakeholders, such as national experts, non-governmental organisations and industrial sectors, to improve the availability of, and access to, up-to-date information understandable to non-specialists on wireless technology and protection standards;

24. Proposes that the EU's indoor air quality policy should encompass the study of "wireless" domestic appliances, which, like Wi-Fi for Internet access and digital enhanced cordless telecommunications (DECT) telephones, have been widely adopted in recent years in public places and in the home, with the result that citizens are being continuously exposed to microwave emissions;

29. Instructs its President to forward this resolution to the Council, the Commission, the

This revision essentially neutralized the chance for an independent and unbiased review of health effects and assessment of the adequacy of the ICNIRP/FCC thermally-based public health standards by designating the SCENIHR Committee to be the arbiter. The SCENIHR Committee ignored the non-thermal science and public health issues on EMF in past reviews. Appointing SCENIHR to provide the 'official' report to Parliament on health effects of EMF essentially guaranteed the outcome would be ineffectual for precautionary action, that the standard of evidence for judging would be "causal" evidence; and a public health standard for judging the evidence would not prevail. Reaching the very high bar of establishing 'causal evidence of risk' is not in line with precautionary, prudent public health decision-making. It will delay necessary actions for avoidance long past the 'early warning' stage when such actions may reasonably prevent substantial health harm.

However many points adopted in the resolution are in favour of public health and must not be dismissed.

Seletun Statement 2009

In November, 2009, a scientific panel met in Seletun, Norway, for three days of intensive discussion on existing scientific evidence and public health implications of the unprecedented global exposures to artificial electromagnetic fields (EMF). The Scientific Panel recognized that the body of evidence on EMF requires a new approach to protection of public health; the growth and development of the fetus, and of children; and argues for strong preventative actions. The study concluded that "new, biologically-based public exposure standards are urgently needed to protect public health worldwide" (12).

The Seletun Statement was published in 2010 in the journal Reviews on Environmental Health. It was titled *Scientific panel on electromagnetic field health risks: Consensus points, recommendations, and rationales*. Scientific Meeting: Seletun, Norway, November 17-21, 2009. (12).

Specific Recommendations from the Seletun Scientific Panel are:

"Extremely Low Frequency (Fields from Electrical Power)

- *Based on the available evidence, the Seletun Scientific Panel recommends a 0.1 uT (1 mG) exposure limit for all new installations based on findings of risk for leukemia, brain tumours,*

Alzheimer's, ALS, sperm damage and DNA strand breaks. This exposure limit does not include a safety margin;

- *For all newly installed, or newly upgraded electrical power distribution, the Panel recommends a 0.1 uT (1 mG) set-back distance, from residences, hospitals, schools, parks, and playgrounds schools (and similar locations occupied by children) [A 0.1 uT (1 mG) time-weighted average (TWA) using peak loading for transmission lines to ensure that average is about half of this for typical exposures; or equivalent for long-term exposure in interior EMF environments (wiring, trans-formers, appliances, others).];*

- *For all newly constructed residences, offices, schools (and other facilities with children), and hospitals there shall be a 0.1 uT (1 mG) max. 24 hour average exposure limit;*

- *For all new equipment (e.g. transformers, motors, electronic products), where practical, the Panel recommends a 0.1 uT (1 mG) max. 24 hour average exposure limit. Where not practical (e.g. large power transformers), there should be a fence, or boundary marker, with clearly written warning labels that states that within the boundary area the 0.1 uT (1 mG) maximum, 24 hour average exposure limit is exceeded;*

- *The Panel recommends all countries should adopt electrical code requirements to disallow conduction of high-frequency voltage transients back into electrical wiring systems;*

- *All new electronic devices including compact fluorescent lamps (CFLs) should be constructed with filters to block high-frequency voltage transients from being conducted back onto electrical wiring systems;*

- *The Panel recommends electric field reductions from electrical wiring in buildings based on evidence of increased cancer risk from prolonged or repetitive electric field exposure. The United States National Electrical Code (NEC) and other govern-mental codes relating to building design and construction should be revised so that all new electrical wiring is enclosed in a grounded metal shield;*

- *The United States NEC and other govern-mental codes that disallow net current on electrical wiring should be better enforced, and ground fault interrupters (GFIs) should be installed on all electrical circuits in order to reduce net current.*

<u>Radiofrequency/Microwave Radiation Exposure Limit Recommendations</u>

- *Present guidelines, such as IEEE, FCC, and ICNIRP, are not adequate to protect humans from harmful effects of chronic EMF exposure. The existing scientific knowledge is, however, not sufficient at this stage to formulate final and definite science-based guidelines for all these fields and conditions, particularly for such chronic exposure as well as contributions of the different parameters of the fields, e.g. frequency, modulation, intensity, and window effects. The values suggested below are, thus, provisional and may be altered in the future.*

- *For whole-body (in vivo experiments) or cell culture-based exposure, the Seletun Scientific Panel finds sufficient evidence to establish a scientific benchmark for adverse health effect at 0.0166 W/kg based on at least 32 scientific studies reporting low-intensity effects (defined as studies reporting effects at exposures of 0.1 W/kg or lower) /8-39/.*

- *The Panel recommends a provisional whole-body limit of 0.00033 W/kg by incorporation of an additional 50-fold safety margin applied to the scientific benchmark of 0.0166 W/kg. This is consistent with both ICNIRP and IEEE/FCC safety factors. An additional 10-fold reduction is applied to take prolonged exposure into account (because 29 of the 32 studies are acute exposure only), giving a final whole-body limit of 0.000033 W/kg (33 μW/kg). No further safety margin or provision for sensitive populations is incorporated. This may need to be lowered in the future.*

- *Based on power density measurements, the Seletun Scientific Panel finds sufficient evidence for a whole-body scientific bench-mark for adverse health effect exists down to 85 mW/m^2 (0.0085 mW/cm^2 or 8.5 μW/cm^2) based on at least 17 scientific studies reporting low-intensity effects on humans. Taking more recent human studies conducted near base stations, or at base-station RF levels, Kundi and Hutter /57/ report that the levels must exceed 0.5-1.0 mW/m^2 (0.05 to 0.1 uW/cm^2) for effects to be seen; /40-57/.*

- *The Panel recommends a provisional whole-body (far-field) limit of 1.7 mW/m^2 (also = 0.00017 mW/cm^2 = 0.17 μW/cm^2) by incorporation of an additional 50-fold safety margin applied to the scientific benchmark of 85 mW/m^2. This is consistent with both ICNIRP and IEEE/FCC safety factors. This may need to be lowered in the future.*

- *It can be argued that a further 10-fold reduction is not justified since 13 of the 17 studies are already testing for long-term RF exposure. However, considering that the latest human population studies as reported by Kundi & Hutter (2009) do not show effects below 0.5-1.0 mW/m2, it can also then be argued that an additional 10-fold reduction on precautionary grounds is justified. If another 10-fold reduction is applied, the recommended level would then be 0.17 mW/m^2 (also 0.000017 mW/cm^2 = 0.017 μW/cm^2);*

- *The Seletun Scientific Panel recommends these numeric limits to governments and health agencies for adoption in place of ICNIRP, IEEE/FCC and other outdated public safety guidelines and limits in use around the world. This approach is based on traditional public health principles that support taking actions to protect public health when sufficient evidence is present. Sufficient scientific evidence and public health concern exist today based on increased risk for cancer, adverse fertility and reproductive outcomes, immune disruption, neurological diseases, increased risk of road collisions and injury-producing events, and impairment of cognition, behaviour, performance, mood status, and disruption of sleep;*

- *Numeric limits recommended here do not yet take into account sensitive populations (EHS, immune-compromised, the fetus, developing children, the elderly, people on medications, etc). Another safety margin is, thus, likely justified further below the numeric limits for EMF exposure recommended here;*

- *The Scientific Panel acknowledges that numeric limits derived here for new biologically-based public exposure standards are still a billion times higher than natural EMF levels at which all life evolved.*

<u>Specific Recommendations for mobile (cell) and cordless phone use</u>

- *The Seletun Scientific Panel recommends that users keep mobile (cell) phones away from head and body;*

- *The Seletun Scientific Panel recommends that users keep mobile (cell) phones and PDAs* switched off if worn or carried in a pocket or holster, or on a belt near the body. *PDA is generic for any type of Personal Digital Assistant or hand-held computer device;*

- *The Panel strongly recommends against the use of mobile (cell) and cordless phones and PDAs by children of any age;*

- *The Panel strongly recommends against the use of mobile (cell) and cordless phones and PDAs by pregnant women;*

- *The Panel recommends that use of mobile (cell) and cordless phones and PDAs be curtailed near children or pregnant women, in keeping with preventative and precautionary strategies. The most vulnerable members of society should have access to public places without fear of harm to health;*

- *Public access to public places and public transportation should be available without undue risk of*

EMF exposure, particularly in enclosed spaces (trains, airplanes, buses, cars, etc) where the exposure is likely to be involuntary;

- *The Panel recommends wired internet access in schools, and strongly recommends that schools do not install wireless internet connections that create pervasive and prolonged EMF exposures for children;*

- *The Panel recommends preservation of existing land-line connections and public telephone networks;*

- *The Panel recommends against the use of cordless phones (DECT phones) and other wireless devices, toys and baby monitors, wireless internet, wireless security systems, and wireless power transmitters in SmartGrid-type connections that may produce unnecessary and potentially harmful EMF exposures;*

- *The Panel recognizes that wired internet access (cable modem, wired Ethernet connections, etc) is available as a substitute;*

- *The Panel recommends use of wired headsets, preferably with hollow-tube segments;*

- *The Panel recommends avoidance of wireless (Bluetooth-type) headsets in general;*

- *The Panel encourages the removal of speakers from headsets on wireless phones and PDAs;*

- *The Panel encourages _auto-off switches' for mobiles (cells) and PDAs that automatically turn off the device when placed in a holster;*

- *The Panel strongly discourages the technology that allows one mobile (cell) phone to act as a repeater for other phones within the general area. This can increase exposures to EMF that are unknown to the person whose phone is ―piggy-backed upon without their knowledge or permission;*

- *The Panel recommends the use of telephone lines (land-lines) or fiber optic cables for SmartGrid type energy conservation infra-structure. Utilities should choose options that do not create new, community-wide exposures from wireless components of SmartGrid-type projects. Future health risks from prolonged or repetitive wireless exposures of SmartGrid-type systems may be avoided by using telephone lines or fiber-optic cable. The Panel endorses energy conservation but not at the risk of exposing hundreds of millions of families in their homes to a new, involuntary source of wireless radiofrequency radiation."*

<u>Ten Key points had been identified:</u>

- *"The global populations are insufficiently protected, thus currently at risk;*

- *Sensitive Populations are extra vulnerable;*

- *Government actions are urgently warranted now, based on evidence of serious disruption to biological systems;*

- *The Burden of Proof for the safety of radiation-emitting technologies should fall on Producers and Providers, not Consumers;*

- *EMF Exposures should be reduced in advance of complete understanding of mechanisms of action;*

- *The current operative measure of Radiation Risk - the specific absorption rate (SAR) - is inadequate, and misguides on safety and health risks;*

- *An international Disease Registry is needed to track Time Trends of the incidence of Illnesses to correlate the illnesses with exposures;*

- *Pre-market health testing and safety demonstration is needed for all radiation-emitting technologies;*
- *Parity is needed for occupational exposure standards, compared to those for the general public;*
- *Persons with Electrohypersensitivity need the classification Functionally Impaired.*
- *The scientists recommend specific exposure limits for different frequency fields, including microwaves, used in wireless communications, and ELF electric fields and magnetic fields."*

Collegium Ramazzini Publication (2010)

The 400 page review of non-thermal EMF effects by the Ramazzini Institute, and sponsored by the International Commission for Electromagnetic Safety, and the National Institute for the Study and Control of Cancer and Environmental Diseases 'Bernardino Ramazzini' in 2010 provided a substantial evidence foundation for the relationship between low-intensity EMF (ELF-EMF and RFR) exposure and potential health risks (13). Taken as a whole, the two-volume report provides a compelling scientific basis on which to take precautionary, prudent public health actions. The EEA relied heavily on the Collegium Ramazzini publication to buttress their Statement on Mobile Phones, when addressing the Council of Europe the following year.

European Environment Agency (2011)

Dr. Jacqueline McGlade, Executive Director of the European Environment Agency provided key guidance to the Council of Europe in her *Statement on Mobile Phones and the Potential Head Cancer Risk for EMF* to the Council of Europe, Paris, February 25th 2011 (14). It read:

> *"The European Parliament[1] has responded to this public concern with a resolution on EMF in 2009 which, among other things, called for lowering exposure to electromagnetic fields and for lower exposure limits that would better protect the public from health hazards. We share these recommendations."*

[1] European Parliament resolution of 2 April 2009 on health concerns associated with electromagnetic fields (2008/2211(INI))

Further, she urged the Council of Europe take interim actions to protect public health, particularly for children, with the following:

> *"The EU Commission and the EEA sees the precautionary principle as central to public policymaking where there is scientific uncertainty and high health, environmental and economic costs in acting, or not acting, when faced with conflicting evidence of potentially serious harm."*
>
> *"This is precisely the situation that characterises EMF at this point in its history. Waiting for high levels of proof before taking action to prevent well known risks can lead to very high health and economic costs, as we have seen with asbestos, leaded petrol and smoking."*

Council of Europe 2011

[1] European Parliament resolution of 2 April 2009 on health concerns associated with electromagnetic fields (2008/2211(INI))

On May 27, 2011 the Standing Committee, acting on behalf of the Parliamentary Assembly of the Council of Europe (PACE), adopted the Resolution 1815 (2011) "The potential dangers of electromagnetic fields and their effect on the environment" (15) based on the Doc. 12608, report of the Committee on the Environment, Agriculture and Local and Regional Affairs, rapporteur: Mr Huss (16). The Parliamentary Assembly of the Council of Europe come from the national parliaments of the Organization's 47 member states and speak for the 800 million Europeans who elected them. The texts adopted by PACE – recommendations, resolutions and opinions – serve as guidelines for the Committee of Ministers, national governments, parliaments and political parties (17).

Recommendations given by the PACE Resolution 1815:

> *"8. In light of the above considerations, the Assembly recommends that the member states of the Council of Europe:*
>
> ***8.1. in general terms:***
>
> *8.1.1. take all reasonable measures to reduce exposure to electromagnetic fields, especially to radio frequencies from mobile phones, and particularly the exposure to children and young people who seem to be most at risk from head tumours;*
>
> *8.1.2. reconsider the scientific basis for the present standards on exposure to electromagnetic fields set by the International Commission on Non-Ionising Radiation Protection, which have serious limitations, and apply ALARA principles, covering both thermal effects and the athermic or biological effects of electromagnetic emissions or radiation;*
>
> *8.1.3. put in place information and awareness-raising campaigns on the risks of potentially harmful long-term biological effects on the environment and on human health, especially targeting children, teenagers and young people of reproductive age;*
>
> *8.1.4. pay particular attention to "electrosensitive" people who suffer from a syndrome of intolerance to electromagnetic fields and introduce special measures to protect them, including the creation of wave-free areas not covered by the wireless network;*
>
> *8.1.5. in order to reduce costs, save energy, and protect the environment and human health, step up research on new types of antenna, mobile phone and DECT-type device, and encourage research to develop telecommunication based on other technologies which are just as efficient but whose effects are less negative on the environment and health;*
>
> ***8.2. concerning the private use of mobile phones, DECT wireless phones, WiFi, WLAN and WIMAX for computers and other wireless devices such as baby monitors:***
>
> *8.2.1. set preventive thresholds for levels of long-term exposure to microwaves in all indoor areas, in accordance with the precautionary principle, not exceeding 0.6 volts per metre, and in the medium term to reduce it to 0.2 volts per metre;*
>
> *8.2.2. undertake appropriate risk-assessment procedures for all new types of device prior to licensing;*

8.2.3. introduce clear labelling indicating the presence of microwaves or electromagnetic fields, the transmitting power or the specific absorption rate (SAR) of the device and any health risks connected with its use;

8.2.4. raise awareness on potential health risks of DECT wireless telephones, baby monitors and other domestic appliances which emit continuous pulse waves, if all electrical equipment is left permanently on standby, and recommend the use of wired, fixed telephones at home or, failing that, models which do not permanently emit pulse waves;

8.3. concerning the protection of children:

8.3.1. develop within different ministries (education, environment and health) targeted information campaigns aimed at teachers, parents and children to alert them to the specific risks of early, ill-considered and prolonged use of mobiles and other devices emitting microwaves;

8.3.2. for children in general, and particularly in schools and classrooms, give preference to wired Internet connections, and strictly regulate the use of mobile phones by schoolchildren on school premises;

8.4. concerning the planning of electric power lines and relay antenna base stations:

8.4.1. introduce town planning measures to keep high-voltage power lines and other electric installations at a safe distance from dwellings;

8.4.2. apply strict safety standards for the health impact of electrical systems in new dwellings;

8.4.3. reduce threshold values for relay antennae in accordance with the ALARA principle and install systems for comprehensive and continuous monitoring of all antennae;

8.4.4. determine the sites of any new GSM, UMTS, WiFi or WIMAX antennae not solely according to the operators' interests but in consultation with local and regional government authorities, local residents and associations of concerned citizens;

8.5. concerning risk assessment and precautions:

8.5.1. make risk assessment more prevention oriented;

8.5.2. improve risk-assessment standards and quality by creating a standard risk scale, making the indication of the risk level mandatory, commissioning several risk hypotheses to be studied and considering compatibility with real-life conditions;

8.5.3. pay heed to and protect "early warning" scientists;

8.5.4. formulate a human-rights-oriented definition of the precautionary and ALARA principles;

8.5.5. increase public funding of independent research, in particular through grants from industry and taxation of products that are the subject of public research studies to evaluate health risks;

8.5.6. create independent commissions for the allocation of public funds;

8.5.7. make the transparency of lobby groups mandatory;

8.5.8. promote pluralist and contradictory debates between all stakeholders, including civil society (Århus Convention)."

European Environment Agency 2011

In October 12 2011, the European Environment Agency (EEA), an agency of the European Union. based in Copenhagen, Denmark, recommends again to take a precautionary approach to policy making in the EMF area (18). The Agency notes:

"The precautionary principle.

Because the evidence on mobile phones and cancer presents a mixed picture, the EEA recommends using the precautionary principle (PP), as recommended in the EU Treaty, to better manage the risk. There is no clear legal definition of the PP so the EEA has produced a working definition:

The precautionary principle provides justification for public policy actions in situations of scientific complexity, uncertainty and ignorance, where there may be a need to avoid, or reduce, potentially serious or irreversible threats to health and the environment, using an appropriate strength of scientific evidence, and taking into account the pros and cons of action and inaction.

The PP requires us to weigh evidence in a different way. This is not new - societies are used to using different strengths of evidence for different reasons, based on the costs of being wrong.
For example, criminals must be found guilty 'beyond all reasonable doubt' before they are convicted; injured people in compensation cases need only show a balance of evidence in order to win compensation for negligence; while doctors only need slight evidence of a serious illness to prescribe treatment. Such precautionary approaches are justified where it is not yet possible to establish causality beyond reasonable doubt.

Implications for policy makers and the mobile phone industry.

Citizens could be better informed about the risks of mobile phone use, as recommended by the EEA in September 2007. There is sufficient evidence of risk to advise people, especially children, not to place the handset against their heads: text messaging, or hands-free kits lead to about ten times lower radiation levels, on average, than when the phone is pressed to the head.

Governments may also wish to label mobile handsets as a 'possible carcinogen', in line with the IARC decision. In addition, more independent research is needed. The cost of these measures is very low, but the potential costs of inaction may be very high."

US Government Accountability Office (2012)

The US Government Accountability Office published a report in 2012 urging the US Federal Communications Commission to revisit the outdated safety standards for the exposures from wireless devices. (19)

The rapid adoption of mobile phones has occurred amidst controversy over whether the technology poses a risk to human health as a result of long-term exposure to RF energy from mobile phone use.

FCC and FDA share regulatory responsibilities for mobile phones. GAO was asked to examine several issues related to mobile phone health effects and regulation. Specifically, this report addresses:

1. *(1) what is known about the health effects of RF energy from mobile phones and what are current research activities,*
2. *(2) how FCC set the RF energy exposure limit for mobile phones, and*
3. *(3) federal agency and industry actions to inform the public about health issues related to mobile phones, among other things.*
4. *GAO reviewed scientific research; interviewed experts in fields such as public health and engineering, officials from federal agencies, and representatives of academic institutions, consumer groups, and the mobile phone industry; reviewed mobile phone testing and certification regulations and guidance; and reviewed relevant federal agency*
websites and mobile phone user manuals.

The Report noted that the FCC's RF energy exposure limit may not reflect the latest research. Redundant and overlapping jurisdiction over the setting of public safety limits is highlighted where the GAO Report notes:

> *"FCC told GAO that it relies on the guidance of federal health and safety agencies when determining the RF energy exposure limit, and to date, none of these agencies have advised FCC to change the limit. However, FCC has not formally asked these agencies for a reassessment. By not formally reassessing it's current limit, FCC cannot ensure it is using a limit that reflects the latest research on RF energy exposure. FCC has also not reassessed it's testing requirements to ensure that they identify the maximum RF energy exposure a user could experience. Some consumers may use mobile phones against the body, which FCC does not currently test, and could result in RF energy exposure higher than the FCC limit." (US GAO, 2012)*

The GAO Report recommends to the FCC that it formally reassess, and, if appropriate, change it's current RF energy exposure limit and mobile phone testing requirements related to likely usage configurations, particularly when phones are held against the body. FCC noted that a draft document that is now under consideration by the FCC has the potential to address GAO's recommendations. (US GAO, 2012)

European Environment Agency: Late Lessons II - Mobile Phone Chapter (2012)

The European Environment Agency (EEA) has Late Lessons from Early Warnings: Science, Precaution, Innovation (20). It includes a new chapter on Mobile Phone Use and Brain Tumor Risk (Hardell et al., 2012 (21). It addresses the early 'lessons' learned about carcinogenicity of EMF hazards from power lines and visual display units or VDUs. ELF-EMF was classified in 2001 by IARC as a 2B Possible Human Carcinogen. It provides a chronology of the publication of studies,

including the Final Interphone Report, the combined Hardell et al. papers (1999-2011) on brain tumor risks, and finally the classification in 2011 by IARC of radiofrequency radiation also to be a Group 2B Possible Human Carcinogen. The paper includes a section on risks to children. It shows that for children who start using a mobile phone in their early teenage years, by the time these children are in the 20-29 age group, they have a 500%+ increased risk of glioma and a 600%+ increased risk of acoustic neuroma when they are young adults. The risks for adults (ipsilateral, 10+ years of mobile phone use are roughly 200% or doubled.

III. EXPERT RESEARCH GROUP AND PHYSICIANS' ADVISORIES (2007 – 2012)

American Academy of Environmental Medicine Statement

In a landmark statement adopted early 2012, the American Academy of Medicine (AAEM) signaled it's opposition to the California Public Utilities Commission proposal to install wireless utility meters in California that create new sources of elevated radiofrequency radiation wherever buildings have electrical meters (22 and Appendix C). The letter stated:

> *"The American Academy of Environmental Medicine opposes the installation of wireless 'smart meters' in homes and schools based on a scientific assessment of the current medical literature (references available on request). Chronic exposure to wireless radiofrequency radiation is a preventable environmental hazard that is sufficiently well-documented to warrant immediate preventative public health action."*

The American Academy of Environmental Medicine was founded in 1965, and is an international association of physicians and other professionals interested in the clinical aspects of humans and their environment. The Academy is interested in expanding the knowledge of interactions between human individuals and their environment, as these may be demonstrated to be reflected in their total health. The AAEM provides research and education in the recognition, treatment and prevention of illnesses induced by exposures to biological and chemical agents encountered in air, food and water. This represents the first national physician's group to look in-depth at wireless health risks; and to advise the public and decision-makers about preventative public health actions that are necessary. The AAEM based its opinion in part on the established scientific evidence, and on the recent classification by the WHO International Agency for Research on Cancer (IARC) that radiofrequency radiation, like ELF-EMF is a Group 2B Possible Human Carcinogen. The rationale for widespread public exposure to a new source of radiofrequency radiation in every home and classroom, after being designated a Possible Human Carcinogen, is clearly unacceptable from a medical and public health standpoint. The full text of the letter is Appendix A.

International Doctors´ Appeal (2012)

In 2002 more than 1000 physicians signed the "Freiburg Appeal" (23). It was translated into many languages. As many as 36,000 people from all over the world support its warning about the dangers of wireless communication. Ten years later, in October 2012 the 'International Doctors´ Appeal 2012' was published (24).

"As physicians and scientists, we hereby call on our colleagues and the wider global community to support us with their signature in our fight for the protection of life. However, we also appeal to the politicians to ensure that the people are protected by the following precautionary measures, which also include fundamental human rights:

- *Protect the inviolability of the home by minimizing radio-frequency exposure levels, which penetrate through the walls of one's own home.*
- *Considerably lower radio-frequency radiation exposures as well as exposure limits to a level that reliably protects humans and nature from adverse biological effects of electromagnetic fields.*
- *Convert devices/transmitters that transmit continuously (e.g. cordless phones, wireless Internetaccess (Wi-Fi), and wireless meters) to technologies that only emit radio-frequency radiation on demand when being used.*
- *Children and adolescents need special protection: Children below the age of 8 should not use cell phones and cordless phones; children and adolescents between the ages 8 and 16 should not use cell phones or only use them in the case of an emergency.*
- *Attach clearly visible warning labels and safety guidelines for lowering the radiation exposure on cell phones and other wireless devices, including instruction manuals. An important reminder: Try not to carry a cell phone right next to your body when it is turned on.*
- *Identify and clearly mark protected zones for electrohypersensitive people; establish public areas without wireless access or coverage, especially on public transport, similar to smoke-free areas for nonsmokers.*
- *Promote the development of communication technologies and electricity use that is more compatible with health. Prefer wired solutions for home use and public facilities. Expand fiberoptic networks as the foundation of a modern, sustainable, and performance-based technology that meets the ever-increasing demand for higher data transmission rates.*
- *Provide government funding for industry-independent research and education that do not dismiss strong scientific and medical findings of potential risks, but rather work to clarify those risks.*

We also call on you as an individual: Prefer wired communication technologies. Inform yourself and pass this information on to your family, neighbors, friends, and politicians. You can make a difference by sharing information and making precautionary choices so that the protection of human health and the environment is not left to and limited by commercial interests."

American Academy of Pediatrics (July 2012)

The American Academy of Pediatrics (AAP), a non-profit professional organization of 60,000 primary care pediatricians, pediatric medical subspecialists, and pediatric surgical specialists in the

United States dedicated to the health, safety and well-being of infants, children, adolescents, and young adults strongly supports the proposal for a formal inquiry into radiation standards for cell phones and other wireless products. The Academy encourages the Federal Communications Commission (FCC) to vote to move forward with it's proposed inquiry into the adequacy of the existing FCC public safety limits (25 and Appendix D).

> *"The FCC has not assessed the standard for cell phone radiation since 1996. According to industry groups, approximately 44 million people had mobile phones when the standard was set; today, there are more than 300 million mobile phones in use in the United States. While the prevalence of wireless phones and other devices has sky-rocketed, the behaviors around cell phone uses have changed as well. The number of mobile phone calls per day, the length of each cell phone call, and the amount of time people use mobile phones has increased, while cell phone and wireless technology has undergone substantial changes. Many more people, especially adolescents and young adults, now use cell phones as their only phone line and they begin using wireless phones at much younger ages."*
>
> *"The AAP believes the inquiry to reassess the radiation standard presents an opportunity to review its impacts on children's health and well-being. In the past, such standards have generally been based on the impact of exposure on an adult male. Children, however, are not little adults and are disproportionately impacted by all environmental exposures, including cell phone radiation. In fact, according to IARC, when used by children, the average RF energy deposition is two times higher in the brain and 10 times higher in the bone marrow of the skull, compared with mobile phone use by adults. While the Academy appreciates that the FCC is considering investigating whether the emission standards should be different for devices primarily used by children, it is essential that any new standard for cell phones or other wireless devices be based on protecting the youngest and most vulnerable populations to ensure they are safeguarded throughout their lifetimes."*
>
> *"Finally, in reviewing the SAR standard, the FCC has the opportunity to highlight the importance of limiting media use among children. The Academy has found potentially negative effects and no known positive effects of media use by children under the age of two, including television, computers, cell phones, and other handheld wireless devices. In addition, studies consistently show that older children and adolescents utilize media at incredibly high rates, which potentially contributes to obesity and other health and developmental risks. In reviewing the SAR limit, the FCC has the opportunity to improve the health of our nation by highlighting the importance of limiting screen time and media use for children and adolescents."*

IV. LOCAL AND NATIONAL COUNTRY ACTIONS (2007 – 2012)

City of Brussels

The order of 1 March 2007 on the protection of the environment against the potentially harmful effects and nuisances caused by non-ionizing radiation, established a new regional framework legislation. Installations emitting electromagnetic radiation in the Brussels-Capital Region need environmental permits to be issued by Brussels Environment (26). The ordinance defines a standard of 3 V/m (also ~ 24 mW/m² ~ 2.4 µW/cm²) is not exceeded by the transmitting mobile phone antennas. Compliance with this standard is applied since 14 March 2009.

"Environmental permit for antennas: The steps of the procedure (27)

1. *Introduction of the permit application*
   The application of the *environment permit is introduced by the operator of the antenna to Brussels Environment includes a technical dossier containing plans from a simulation of the electromagnetic field in a radius of influence of 200 meters from the transmitting antenna.*
   This simulation takes into account the technical characteristics of the antenna and the surrounding environment (presence of buildings ...). It aims to ensure that 25% of the 3 V/m standard (also ~ 24 mW/m² ~ 2.4 µW/cm²) [given as power density = 1.5 V ~ 6 mW/m² ~ 0.6 µW/cm²/m] *is not exceeded in any place accessible to the public.*
2. *Site visit and review of the record*
   A Brussels Environment agent reviews the application and conducts a site visit to see if the simulation is correct and if the environmental situation close to the antenna described in the application file corresponds reality given. If this is the case, the file is submitted to public inquiry.
3. *Public Inquiry*
   The application is submitted to a 15 days public inquiry to notify you and allow you to give your opinion. Public inquiry was announced by red posters usual affixed near the place of the antenna location. Any citizen can go to municipal services concerned to take note of the case.
4. *Decision*
   The environmental permit is granted or refused by Brussels Environment. This license ensures that all measures for safety and protection of the environment and residents are provided."

Principality of Liechtenstein

In 2008 in the Principality of Liechtenstein a new environmental law came into effect including regulations and legal limits for cellular transmitters (28). The complete text for article 31 and 34 is given below. Article 31 defines locations with sensitive use where site specific limits have to be applied. However article 34, paragraph 4 (0.6 V/m limit) had been repealed in 2009 after business associations had initiated a national referendum (29).

Article 31 - Places of Sensitive Use

Regarded as places of sensitive use:

a) rooms in buildings where people stay regularly over a long period;
b) playgrounds and rest places of schools, kindergartens and nursery schools operated by the public;
c) fixed outdoor workplaces where work-related to the same person is shown during more than 800 hours a year. Including, in particular fixed sales stands and Jobs at permanently installed equipment, but not outside areas of restaurants and construction sites;
d) those areas of undeveloped land in construction zones on which uses are permitted by letters a and b.

Article 34 transmitters for cellular and wireless local loops

Site specific limits

1) For transmitters of mobile cellular networks and transmitters for wireless local loops with a total effective radiated power of at least 6 watts, the site specific limits under paragraph 2 and 4 apply. They do not apply for radio relay systems, the wireless network security "Polycom" and other radio networks of security and rescue organizations.
2) The site specific limit for the effective value (rms) of the electric field strength is:
a) for installations transmitting exclusively in the frequency range of 900 MHz: 4.0 V/m (also =

42 mW/m² = 4.2 µW/cm²);
b) for facilities that broadcast exclusively in the frequency range of 1800 MHz or in a higher frequency range: 6.0 V/m (also ~ 100 mW/m² = 10 µW/cm²).;
c) for facilities that broadcast in both frequency ranges specified in letters a and b: 5.0 V/m (also = 66 mW/m² = 6.6 µW/cm²).

3) *Whereas the operative mode and the maximum call and data traffic is at maximum transmission power.*
4) *Holder of a broadcast system are required to reduce the actual electric filed strength to the lowest technically feasible value, using appropriate measures and to accomplish by the end of 2012 an actual electric field strength of 0.6 V/m (also ~ 1 mW/m² ~ 0,1 µW/cm²) on average.*
5) *The Government shall provide further details by ordinance.*

Italy – Autonomous Province of Bolzano - South Tyrol (2009)

In a Decree dated April 29, 2009, the governor of the Autonomous Province Bolzano issued Regulation No. 24 concerning telecommunications infrastructure. In the autonomous province of Bolzano radio- and cellular transmitter sites have to be operated that take health aspects into account (30, 31). In practice e.g. radio transmitters had been aggregated on tall mast sites preferably outside residential areas on mountains. The population exposure from cellular antenna sites is calculated with help of predictive software and the best possible sites are evaluated. Each site has to be approved by a communications commission. The national limit for the sum of all RF sources in Italy is 6 V/m (also ~ 100 mW/m² ~ 10 µW/cm²). In the autonomous province of Bolzano the competent authority - State Agency for Environment - negotiates each cellular site with the relevant operator(s) in order to achieve a site specific exposure of 3 V/m (also ~ 24 mW/m² ~ 2.4 µW/cm²) and lower (32).

Austria – Ministry of Health 2010

In December 2010 the document "Aspects of the current health assessment of mobile communications - Recommendation of the Supreme Health Council" was published (33). Some of the recommendations are listed below.

"... Radio equipment, which leads to a prolonged exposure of people should be set up using a precautionary target value, since long-term effects can not be excluded with sufficient certainty. This target value should be set for high-frequency effects at least a factor of 100 below the limit for the power density of the ÖNORM E 8850 (note by the author: similar to ICNIRP 1998). In addition, legal measures should be taken, that
a) in case that various electromagnetic fields acting simultaneously, all relevant frequencies of different emitters are not to exceed the limits and
b) operators are encouraged to minimize exposure from electromagnetic fields well below the limit values during planning and operation."

,, ... In view of the many pending issues, the rational use of mobile phones should be taken generally, which seeks to have meaningful use and avoid unnecessary exposure. This is especially true for children and adolescents, since they will be predictable more exposed over their lifetime and

the organ-specific exposure through anatomical and developmental differences in certain tissues may be higher than in adults."

Nine specific recommendations were given by the Austrian Supreme Health Council:

1. *"If possible, do not call, when the reception is poor.*
2. *Keep calls short.*
3. *In situations where you can choose between mobile and fixed-line, use the landline.*
4. *Make calls in the car as little as possible.*
5. *With GSM (2 G) phones, wait a little time while connecting, before you run the phone to your head. Exposure by UMTS (3 G) mobile phones is usually much lower. Make sure to set the connection in multi-band-mobiles preferably via UMTS (3 G)*
6. *Use headsets or speakerphones.*
7. *When buying a cell phone mind low SAR values.*
8. *Wear the mobile not directly on the body.*
9. *Send an SMS instead of calling."*

France (2010)

In 2010 in France the Environmental Law some regulations concerning EMF issues had been supplemented (34, 35). Some excerpts are given below:

Article 183

- *Wireless terminals that are intended to be connected with a public telephone network may not be placed on the market without additional equipment, which allows to limit the exposure of the head during communication.*
- *The Higher Audiovisual Council shall ensure that the development of the sector of audiovisual communication goes along with an increased level of protection of the environment and the health of the population.*
- *Any advertising, about what aid whatsoever, with the direct aim to promote the sale, the provision or the use of a mobile phone by children under 14 is prohibited.*
- *The payment or free circulation of goods which contain a radio equipment and their use is specifically designed for children under six may be banned by decree of the Minister of Health, in order to avoid excessive exposure of children.*
- *Individuals who are responsible for the transport of electrical energy have to carry out a regular control of the electromagnetic fields, which are induced by power lines. The result of these measurements is to report annually to the French Agency for Sanitary Safety of environment and labor, which will publish them.*
- *In kindergarten (pre-), in the primary schools and in secondary schools (secondary) the use of a mobile phone is prohibited by a student during the entire lesson and at the designated places given in the house rules.*

Article 184

For any mobile telephone that is offered for sale [in France], the specific absorption rate is legible and in French. It must also provide a recommendation for the use of additional equipment, by means

of which the radio exposure of the head can be limited during the communication, as in the fifth Paragraph of point I of Article 183 of this law provided.

Austria – Austrian Medical Association (2012)

In 2012 the Austrian Medical Association published the "Guideline of the Austrian Medical Association for the diagnosis and treatment of EMF-related health problems and illnesses (EMF syndrome)"(36). The guideline is recommended to doctors of all disciplines in Austria. The guideline says in part:

"There has been a sharp rise in unspecific, often stress-associated health problems that increasingly present physicians with the challenge of complex differential diagnosis. A cause that has been accorded little attention so far is increasing electrosmog exposure at home, at work and during leisure activities, occurring in addition to chronic stress in personal and working life. It correlates with an overall situation of chronic stress that can lead to burnout.

How can physicians respond to this development?

The Austrian Medical Association has developed a guideline for differential diagnosis and potential treatment of unspecific stress-related health problems associated with electrosmog. Its core element is a patient questionnaire consisting of a general assessment of stress symptoms and a specific assessment of electrosmog exposure. The guideline is intended as an aid in diagnosing and treating EMF-related health problems."

Key elements of the guideline are:

1. *History of health problems and EMF exposure*
2. *Examination and findings*
3. *Measurement of EMF exposure*
4. *Prevention or reduction of EMF exposure*
5. *Diagnosis*
6. *Treatment*

Russian National Committee on Non-Ionizing Radiation (2011 and 2012)

On March 3, 2011 the Russian National Commitee on Non-Ionizing Radiation Protection approved the "Resolution: Electromagnetic Fields from Mobile Phones: Health Effects on Children and Teenagers" (37 and Appendix E). Parts of the resolution are given below.

"The Resolution evolved from scientific statements adopted by RNCNIRP in 2001, 2004, 2007, 2008 and 2009, taking into account contemporary views and actual scientific data. The Resolution represents a viewpoint of the professional scientific community and is meant for public dissemination, for the consumers of the mobile telecommunications services, as well as for the legislative and executive authorities who develop and implement health protection, environmental, communication, scientific and safety policies."

In 2012, the RCNIRP issued an update to this Resolution, calling on all countries to halt the use of wireless technologies in the school classrooms, and to move quickly to replace wireless with wired internet and teaching technologies (38 and Appendix F).

V. INTERNATIONAL HEALTH AGENCY ACTION

WHO International Agency for Research On Cancer – Formal Classification (2011)

On May 31, 2011 the WHO/International Agency for Research on Cancer (IARC) classified radiofrequency electromagnetic fields as possibly carcinogenic to humans (Group 2B), based on an increased risk for glioma, a malignant type of brain cancer, associated with wireless phone use (39, 40).

A group of 30 researchers, scientists and medical doctors were invited to participate in an assessment of the scientific literature on radiofrequency radiation carcinogenicity in Lyon, France. Under the auspices of IARC, this IARC Monograph Working Group on RFR conducted a comprehensive scientific assessment of RF studies and determined:

> *"In view of the limited evidence in humans and in experimental animals, the Working Group classified RF- EMF as "possibly carcinogenic to humans" (Group 2B). This evaluation was supported by a large majority of Working Group members."*
>
> *"The Working Group concluded that the (Interphone Final Report) findings could not be dismissed as reflecting bias alone, and that a causal interpretation between mobile phone RF-EMF exposure and glioma is possible. A similar conclusion was drawn from these two studies for acoustic neuroma, although the case numbers were substantially smaller than for glioma."*

It is important to recognize that the IARC RF Working Group did not find the evidence insufficient to classify (Group 3) or not a carcinogen (Group 4). Both of these possible outcomes to the scientific assessment could have rendered a substantially weaker conclusion. Where there has been the necessity of a virtual scientific paradigm shift to accommodate ANY consideration of both ELF-EMF and RFR to the status where legitimate scientific attention is achieved is a notable achievement. There is a very high bar set to show that non-chemical carcinogens warrant IARC carcinogenicity evaluation - it greatly exceeds that necessary for chemicals and other toxins.

The WHO press release No° 208 states

> *"The IARC Monograph Working Group discussed the possibility that these exposures might induce long-term health effects, in particular an increased risk for cancer. This has relevance for public health, particularly for users of mobile phones, as the number of users is large and growing,*

particularly among young adults and children."

The corresponding monograph has not been published as of October 2012. On request, IARC clarified the frequency range covered by the monograph (41).

> *"The IARC Monographs classification of Radiofrequency Electromagnetic Fields (RF-EMF) covers the entire radiofrequency segment of the electromagnetic spectrum (30 kHz-300 GHz). Within this spectrum, the electromagnetic fields around (or the radiation emitted by) mobile telephones represent the most intense and most wide-spread exposure situation, for which a small increase in risk for glioma and acoustic neuroma has been found in the group of 'heavy users'. Other devices that emit the same type of RF radiation - base-station antennas, radio/tv antennas, WiFi stations, smart meters - fall under the same evaluation. However, because the exposure levels for many of these other devices and exposure situations are so much lower than the exposure to someone who has a functioning cell phone against her/his ear, the risk will be considerably less (although the hazard still exists)."*

VI. CONCLUSIONS

1) The European Environmental Agency (2007) concludes that: "(*T)here are many examples of the failure to use the precautionary principle in the past, which have resulted in serious and often irreversible damage to health and environments. Appropriate, precautionary and proportionate actions taken now to avoid plausible and potentially serious threats to health from EMF are likely to be seen as prudent and wise from future perspectives. We must remember that precaution is one of the principles of EU environmental policy*."

2) The European Parliament, the Council of Europe and various governmental agencies in Europe, Scandinavia, Israel, North America, India and Asia have called for better warnings, to reduce or eliminate exposures from wireless devices, to label devices with health warnings, to develop new, lower public safety standards, to protect sensitive subgroups (children, people who are sensitized to EMF and wireless radiation already (electrosensitivity), and to inform and protect pregnant women and their young from unnecessary exposures. The countries of France, Italy, Belgium, the Principality of Liechtenstein, Switzerland, Austria, the United Kingdom, and others have led in proposing new restrictions on wireless exposures, based on scientific and public health reviews of the evidence. The US Government Accountability Office has called for review of American (FCC) safety limits for wireless devices.

3) Physicians and health advisory groups around the world have called for prudent public health actions that include reducing or eliminating ELF and RFR exposures, especially for pregnant women and for the developing fetus, and children, and particularly where other options are available (in the case of wireless exposures in particular). Some of these groups include the Austrian Ministry of Health, the Russian National Committee on Non-Ionizing Radiation, the American Academy of Environmental Medicine, the American Academy of Pediatrics, the British Chief Medical Officer, and many more governmental agencies across Europe, Scandinavia, North America, India and Asia.

4) Physicians and researchers who have published in-depth reviews on the science and public health policy implications of ELF and RFR risks to health include Pathophysiology, Vol 16 (2,3); 2009; the two-volume *Non Thermal effects and Mechanisms of interaction between Electromagnetic Fields and Living Matter*. eds Giuliani L and Soffritti, M, ICEMS, Ramazzini Institute, Bologna, Italy., 2010; the World Health Organization INTERPHONE Final Report, 2010; and the WHO International Agency for Research on Cancer RFR Monograph (Baan et al, 2011) designating RFR

as a Group 2B Possible Human Carcinogen.

5) Overall, these provide support for warnings and advice to consumers and the public that the body of evidence for bioeffects from daily exposure levels of ELF and RFR can reasonably be presumed to result in adverse health impacts with chronic exposure. The studies on which these warnings rely establish that bioeffects from exposure to ELF and RFR are established, not speculative or weak. Further, they establish that existing ICNIRP and FCC public safety limits are inadequate to protect public health; and underscore the need for new, biologically-based public exposure standards.

VIII. APPENDICES

APPENDIX A Full Text of European Parliament Statement - 2008

"The European Parliament ,

– having regard to the Communication from the Commission to the Council, the European Parliament and the European Economic and Social Committee on the mid-term review of the European Environment and Health Action Plan 2004-2010 (COM(2007)0314),

– having regard to its resolution of 23 February 2005 on the European Environment and Health Action Plan 2004-2010(1) ,

– having regard to the World Health Organisation (WHO) report of 27 July 2007 entitled 'Principles for evaluating health risks in children associated with exposure to chemicals',

– having regard to Articles 152 and 174 of the EC Treaty targeting a high level of protection for human health and the environment,

– having regard to Decision No 1350/2007/EC of the European Parliament and of the Council of 23 October 2007 establishing a second programme of Community action in the field of health (2008-13)(2) ,

– having regard to Rule 45 of its Rules of Procedure,

– having regard to the report of the Committee on the Environment, Public Health and Food Safety (A6-0260/2008),

A. noting with interest the fact that, since 2003, the EU has based its health-protection policy on closer cooperation between the health, environment and research sectors, so that it may be hoped that a coherent and integrated European environmental health strategy will eventually be introduced,

B. whereas the courses of action currently being followed by the EU as part of its first environment and health action plan (2004-2010) (COM(2004)0416) - namely, the preparation of indicators, the development of integrated monitoring, the collection and evaluation of relevant data as well as an increase in the volume of research - will allow greater insight into the interactions between sources of pollution and health effects but are known to be inadequate as a means of reducing the growing number of diseases related to environmental factors,

C. whereas it is virtually impossible to establish a mid-term assessment of the aforementioned action plan, since the latter pursues no clear, quantified objective and the total budget allocated to it is difficult to determine and definitely insufficient for its efficient promotion,

D. whereas the main objective of the 2008-2013 health programme is to act upon the factors which traditionally determine health (diet, smoking, alcohol consumption and the use of drugs); whereas this 2004-2010 action plan should focus on certain new health challenges and in addition address the determining environmental factors which affect human health, such as indoor and outdoor air quality, electromagnetic waves, nanoparticles and chemicals which are a cause for serious concern (substances classed as carcinogenic, mutagenic or toxic to reproduction [CMR], endocrine disruptors), as well as risks to health arising from climate change,

E. whereas respiratory illnesses rank second as a cause of death and in terms of incidence, prevalence and cost within the EU, whereas they constitute the main cause of death amongst children under the age of five

and whereas such diseases are continuing to progress on account of - in particular - indoor and outdoor air pollution,

F. whereas atmospheric pollution caused, in particular, by fine particles and ground-level ozone, is a significant threat to human health which is affecting the proper development of children and reducing life expectancy in the EU(3) ,

G. whereas, with reference to the issue of urban environmental health, particularly the quality of indoor air, the Community - in accordance with the subsidiarity and proportionality principles - should do more to combat domestic pollution, since Europeans spend on average 90% of their time inside buildings,

H. whereas at the 2004 and 2007 WHO ministerial conferences on health and the environment, attention was drawn to the links between the complex combined influence of chemical pollutants and a number of chronic illnesses and disorders (affecting children in particular); whereas those concerns are also expressed in official documents issued in connection with the United Nations Environment Programme (UNEP) and by the Intergovernmental Forum on Chemical Safety (IFCS),

I. whereas there is increasing scientific evidence that certain cancers, such as cancer of the bladder, bone cancer, lung cancer, skin cancer, breast cancer and others are caused not only by the effects of chemical substances, radiation and airborne particles but also by other environmental factors,

J. whereas these problematic developments in environmental health have been accompanied in recent years by the emergence of new diseases or syndromes, such as multiple chemical hypersensibility, dental-amalgam syndrome, hypersensitivity to electromagnetic radiation, sick-building syndrome and attention-deficit and hyperactivity syndrome in children,

K. whereas the precautionary principle has been enshrined in the Treaty since 1992 and whereas the European Court of Justice has repeatedly specified the substance and the scope of that principle in Community law, which constitutes one of the cornerstones of the protection policy pursued by the Community in the field of health and the environment(4) ,

L. having regard to the highly restrictive - if not to say impracticable - nature of the criteria adopted by the Commission in its 2 February 2000 Communication on the precautionary principle (COM(2000)0001),

M. having regard to the importance of human biological monitoring as a tool for assessing the European population's degree of exposure to the effects of pollution and the determination (repeatedly expressed by Parliament in Paragraph 3 of its aforementioned resolution of 23 February 2005 and in the conclusions issued at the end of the 20 December 2007 Council meeting of Environment Ministers) to expedite the introduction of a biological-monitoring programme at EU level,

N. whereas it is readily acknowledged that climate change can play an important role in increasing the severity and incidence of certain diseases and in particular that heat-wave frequency, flooding and wildfires as the most frequent natural disasters in the EU can lead to additional diseases, poor sanitation and deaths, while at the same time recognising the beneficial effects on health of measures to alleviate climate change,

O. whereas climate change will have significant effects on human health, inter alia by encouraging the development of certain infectious and parasitic diseases mainly because of changes in temperature and humidity and their impact on ecosystems, animals, plants, insects, parasites, protozoa, microbes and viruses,

P. whereas Directive 2000/60/EC of the European Parliament and of the Council of 23 October 2000 establishing a framework for Community action in the field of water policy(5) and its daughter directives contain clear provisions concerning the preservation and restoration of healthy waters,

Q. whereas environmental medicine is a new medical discipline based on university teaching which is still too fragmentary and unevenly distributed amongst the Member States and which thus deserves to be supported and promoted within the EU,

R. whereas the number of persons suffering as a result of environmental factors is increasing and epidemiologies should be developed in order to obtain a full picture of diseases which are caused wholly or in part by environmental factors,

1. Acknowledges the efforts made by the Commission since the action plan was launched in 2004, particularly in terms of improving the chain of information concerning health and the environment, integrating and expanding European research in this area and cooperating with specialist international organisations such as the WHO;

2. Considers, however, that such an action plan is bound to fail at least in part, since it is designed solely to accompany existing Community policies, it is not based upon a preventive policy intended to reduce illnesses linked to environmental factors, and it pursues no clear, quantified objective;

3. Draws the Commission's attention to the fact that a programme has already been carried out under the aegis of the WHO as part of which the WHO Member States established their own national and local environmental health action plans comprising specific objectives and implementation plans; recommends to the Commission therefore that it review this WHO programme as a possible model which could also serve as a useful example to the Union in the future;

4. Deeply regrets the fact that the Commission (and in particular its Research DG) has not provided sufficient funding for human biological monitoring in 2008 to enable it (as it had promised Parliament and the Member States) to introduce a consistent approach to biological monitoring within the EU;

5. Calls upon the Commission to respond by 2010 to two essential objectives which the Commission set itself in 2004 and to establish and carry out a practicable communication strategy for these objectives, namely to make members of the general public aware of environmental pollution and the impact thereof on their health, and to reconsider and adapt European risk-reduction policy;

6. Strongly recommends that the Commission and Member States meet their obligations as regards implementation of Community legislation;

7. Stresses that, when it comes to assessing the impact of environmental factors on health, consideration should be given first and foremost to vulnerable groups such as pregnant women, newborn babies, children and the elderly;

8. Calls for special attention to be given to vulnerable groups, who are the most susceptible to pollutants, by introducing measures to reduce exposure to indoor environmental contaminants in healthcare facilities and schools through the adoption of sound indoor air quality management practices;

9. Urges the Commission, when drafting proposals for the revision of existing laws, not to weaken those laws under pressure from lobbies or regional or international organisations;

10. Points that the EU needs to apply a continuous dynamic and flexible approach to the Action Plan; considers that it is therefore of paramount importance to acquire specific expertise on the subject of environmental health, to be based on transparency and on a multidisciplinary and adversarial approach which would thus enable the general public's distrust of official agencies and committees of experts to be countered; points to the importance of improving the training of health experts by means, in particular, of exchanges of best practice at Community level;

11. Points out that in recent years there have been genuine advances in environmental policy in the form of (for example) a reduction in air pollution, an improvement in water quality, the collection and recycling of waste, the monitoring of chemicals and a ban on leaded petrol, but notes at the same time that EU policy still lacks a comprehensive preventive strategy and fails to apply the precautionary principle;

12. Calls, therefore, on the Commission to revise the criteria laid down in its aforementioned Communication as regards recourse to the precautionary principle pursuant to European Court of Justice case-law, in order to ensure that an action and security principle based on the adoption of provisional and proportionate measures lies at the heart of Community health and environment policies;

13. Considers that shifting the burden of proof onto producers or importers and requiring them to demonstrate that a product is harmless would make it possible for a policy based on prevention to be promoted (as provided for in European Parliament and Council Regulation (EC) No 1907/2006 of 18 December 2006 concerning the registration, evaluation, authorisation and restriction of chemicals (REACH) and establishing a European Chemicals Agency(6)), and encourages the Commission to extend that obligation to Community legislation concerning all products; considers that any increase in animal testing under the Action Plan should be avoided and full regard should be paid to the development and use of alternative methods;

14. Calls once again upon the Commission to come forward as soon as possible with concrete measures on indoor air quality which would ensure a high level of protection of health and safety indoors to be established, in particular when revising Council Directive 89/106/EEC of 21 December 1988 on the approximation of laws, regulations and administrative provisions of the Member States relating to construction products(7) , and to propose measures to increase the energy efficiency of buildings and the safety and the harmlessness of chemical compounds used in equipment and furnishings;

15. Recommends that, in order to reduce damaging effects of the environment on health, the Commission should call upon Member States, by means of tax concessions and/or other economic incentives, to interest market operators in improving the quality of indoor air and reducing exposure to electromagnetic radiation in their buildings, branch establishments and offices;

16. Recommends that the Commission draft appropriate minimum requirements to guarantee the quality of indoor air in buildings to be newly built;

17. Recommends that, in awarding individual European Union support, the Commission bear in mind its impact on the quality of indoor air, exposure to electromagnetic radiation and the health of particularly endangered sections of the population in the projects concerned in a similar way to that in which attention is devoted to environmental protection criteria;

18. Calls for environmental quality standards for priority substances in water to be laid down in accordance with the latest scientific knowledge and regularly brought into line with current scientific thinking;

19. Points out that certain Member States have successfully introduced mobile analysis laboratories (or "green ambulances") to enable habitat pollution in public and private places to be diagnosed swiftly and reliably; considers that the Commission could promote such a practice within the Member States which have not yet acquired such a means of direct intervention at a polluted site;

20. Is concerned about the lack of specific legal provisions to ensure the safety of consumer products containing nanoparticles and the relaxed attitude of the Commission with regard to the need to review the regulatory framework for the use of nanoparticles in consumer products in light of the increasing number of consumer products containing nanoparticles being put on the market;

21. Is greatly concerned at the Bio-Initiative international report(8) concerning electromagnetic fields, which summarises over 1500 studies on that topic and which points in its conclusions to the health risks posed by emissions from mobile-telephony devices such as mobile telephones, UMTS, Wifi, Wimax and Bluetooth, and also DECT landline telephones;

22. Notes that the limits on exposure to electromagnetic fields which have been set for the general public are obsolete, since they have not been adjusted in the wake of Council Recommendation 1999/519/EC of 12 July 1999 on the limitation of exposure of the general public to electromagnetic fields (0Hz to 30 GHz)(9) , obviously take no account of developments in information and communication technologies, of the recommendations issued by the European Environment Agency or of the stricter emission standards adopted, for example, by Belgium, Italy and Austria, and do not address the issue of vulnerable groups, such as pregnant women, newborn babies and children;

23. Calls, consequently, upon the Council to amend its Recommendation 1999/519/EC in order to take into account the Member States' best practices and thus to set stricter exposure limits for all equipment which emits electromagnetic waves in the frequencies between 0.1 MHz and 300 GHz;

24. Takes a very serious view of the multiple health risks created by global warming on EU territory and calls for enhanced cooperation between the WHO, the Member States" monitoring authorities, the Commission and the European Centre for Disease Prevention and Control in order to bolster the early-warning system and thus to curb the harmful effects which climate change has on health;

25. Highlights that this Action Plan would benefit from being extended to cover negative impacts of climate change on human health by elaborating on effective adaptation measures necessary at Community level, such as:

- *systematic public education programmes and awareness-raising;*
- *integration of climate change adaptation measures into public health strategies and programmes, such as communicable and non-communicable diseases, workers' health and animal diseases hazardous to health;*
- *proper surveillance aiming at the early detection of disease outbreaks;*
- *health-related early warning systems and response;*
- *coordination of existing environmental data monitoring networks with disease outbreak networks;*

26. Calls on Member States and the Commission to respond adequately to the new threats posed by climate change such as the increased presence of emerging viruses and undetected pathogens and therefore implement new existing pathogen reduction technologies that reduce known and undetected viruses and other pathogens transmitted by blood;

27. Regrets that the current cost benefit impact assessment of the '20 20 by 2020 Europe's Climate Change Opportunity' (COM(2008)0030) only considers the health benefits of reduced air pollution at a 20% reduction of greenhouse gas emissions by 2020; calls on the Commission to ensure that the (ancillary) co-benefits to health of various levels of ambition, in line with the International Panel on Climate Change recommendations of domestic 25% to 40% as well as possibly 50% or more of greenhouse gas emission reduction by 2020, are urgently investigated and modelled into an impact assessment by the Commission;

28. Calls on the Commission to pay attention to the serious problem of mental health, considering the number of suicides in the EU, and to devote more resources to the development of adequate prevention strategies and therapies;

29. Reiterates that the Commission and the Member States should support the WHO Children's Environment and Health Action Plan in Europe, to encourage it both through EU and bilateral development policy, and to encourage similar processes outside the WHO Europe Region;

30. Calls on the Commission to reincorporate into its second action plan the initiative SCALE (Science, Children, Awareness, Legal instruments, Evaluation) relating to the reduction of exposure to pollution, as set out in the European Environment and Health Strategy (COM(2003)0338);

31. Urges the Commission to work on and provide instruments that would foster the development and promotion of innovative solutions, as stressed within the Lisbon agenda framework, in order to minimise major health risks from environmental stressors;

32. Urges the Council to take a decision without delay on the proposal for a regulation establishing the Union Solidarity Fund, as Parliament adopted its position as long ago as 18 May 2006(10) ; considers that the new regulation, which, together with other measures, will lower thresholds for the entry into force of the Union Solidarity Fund, will make it possible to alleviate more effectively, flexibly and quickly damage caused by natural or man-made disasters; stresses that such a financial instrument is very important, particularly because it is assumed that natural disasters will occur more frequently in future, partly on account of climate change;

33. Recommends, as SMEs are of decisive economic importance in Europe, that the Commission should provide technical support to SMEs to make it possible, and help them, to comply with binding environmental health regulations and encourage them to make other changes which are positive from the point of view of environmental health and affect the operation of enterprises;

34. Advises the Commission to envisage (by 2010 and under the "second cycle" of the health and environment action plan) refocusing its initiatives on vulnerable populations and to devise new methods of risk assessment, taking into account the fundamental fact that children, pregnant women and older people are particularly vulnerable;

35. Urges the Commission and Member States therefore to acknowledge the advantages of the prevention and precautionary principles and to develop and implement tools enabling potential environmental and health threats to be anticipated and countered; recommends that the Commission cost the 'second cycle' of this action plan and make provision for appropriate funding covering a larger number of practical measures to reduce environmental impact on health and to implement prevention and precautionary measures;

36. Instructs its President to forward this resolution to the Council, the Commission, the governments and parliaments of the Member States and the WHO.

APPENDIX B Full Text of European Parliament Resolution – 2009

European Parliament 2009

On April 2, 2009, the European Parliament adopted the "European Parliament resolution of 2 April 2009 on health concerns associated with electromagnetic fields (2008/2211(INI))" (10). The Document was based on the "Report on health concerns associated with electromagnetic fields", Rapporteur: Frederique Ries (11) Committee on the Environment, Public Health and Food Safety.

A. whereas electromagnetic fields (EMFs) exist in nature and have consequently always been present on earth; whereas, however, in recent decades, environmental exposure to man-made sources of EMFs has risen constantly, driven by demand for electricity, increasingly more specialised wireless technologies, and changes in the organisation of society; whereas the end effect is that every individual is now being exposed to a complex mixture of electric and magnetic fields of different frequencies, both at home and at work,

B. whereas wireless technology (mobile phones, Wi-Fi/WiMAX, Bluetooth, DECT landline telephones) emits EMFs that may have adverse effects on human health,

C. whereas most European citizens, especially young people aged from 10 to 20, use a mobile phone, an object serving a practical purpose and as a fashion accessory, and whereas there are continuing uncertainties about the possible health risks, particularly to young people whose brains are still developing,

D. whereas the dispute within the scientific community regarding the potential health risks arising from EMFs has intensified since 12 July 1999, when exposure limits for fields in the 0 Hz to 300 GHz range were laid down in Recommendation 1999/519/EC,

E. whereas the fact that the scientific community has reached no definite conclusions has not prevented some national or regional governments, in China, Switzerland, and Russia, as well as in at least nine EU Member States, from setting what are termed "preventive" exposure limits, that is to say, lower than those advocated by the Commission and its independent scientific committee, the Scientific Committee on Emerging and Newly Identified Health Risks(7) ,

F. whereas actions to limit the exposure of the general public to EMFs should be balanced against improvements to quality of life, in terms of safety and security, brought about by devices transmitting EMFs,

G. whereas among the scientific projects arousing both interest and controversy is the Interphone epidemiological study, financed by an EU contribution of EUR 3 800 000, primarily under the Fifth RTD Framework Programme(8) , the findings of which have been awaited since 2006,

H. whereas, however, there are some points that appear to be the subject of general agreement, in particular the idea that reactions to microwave exposure vary from one person to another, the need, as a matter of priority, to conduct exposure tests under actual conditions in order to assess the non-thermal effects associated with radio-frequency (RF) fields, and the fact that children exposed to EMFs are especially vulnerable(9) ,

I. whereas the EU has laid down exposure limits to protect workers from the effects of EMFs; whereas on the basis of the precautionary principle such measures should also be taken for the sections of population concerned, such as residents and consumers,

J. whereas the Special Eurobarometer report on Electromagnetic Fields (No 272a of June 2007) indicates that the majority of citizens do not feel that the public authorities inform them adequately on measures to protect them from EMFs,

K. whereas it is necessary to continue investigations into intermediate and very low frequencies so that conclusions can be drawn as to their effects on health,

L. whereas the use of Magnetic Resonance Imaging (MRI) must not be threatened by Directive 2004/40/EC as MRI technology is at the cutting edge of research, diagnosis and treatment of life-threatening diseases for patients in Europe,

M. whereas the MRI safety standard IEC/EN 60601-2-33 establishes limit values for EMFs which have been set so that any danger to patients and workers is excluded.

1. Urges the Commission to review the scientific basis and adequacy of the EMF limits as laid down in Recommendation 1999/519/EC and report to the Parliament; calls for the review to be undertaken by the Scientific Committee on Emerging and Newly Identified Health Risks;

2. Calls for particular consideration of biological effects when assessing the potential health impact of electromagnetic radiation, especially given that some studies have found the most harmful effects at lowest levels; calls for active research to address potential health problems by developing solutions that negate or reduce the pulsating and amplitude modulation of the frequencies used for transmission;

3. Maintains that as well as, or as an alternative to, amending European EMFs limits, the Commission, working in coordination with experts from Member States and the industries concerned (electricity companies, telephone operators and manufacturers of electrical appliances including mobile phones), should draw up a guide to available technology options serving to reduce exposure to EMFs;

4. Notes that industry stakeholders as well as relevant infrastructure managers and competent authorities can already influence certain factors, for example setting provisions with regards to the distance between a given site and the transmitters, the height of the site in relation to the height of the base station, or the direction of a transmitting antenna in relation to living environments, and, indeed, should obviously do so in order to reassure, and afford better protection to, the people living close to such facilities; calls for optimal placement of masts and transmitters and further calls for the sharing of masts and transmitters placed in this way by providers so as to limit the proliferation of poorly positioned masts and transmitters; calls on the Commission and Member States to draw up appropriate guidance;

5. Invites the Member States and local and regional authorities to create a one-stop shop for authorisation to install antennas and repeaters, and to include among their urban development plans a regional antenna plan

6. Urges the authorities responsible for authorising the siting of mobile telephony antennas to reach agreement, jointly with the operators in that sector, on the sharing of infrastructure, in order to reduce the volume thereof and the exposure of the public to EMFs;

7. Acknowledges the efforts of mobile communications and other EMF-transmitting wireless technologies to avoid damaging the environment, and in particular to address climate change;

8. Considers that, given the increasing numbers of legal actions and measures by public authorities having the effect of a moratorium on the installation of new EMF-transmitting equipment, it is in the general interest to encourage solutions based on negotiations involving industry stakeholders, public

authorities, military authorities and residents" associations to determine the criteria for setting up new GSM antennas or high-voltage power lines, and to ensure at least that schools, crèches, retirement homes, and health care institutions are kept clear, within a specific distance determined by scientific criteria, of facilities of this type;

9. Calls on the Member States to make available to the public, jointly with the operators in the sector, maps showing exposure to high-voltage power lines, radio frequencies and microwaves, and especially those generated by telecommunications masts, radio repeaters and telephone antennas. Calls for that information to be displayed on an internet page so that it can easily be consulted by the public, and for it to be disseminated in the media;

10. Proposes that the Commission consider the possibility of using funding from the Trans-European Energy Networks to investigate the effects of EMFs at very low frequencies, and particularly in electrical power lines,

11. Calls on the Commission, during the 2009-2014 parliamentary term, to launch an ambitious programme to gauge the electromagnetic compatibility between waves created artificially and those emitted naturally by the human body with a view to determining whether microwaves might ultimately have undesirable consequences for human health;

12. Calls on the Commission to present a yearly report on the level of electromagnetic radiation in the EU, its sources, and actions taken in the EU to better protect human health and the environment;

13. Calls on the Commission to find a solution enabling Directive 2004/40/EC to be implemented more rapidly and thus ensure that workers are properly protected against EMFs, just as they are already protected under two other Community acts against noise(10) and vibration(11) and to introduce a derogation for MRI under Article 1 of that Directive.

14. Deplores the fact that, as a result of repeated postponements since 2006, the findings of the Interphone study have yet to be published, the purpose of this international epidemiological study being to establish whether there is a link between use of mobile phones and certain types of cancer, including brain, auditory nerve, and parotid gland tumours;

15. Draws attention in this context to the appeal for caution from the coordinator of the Interphone study, Elisabeth Cardis, who, in the light of existing knowledge, recommends, as far as children are concerned, that mobile phones should not be used beyond reasonable limits and that landlines should be preferred;

16. Believes in any event that it is up to the Commission, which has an important contribution to the financing of this global study, to ask those in charge of the project why no definitive findings have been published and, should it receive an answer, to inform Parliament and the Member States without delay;

17. Also suggests to the Commission, to make for efficiency in policy and budget terms, that the Community funding earmarked for studies on EMFs be partly switched to finance a wide-ranging awareness campaign to familiarise young Europeans with good mobile phone techniques, such as the use of hands-free kits, keeping calls short, switching off phones when not in use (such as when in classes) and using phones in areas that have good reception;

18. Considers that such awareness-raising campaigns should also familiarise young Europeans with the health risks associated with household devices and the importance of switching off devices rather than leaving them on stand-by;

19. Calls on the Commission and Member States to increase research and development funding for the evaluation of potential long-term adverse effects of mobile telephony radio frequencies; calls also for an increase in public calls for proposals for investigation of the harmful effects of multiple exposure to different sources of EMFs, particularly where children are concerned;

20. Proposes that the European Group on Ethics in Science and New Technologies be given the additional task of assessing scientific integrity in order to help the Commission forestall possible cases of risk, conflict of interests, or even fraud that might arise now that competition for researchers has become keener;

21. Calls on the Commission, in recognition of the public concern in many Member States, to work with all relevant stakeholders, such as national experts, non-governmental organisations and industrial sectors, to improve the availability of, and access to, up-to-date information understandable to non-specialists on wireless technology and protection standards;

22. Calls on the International Commission on Non-Ionising Radiation Protection and the World Health Organisation (WHO) to be more transparent and open to dialogue with all stakeholders in standard setting;

23. Condemns certain particularly aggressive marketing campaigns by telephone operators in the run-up to Christmas and other special occasions, including for example the sale of mobile phones designed solely for children or free call time packages aimed at teenagers;

24. Proposes that the EU's indoor air quality policy should encompass the study of "wireless" domestic appliances, which, like Wi-Fi for Internet access and digital enhanced cordless telecommunications (DECT) telephones, have been widely adopted in recent years in public places and in the home, with the result that citizens are being continuously exposed to microwave emissions;

25. Calls, given its constant concern to improve consumer information, for the technical standards of the European Committee for Electrotechnical Standardisation to be amended with a view to imposing labelling requirements whereby the transmitting power would have to be specified and every wireless-operated device accompanied by an indication that it emitted microwaves;

26. Calls on the Council and Commission, in coordination with the Member States and the Committee of the Regions, to encourage the introduction of a single standard designed to ensure that local residents are subjected to as low a degree of exposure as possible when high-voltage grids are extended;

27. Is greatly concerned about the fact that insurance companies are tending to exclude coverage for the risks associated with EMFs from the scope of liability insurance policies, the implication clearly being that European insurers are already enforcing their version of the precautionary principle;

28. Calls on Member States to follow the example of Sweden and to recognise persons that suffer from electrohypersensitivity as being disabled so as to grant them adequate protection as well as equal opportunities;

29. Instructs its President to forward this resolution to the Council, the Commission, the governments and parliaments of the Member States, the Committee of the Regions, and the WHO.

Decision Proposed Decision of Commissioner Peevy (Mailed 11/22/2011)
BEFORE THE PUBLIC UTILITIES COMMISSION OF THE STATE OF CALIFORNIA
On the proposed decision 11-03-014

Dear Commissioners:

The Board of the American Academy of Environmental Medicine opposes the installation of wireless "smart meters" in homes and schools based on a scientific assessment of the current medical literature (references available on request). Chronic exposure to wireless radiofrequency radiation is a preventable environmental hazard that is sufficiently well documented to warrant immediate preventative public health action.

As representatives of physician specialists in the field of environmental medicine, we have an obligation to urge precaution when sufficient scientific and medical evidence suggests health risks which can potentially affect large populations. The literature raises serious concern regarding the levels of radio frequency (RF - 3KHz – 300 GHz) or extremely low frequency (ELF – 300Hz) exposures produced by "smart meters" to warrant an immediate and complete moratorium on their use and deployment until further study can be performed. The board of the American Board of Environmental Medicine wishes to point out that existing FCC guidelines for RF safety that have been used to justify installation of "smart meters" only look at thermal tissue damage and are obsolete, since many modern studies show metabolic and genomic damage from RF and ELF exposures below the level of intensity which heats tissues. The FCC guidelines are therefore inadequate for use in establishing public health standards. More modern literature shows medically and biologically significant effects of RF and ELF at lower energy densities. These effects accumulate over time, which is an important consideration given the chronic nature of exposure from "smart meters". The current medical literature raises credible questions about genetic and cellular effects, hormonal effects, male fertility, blood/brain barrier damage and increased risk of certain types of cancers from RF or ELF levels similar to those emitted from "smart meters". Children are placed at particular risk for altered brain development, and impaired learning and behavior. Further, EMF/RF adds synergistic effects to the damage observed from a range of toxic chemicals. Given the widespread, chronic, and essentially inescapable ELF/RF exposure of everyone living near a "smart meter", the Board of the American Academy of Environmental Medicine finds it unacceptable from a public health standpoint to implement this technology until these serious medical concerns are resolved. We consider a moratorium on installation of wireless "smart meters" to be an issue of the highest importance.

The Board of the American Academy of Environmental Medicine also wishes to note that the US NIEHS National Toxicology Program in 1999 cited radiofrequency radiation as a potential Carcinogen. Existing safety limits for pulsed RF were termed 'not protective of public health' by the Radiofrequency Interagency Working Gropu (a federal interagency working group includeing the FDA, FCC, OSHA, the EPA and others). Emissions given off by 'smart meters' have been classified by the World Health Organization International Agency for Research on Cancer (IARC) as a Possible Human Carciongen.

Hence, we call for:

- An immediate moratorium on "smart meter" installation until these serious public health issues are resolved. Continuing with their installation would be extremely irresponsible.
- Modify the revised proposed decision to include hearings on health impact in the second proceedings, along with cost evaluation and community wide opt-out.
- Provide immediate relief to those requesting it and restore the analog meters.

July 12, 2012

The Honorable Julius Genachowski
Commissioner
Federal Communications Commission
445 12th Street SW
Washington, DC 20554

Dear Chairman Genachowski:

The American Academy of Pediatrics (AAP), a non-profit professional organization of 60,000 primary care pediatricians, pediatric medical sub-specialists, and pediatric surgical specialists dedicated to the health, safety and well-being of infants, children, adolescents, and young adults strongly supports the proposal for a formal inquiry into radiation standards for cell phones and other wireless products. The Academy encourages the Federal Communications Commission (FCC) to vote to move forward with this inquiry in an expeditious manner.

The FCC has not assessed the standard for cell phone radiation since 1996. According to industry groups, approximately 44 million people had mobile phones when the standard was set; today, there are more than 300 million mobile phones in use in the United States. While the prevalence of wireless phones and other devices has sky-rocketed, the behaviors around cell phone uses have changed as well. The number of mobile phone calls per day, the length of each cell phone call, and the amount of time people use mobile phones has increased, while cell phone and wireless technology has undergone substantial changes. Many more people, especially adolescents and young adults, now use cell phones as their only phone line and they begin using wireless phones at much younger ages.

The FCC standard for maximum radiation-exposure levels are based on the heat emitted by mobile phones. These guidelines specify exposure limits for hand-held wireless devices in terms of the Specific Absorption Rate (SAR), which measures the rate the body absorbs radiofrequency (RF). The current allowable SAR limit is 1.6 watts per kilogram (W/kg), as averaged over one gram of tissue. Although wireless devices sold in the United States must ensure that they do not exceed the maximum allowable SAR limit when operating at the device's highest possible power level, concerns have been raised that long-term RF exposure at this level affects the brain and other tissues and may be connected to types of brain cancer, including glioma and meningioma.

In the past few years, a number of American and international health and scientific bodies have contributed to the debate over cell phone radiation and its possible link to cancer. The International Agency for Research on Cancer (IARC), part of the

United Nations' World Health Organization, said in June 2011 that a family of frequencies that includes mobile-phone emissions is "possibly carcinogenic to humans." The National Cancer Institute has stated that although studies have not demonstrated that RF energy from cell phones definitively causes cancer, more research is needed because cell phone technology and cell phone use are changing rapidly. While a definitive link between cell phone radiation and brain cancer has not been established, these studies and others clearly demonstrate the need for further research into this area and highlight the importance of reassessing the current SAR to determine if it is protective of human health.

The AAP believes the inquiry to reassess the radiation standard presents an opportunity to review its impacts on children's health and well-being. In the past, such standards have generally been based on the impact of exposure on an adult male. Children, however, are not little adults and are disproportionately impacted by all environmental exposures, including cell phone radiation. In fact, according to IARC, when used by children, the average RF energy deposition is two times higher in the brain and 10 times higher in the bone marrow of the skull, compared with mobile phone use by adults. While the Academy appreciates that the FCC is considering investigating whether the emission standards should be different for devices primarily used by children, it is essential that any new standard for cell phones or other wireless devices be based on protecting the youngest and most vulnerable populations to ensure they are safeguarded throughout their lifetimes.

Finally, in reviewing the SAR standard, the FCC has the opportunity to highlight the importance of limiting media use among children. The Academy has found potentially negative effects and no known positive effects of media use by children under the age of two, including television, computers, cell phones, and other handheld wireless devices. In addition, studies consistently show that older children and adolescents utilize media at incredibly high rates, which potentially contributes to obesity and other health and developmental risks. In reviewing the SAR limit, the FCC has the opportunity to improve the health of our nation by highlighting the importance of limiting screen time and media use for children and adolescents.

The AAP supports the proposal for a formal inquiry into radiation standards for cell phones and other wireless products and the Academy encourages the FCC to vote in favor of moving forward with this investigation. If you have questions or concerns, please contact Kristen Mizzi in the AAP's Washington Office at 202/347-8600.

Sincerely,

Robert W. Block, MD FAAP President

Appendix E RCNIRP Resolution: Electromagnetic Fields from Mobile Phones: Health Effects on Children and Teenagers

"The Resolution evolved from scientific statements adopted by RNCNIRP in 2001, 2004, 2007, 2008 and 2009, taking into account contemporary views and actual scientific data. The Resolution represents a viewpoint of the professional scientific community and is meant for public dissemination, for the consumers of the mobile telecommunications services, as well as for the legislative and executive authorities who develop and implement health protection, environmental, communication, scientific and safety policies."

" ... Thus, for the first time in the human history, children using mobile telecommunications along with the adult population are included into the health risk group due to the RF EMF exposure. A situation has emerged that cumulative EMF exposure of children may be comparable to adult exposure and may be equal to the levels of occupational exposure of workers. At the same time, the society, with all its administrative and social structures, remain in a "waiting" position."

"Priority measures aimed at protection of children and teenagers

Taking into account the RNCNIRP position and the precautionary measures suggested by WHO, the Committee considers that urgent measures must be taken because of the inability of children to recognize the harm from the mobile phone use and that a mobile phone itself can be considered as an uncontrolled source of harmful exposure.

1. *It is required that the information that a mobile phone is a source of RF EMF is clearly shown on the phone's body (or any other telecommunication device).*
2. *It is required that the "User's Guide" contains information that a mobile phone (personal wireless communication tool using electromagnetic communication method, etc.) is a source of harmful RF EMF exposure. Usage of a mobile phone by children and adolescents under 18 years old is not recommended by the Sanitary Rule SanPiN 2.1.8/2.2.4.1190-03, and mobile phone use requires implementation of precautionary measures in order to prevent health risks. Mobile phone use by pregnant women is not recommended in order to prevent risk for a fetus.*
3. *The easiest way to reduce RF EMF exposure is to move the mobile phone away from one's head during the phone call which may be achieved by using the hands-free sets (protection by distance). Shortening the call duration is another way to reduce the exposure (protection by time).*
4. *The RNCNIRP considers it is reasonable to develop mobile phones with reduced EMF exposure (with hands-free sets, included limitation functions, such as limitation of the number of daily phone calls, possibility of forced limitation of phone call duration, etc.).*
5. *It is required to include courses on mobile phones use and issues concerning EMF exposure in the educational program in schools.*
6. *It is reasonable to set limits on mobile telecommunications use by children and adolescents, including ban on all types of advertisement of mobile telecommunications for children (teenagers) and with their participation.*
7. *The RNCNIRP is ready to assist the mass-media in their awareness-raising work and educational activities in the area of EMF and, in particular, to provide information about the newest research of the impact of EMF on human health and the measures to curb the negative impact of this physical agent.*
8. *Better safety criteria for children and teenagers are required in the nearest term. Features of the developing organism should be taken into account, as well as the significance of bioelectric processes for human life and activities, present and future conditions of EMF, prospects of technological and technical development should be addressed in a document of legal status.*
9. *Development of a funded national program for studying possible health effects from chronic EMF exposure of the developing brain is necessary."*

Appendix F RCNIRP Resolution to Regulate the Use of WI-FI in Schools

RUSSIAN NATIONAL COMMITTEE
ON NON-IONIZING RADIATION PROTECTION

June 19, 2012 *Moscow, Russia*

Recommendations

of the Russian National Committee on Non-Ionizing Radiation Protection of the necessity to regulate strictly the use of Wi-Fi in kindergartens and schools

Mobile cellular communication is getting more popular among children of different ages. Children excel adult population in the mobile phone calls use. At the same time, there is a daily brain exposure of EMF RF. In addition, all children are constantly exposed of EMF RF from base stations. The problem of the children's health maintenance in the development of wireless communications was set up as priority by World Health Organization.

Electromagnetic radiation from Wi-Fi creates an additional burden for the child brain, whose body is in a state of development and the formation of mental activity. During this period, children are most susceptible to adverse environmental factors (WHO, publication number 3, April 2003).

It is necessary to note that the existing standards have been developed, without consideration of this additional exposure of EMF.

RussCNIRP consider necessary:

1. Ministry of Health and other organizations, responsible for the population safety (including children), should pay attention to the regulation of Wi-Fi use in kindergartens and schools; to the strengthening of sanitary control of the Wi-Fi using and to the development of an appropriate regulatory framework.
2. To recommend the usage of wired networks in schools and educational institutions, rather than a network using wireless broadband systems, including Wi-Fi.

Chairman of RussCNIRP,
Professor

Yury G. Grigoriev

SECTION 23

The Precautionary Principle

"Late Lessons from Early Warnings: Towards Realism and Precaution with EMF?"

2007

TABLE OF CONTENTS

I. INTRODUCTION

The histories of selected public and environmental hazards, from the first scientifically based early warnings about potential harm, to the subsequent precautionary and preventive measures, have been reviewed by the European Environment Agency.("Late Lessons from Early Warnings: the Precautionary Principle 1896-2000", EEA,2001). This paper summarises some of the definitional and interpretative issues that arise from the report and subsequent debates, such as the contingent nature of knowledge; the definitions of precaution, prevention, risk, uncertainty, and ignorance; the use of differential levels of proof; and the nature and main direction of the methodological and cultural biases within the environmental health sciences. These issues are relevant to EMF.

II. THE TWELVE "LATE LESSONS FROM EARLY WARNINGS

The paper does not address the specifics of EMF hazards, leaving it to the reader to apply, or not, the "Twelve late Lessons" that conclude the report. These lessons attempt to synthesise the fourteen historical experiences from the very different case study chapters into generic knowledge that can help inform policy-making on current issues such as GMO,, nanotechnologies, mobile phones, and endocrine disrupting substances where the luxuries of hindsight are not yet available but where exposures are already widespread and rising.

The idea of the twelve late lessons is to make the most of past experience to help anticipate future surprises whilst recognising that history never exactly repeats itself. When adopted alongside the best available science the lessons aim to help minimize hazards without compromising innovation. The "lessons" are reproduced below.

A. "Identify/Clarify the Framing and Assumptions"

1. Manage "risk", "uncertainty" and "ignorance"
2. Identify/reduce "blind spots" in the science
3. Assess/account for all pros and cons of action/inaction
4. Analyse/evaluate alternative options

5. Take account of stakeholder values
6. Avoid "paralysis by analysis" by acting to reduce hazards via the precautionary principle.

B. "Broaden Assessment Information"

7. Identify/reduce interdisciplinary obstacles to learning
8. Identify/reduce institutional obstacles to learning
9. Use "lay", local as well as specialist knowledge
10. Identify/anticipate "real world" conditions
11. Ensure regulatory and informational independence
12. Use more long-term (ie. decades) monitoring and research

III. EARLY USE OF PRECAUTION

The Vorsorgeprinzip, or "foresight" principle, only emerged as a specific policy tool during the German debates on the possible role of air pollution as a cause of "forest death" in the 1970-80s. However, John Graham, one of Bush's science policy advisors, and trenchant critic of the precautionary principle, has noted that:

> *"Precaution, whether or not described as a formal principle, has served mankind well in the past and the history of public health instructs us to keep the spirit of precaution alive and well"*. (Graham 2002).

Graham might have been thinking of the cholera episode of 1854 when precaution did indeed serve the people of London well. Dr. John Snow, a London physician, used the spirit of precaution to advise banning access to the polluted water of the Broad St. pump which he suspected was the cause of the cholera outbreak. He based his recommendation on the evidence he had been accumulating for some years including his study of S. London populations served by both piped and well water. Snow's views on cholera causation were not shared by The Royal College of Physicians who considered Snow's thesis and rejected it as 'untenable' as they and other "authorities" of the day believed that cholera was caused by airborne contamination. This particular scientific "certainty" soon turned out to be certainly mistaken, with the last remaining doubt being removed when Koch in Germany isolated the cholera vibrio in 1883.

From the *association* between exposure to water polluted with human faeces, and cholera, observed by Snow in 1854, to Koch's discovery of the *"mechanism of action"*, took 30 years of further scientific inquiry. Such a long time lag between acknowledging compelling associations and understanding their mechanisms of action is a common feature of scientific inquiry, as the histories of TBT, PCBs, DES, the Great Lakes pollution, beef hormones and the other cases in the EEA report illustrate.

IV. KNOWLEDGE AND IGNORANCE REQUIRES BOTH PREVENTION AND PRECAUTION

The Broad St. pump, TBT, DES, PCBs and Great Lakes Pollution examples described here also serve to illustrate the contingent nature of knowledge. Today's scientific certainties can be tomorrow's mistakes, and today's research can both reduce and increase scientific uncertainties, as the boundaries of the "known" and the unknown expand. Waiting for the results of more research before taking action to reduce threatening exposures may not only take decades but the new knowledge may identify previously unknown sources of both uncertainty and ignorance, as awareness of what we do not know expands, thereby supplying further reasons for inaction. "Paralysis by Analysis " can then follow.

"The more we know, the more we realise what we don't know" is not an uncommon scientific experience. Socrates observed some time ago:
"I am the wisest man alive, for I know one thing, and that is that I know nothing". (Plato's Apology 1.21).

This was an early lesson in humility that has been lately forgotten by many scientists and politicians, who often put what turns out to be "misplaced certainty" in today's scientific knowledge: or assume that uncertainty can only be reduced, and not increased, by further research.

The distinction between uncertainty and ignorance is important. (Stirling, 1999) Ignorance is knowing that today's knowledge is very limited: it is the source of scientific surprises, such as the hole in the ozone layer, the mesothelioma cancer from asbestos, imposex in sea snails etc. It is distinct from the uncertainties that arise from

gaps in knowledge and from variances in sampling and monitoring; parameter variability; model assumptions; and from the other attempts to approximate, model and predict unfolding realities.

Foreseeing and preventing hazards in the context of ignorance presents particular challenges to decision-makers. At first sight it looks impossible to do anything to avoid or mitigate "surprises". And ignorance ensures that there will always be surprises. However, some measures that could help limit the consequences of ignorance and the impacts of surprises are:

- using intrinsic properties as generic predictors for unknown but possible impacts e.g. the persistence, bioaccumulation and spatial range potential of chemical substances. (Stroebe et al., 2004)
- reducing specific exposures to potentially harmful agents on the basis of credible 'early warnings' of *initial* harmful impacts, thus limiting the size of any other 'surprise' impacts from the same agent, such as the asbestos cancers that followed asbestosis; and the PCB neurotoxicological effects that followed its wildlife impacts.
- promoting a diversity of robust and adaptable technological and social options to meet needs, which limits technological 'monopolies' (such as those like asbestos, CFCs, PCBs etc.), and therefore reduces the scale of any 'surprise' from any one technological option.
- using more long-term research and monitoring of what appear to be "surprise sensitive sentinels", such as frogs and foetuses.

A. Prevention and Precaution

The distinction between *prevention* and *precaution* is also important. Preventing hazards from "known" risks is relatively easy and does not require precaution. Banning smoking, or asbestos, today requires only acts of prevention to avoid the well-known risks. However, it would have needed precaution, (or foresight, based on a sufficiency of evidence), to have justified acts to avoid exposure to the then uncertain hazards of asbestos in the 1930s –50s, or of tobacco smoke in the 1960's). Such precautionary acts then, if implemented successfully, would have saved many more lives in Europe than today's bans on asbestos and smoking are doing. As

Cogliano has recently pointed out, the difference between prevention and precaution can be further illustrated by showing that *prevention* is used to justify the restriction of exposure to an IARC Category 1 carcinogen whereas *precaution* is necessary to justify restricting exposure to a Category 2A or B carcinogen, where the evidence is less strong. The section below. on different levels of proof , further elaborates this point.
For EMF, the question is, does the existing strength of evidence justify *precautionary* actions now? Or will exposure reduction be delayed until the evidence is clear enough to justify the more belated and overall less protective *prevention* of "known" causes, so that EMF replicates the fate of asbestos ,smoking and most of the other cases in the EEA report?

Some commentators, who have a long and distinguished history in preventing occupational and environmental risks, have queried the added value of the precautionary principle in the field of public health, with its long traditions of prevention. (Goldstein, 2007).

The key to understanding the added value of the PP requires a) acknowledging the distinction between prevention and precaution described above; b) an appreciation of the further distinctions between the primary, secondary and tertiary preventative *measures* that have long between adopted in public health, and the prior *justification* for any such measure, which the PP brings; and c) a recognition of the increased legitimacy and transparency that arises from the articulation and adoption of the PP in legal texts, international agreements and conventions, as opposed to being merely part of general practice.

More empirically, the evidence that many scientific disciples, legal scholars (de Sadeleer, 2007),and international policymakers, have, since the 1970s, recognised the need for legitimising the PP as a new policy tool that is better able to deal with systems complexities, ignorance and uncertainties, suggests that the PP brings added value to the protection of the environment and the public.

There is much discussion generated by the different meanings often attached to the common terms “prevention”, “precaution”, “risk”, “uncertainty” and “ignorance”. **Table 1** attempts to clarify these so as to help reduce unnecessary argumentation.

Table 1: Clarification of Key Terms

Situation	***State and dates of knowledge***	***“Nature of the justification for Action”***
Risk	**‘Known’ impacts; ‘known’ probabilities e.g. asbestos**	**Prevention: action taken to reduce known hazards e.g. eliminate exposure to asbestos dust**
Uncertainty	**‘Known’ impacts; ‘unknown’ probabilities e.g. antibiotics in animal feed and associated human resistance to those antibiotics**	**Precautionary prevention: action taken to reduce exposure to potential hazards**
Ignorance	**‘Unknown’ impacts and therefore ‘unknown’ probabilities eg the ‘surprises’ of chlorofluorocarbons (CFCs), pre 1974**	**Precaution: action taken to anticipate, identify and reduce the impact of ‘surprises’**

Source: Reproduced, with amendment, from the Late Lessons Report, EEA 2001.

V. THE PRECAUTIONARY PRINCIPLE: DEFINITIONS AND INTERRPRETATIONS

There are some relatively rare but successful acts of “precautionary prevention” in the EEA report such as on cholera in1854, on TBT in France in the 1980s, and on CFCs in the 1970s. Together with the many other examples of the failure to use the precautionary principle in the other case studies (EEA, 2001), these illustrate the wisdom of taking appropriate precautionary actions to avoid plausible and serious threats to health or environments, especially when the impacts are irreversible and likely to be much more costly to society than the precautionary measures.

Some commentators have stressed the need for policymakers to take account of the foreseeable, or plausible, countervailing (secondary) costs of otherwise genuine precautionary attempts to protect the environment and health. (Rushton, 2007). This

consideration of countervailing costs has long been recognised by the better policymakers, even if it is difficult in practice to anticipate and account for all consequences of actions. And of course there are the secondary benefits of precautionary actions as well, which tend to be less stressed, such as the benefit of reduced respiratory and cardiovascular disease from the reduced combustion of fossil fuels: a large and early secondary benefit of that climate change measure.

The outcomes of some controversial actions based on the PP, such as the EU ban on antibiotics as growth promoters, which is a Late Lessons case study, have since been scrutinised, and have been considered sound ,or unsound, depending on the science used and its interpretation by different interests. (Cox, 2007, Angulo et al., 2004).

Any policy effectiveness analysis of measures taken to deal with such multi-causal and long term hazards as antibiotics as growth promoters is fraught with methodological difficulties and is hampered by long latencies and complex biological systems: untangling the causal impact of one stressor amongst many inter-dependent ones is virtually impossible. The value of applying more probabilistic and value of information data to such conundrums is recognised by many risk managers. However, this cannot remove the need for scientific and political judgment about how to take appropriate and proportionate action in the face of irreducible uncertainties, ignorance and plausible hazards which could have serious, widespread and irreversible impacts and for which probabilities are not possible at the time when they are most needed. This is the current case with many EMF exposures.

A. Some Definitions and Interpretations of the Precautionary Principle

The increasing awareness of complexity and uncertainty during the 1980/90's led to the German debates on the Vorsorgeprinzip shifting to the international level, initially in the field of conservation (World Charter for Nature UN 1982), but then particularly in marine pollution, where an overload of data accompanied an insufficiency of knowledge. (Marine Pollution Bulletin, 1997). This generated the need to act with precaution to reduce the large amounts of chemical pollution entering the North Sea. Since then many international treaties have included the PP (including the often cited version from the Third North Sea Ministerial Conference, 1990, have included

reference to the precautionary principle, or, as they refer to it in the USA, the precautionary approach.

The N.Sea declaration called for *"action to avoid potentially damaging impacts of substances, even where there is no scientific evidence to prove a causal link between emissions and effects"*.

This definition has often, and sometimes mischievously, been used to deride the precautionary principle by claims that it appears to justify action even when there is "no scientific evidence" that associates exposures with effects. However, the N. Sea Conference definition clearly links the words "no scientific evidence" with the words. "to prove a causal link". We have already seen with the Broad St. pump and TBT examples that there is a significant difference between evidence about an "association" and evidence that is robust enough to establish a "causal" link. (Hill, 1965).

The Treaty of the European Union also cites the precautionary principle, as well as the other key principles of sound public policy on health:

> "*Community policy on the environment … shall be based on the precautionary principle and on the principles that preventive action should be taken, that environmental damage should, as a priority, be rectified at the source and the polluter should pay*" (Treaty on European Union, 1992).

Other parts of the EU Treaty ,and cases taken at the European Court of Justice, make it clear that these principles also apply to environmental and consumer protection issues.

These principles, as well as the important and legally required *proportionality principle*, which limits disproportion between the costs and benefits of prevention, are not defined in the Treaty but are illuminated by their practical application in case law. However, all serious applications of the precautionary principle require some scientific evidence of a plausible association between exposures and current, or potential, impacts.

There is still much disagreement and discussion about the interpretation and practical application of the precautionary principle, due, in part, to this lack of clarity and consistency over its definition. For example, many definitions in the Treaties and Conventions use a double negative to define the precautionary principle: that is, they

identify reasons that cannot be used to justify not acting, but without specifying that a sufficiency of evidence is needed to justify taking action.

B. Reasonable Grounds for Concern?

The Communication from the EU on the precautionary principle (European Commission 2000) does specify that "reasonable grounds for concern" are needed to justify action under the precautionary principle, but it does not make explicit that these grounds will be case specific: nor does it explicitly distinguish between risk, uncertainty and ignorance. Since the EC Communication, the EU Council of Misisters, EU case law, and the regulation establishing the new European Food Safety Authority, EFSA, (General Food Law Regulation, EC No 178/2002), have further clarified the circumstances of use and application of the precautionary principle.
For example, the judgement of the European Court of Justice in the BSE case contained a general definition which authoritative commentators think contain many of the necessary elements of the precautionary principle that are applicable in all areas of the EC law:

> "*Where there is uncertainty as to the existence or extent of risks to human health, the institutions may take protective measures without having to wait until the reality and seriousness of those risks become fully apparent*" (Christoforou, 2002).

The WHO Declaration from the Fourth Ministerial Conference on Environment and Health (WHO, 2004a) refers explicitly to the precautionary principle with the recommendation:

> *"that it should be applied where the possibility of serious or irreversible damage to health or the environment has been identified and where scientific evaluation, based on available data, proves inconclusive for assessing the existence of risk and its level but is deemed to be sufficient to warrant passing from inactivity to policy alternatives"* (WHO, 2004b).

The American Public Health Association (APHA) affirmed endorsement of the precautionary principle as a cornerstone of public health for the protection of children's health. In a 2000 policy statement, the APHA encouraged governments, the private sector and health professionals to promote and use the precautionary principle to protect the health of developing children (APHA, 2001).

C. The EEA working definition of the Precautionary Principle.

The working definition used in the European Environment Agency that has been developed during debates since 2001 is explicit about specifying both uncertainty and ignorance, as contexts for applying the principle, and in acknowledging that a case-specific sufficiency of scientific evidence is needed to justify public policy actions:

> '*The Precautionary Principle provides justification for public policy actions in situations of scientific complexity, uncertainty and ignorance, where there may be a need to act in order to avoid, or reduce, potentially serious or irreversible threats to health or the environment, using an appropriate level of scientific evidence, and taking into account the likely pros and cons of action and inaction*' (Gee, 2006).

The definition is also explicit about the trade off between action and inaction, and widens the conventionally narrow, and usually quantifiable, interpretation of costs and benefits to embrace the wider and sometimes unquantifiable, "pros and cons". Some of these wider issues, such as loss of the ozone layer, or of public trust in science, are unquantifiable, but they can sometimes be more damaging to society than the quantifiable impacts: and they need to be included in any comprehensive risk assessment. The EEA definition is proving to be useful in clarifying the use and interpretation of the PP, especially in emerging issues such as EMF.

VI. DIFFERENT LEVELS OF PROOF FOR DIFFERENT PURPOSES

The level of proof (or strength of scientific evidence) that would be appropriate to justify public action in each case varies with the pros and cons of action or inaction. These include the nature and distribution of potential harm; the justification for, and the benefits of the agent or activity under suspicion; the availability of feasible alternatives; and the overall goals of public policy. Such policy goals can include the achievement of the "high levels of protection" of public health, of consumer safety, and of the environment, required by the EU Treaty.

The use of different levels of proof is not a new idea: societies often use different levels of proof like for different purposes.

For example, a high level of proof (or strength of evidence) such as “beyond all reasonable doubt” is used to achieve good science where A is seen to cause B only when the evidence is very strong. Such a high level of proof is also used to minimise the costs of being wrong in the criminal trial of a suspected murderer, where it is usually regarded as better to let several guilty men go free than it is to wrongly convict an innocent man. However, in a different, civil trial setting, where, say, a citizen seeks compensation for neglectful treatment at work, which has resulted in an accident or ill health, the court often uses a lower level of proof commensurate with the costs of being wrong in this different situation. I n compensation cases an already injured party is usually given the benefit of the doubt by the use of a medium level of proof, such as “balance of evidence or probability”. It is seen as being less damaging (or less costly in the wider sense) to give compensation to someone who was *not* treated negligently than it is to *not* provide compensation to someone who was treated negligently. The “broad shoulders” of insurance companies are seen as able to bear the costs of mistaken judgements rather better than the much narrower shoulders of an injured citizen. In each of these two illustrations it is the nature and distribution of the costs of being wrong that determines the level of proof (or strength of evidence) that is “appropriate” to the particular case.

Bradford Hill, cited above, was very concerned about the social responsibility of scientists and he concluded his classic 1965 paper on association and causation in environmental health , which was prepared at the height of the smoking controversy, with a “call for action” in which, *inter alia*, he also proposed the concept of case specific and differential levels of proof. His three examples ranged from “relatively slight” to “very strong” evidence, depending on the nature of the potential impacts and of the pros and cons in each specific case, i.e., possibly teratogenic medicine for pregnant women; a probable carcinogen in the workplace; and government restrictions on public smoking or diets. (Bradford Hill 1965).

Identifying an appropriate level of proof has also been an important issue in the climate change debates. The International Panel on Climate Change (IPCC) discussed

at length this issue before formulating their 1995 conclusion that “on the balance of evidence” mankind is disturbing the global climate. They further elaborated on this issue in their 2001 report where they identified 7 levels of proof (or strengths of evidence) that can be used to characterise the scientific evidence for a particular climate change hypothesis.

Table 2 provides the middle 5 of these levels of proof from the IPPC and illustrates their practical application to a variety of different societal purposes. In the cancer field the International Agency for Research on Cancer also uses several strengths of evidence to characterise the scientific evidence on carcinogens. (Cogliano, 2007)

Different Levels of Proof for Different Purposes: Some Examples and Illustrations

Probability	Quantitative descriptor (Probability bands based on IPCC 2001)	Qualitative Descriptor	Illustrations
100 % probability	Very likely (90-99 %)	• "Statistical significance"	• Part of strong scientific evidence for "causation"
		• "Beyond all reasonable doubt"	• Most criminal law. And the Swedish Chemical law, 1973, for evidence of "safety" of substances under suspicion-burden of proof on manufacturers
90 %	Likely (66-90 %)	• "Reasonable certainty"	• Food Quality Protection Act, 1996 (US)
		• "Sufficient scientific evidence"	• To justify a trade restriction designed to protect human, animal or plant health under World Trade Organisation Sanitary and Phytosanitary (SPS) Agreement, Art. 2.2, 1995
50 %	Medium Likelihood (33-66 %)	• "Balance of evidence"	• Intergovernmental Panel on Climate Change 1995 & 2001
		• "Balance of probabilities"	• Much Civil and some administrative law
		• "Reasonable grounds for concern"	• European Commission Communication on the Precautionary Principle 2000
		• "Strong possibility"	• British Nuclear Fuels occupational radiation compensation scheme, 1984 (20-50% probabilities triggering different awards up to 50% +, which then triggers full compensation)
	Low Likelihood (10-33 %)	• "Scientific suspicion of risk"	• Swedish Chemical law, 1973, for sufficient evidence to take precautionary action on potential harm from substances-burden of proof on regulators
0 %		• "Available pertinent information"	• To justify a provisional trade restriction under WTO SPS Agreement, Art. 5.7 where "scientific information is insuffiicient"
	Very Unlikely (1-10 %)	• Low risk	• Household fire insurance
0 % probability		• "Negligible and insignificant"	• Food Quality Protection Act, 1996 (US)

VII. FALSE NEGATIVES AND FALSE POSITIVES.

All of the 14 case studies (tributylin or TBT, benzene, PCBs, CFCs, MTBE, SO_2. Great Lakes pollution. DES, and beef hormones. asbestos. medical x-rays, BSE and Fisheries are all examples of "false negatives" in the sense that the agents or activities were regarded as not harmful for some time before evidence showed that they were indeed hazardous.

We tried to include a "false positive" case study in the report (i.e., where actions to reduce potential hazards turned out to be unnecessary), but failed to find either authors or sufficiently robust examples to use. Providing evidence of "false positives" is more difficult than with "false negatives" (Mazur, 2004). How robust, and over what periods of time, does the evidence on the absence of harm have to be before concluding that a restricted substance or activity is without significant risk?

Volume 2 of "Late Lessons", which the EEA intends to publish in 2008, will explore the issues raised by false positives. including lessons to be learned from such apparent examples as the EU ban on food irradiation and hazardous labelling on saccharin in the US. The Y2K computer bug story may also carry some interesting lessons.

Why are there so many "false negatives" to write about, and how might this be relevant to EMF? Conclusions based on the first Late lessons volume of case studies point to two main answers: the bias within the health and environmental sciences towards avoiding "false positives", thereby generating more "false negatives", and the dominance within decision-making of short-term, specific, economic and political interests over the longer term, diffuse, and overall welfare interests of society.

The latter point needs to be further explored, particularly within the political sciences. Researchers could examine the ways in which society's long-term interests can be more effectively located within political and institutional arrangements that have, or could have, an explicit mandate to look after the longer term welfare of society, and thereby to better resist the short-term pressures of particular economic or political interests. The judiciary in democracies can play part of this role, as can long running

and independent advisory bodies, such as the Royal Commission on Environmental Pollution (UK), or the German Advisory Council on Global Change.

The current and increasing dominance of the short-term in markets and in parliamentary democracies makes this an important issue. The experiments we are conducting with planet earth, its eco-systems and the health of its species, including humans, require, *inter alia*, more long-term monitoring of "surprise-sensitive" parameters which could, hopefully, give us early warnings of impending harm. Such long-term monitoring requires long-term funding, via appropriately designed institutions: such funding and institutions are in short supply. The case studies in Vol. 1 of "Late Lessons" illustrate both the great value, (e.g. in the TBT, DES, Great Lakes and CFCs stories), yet relative paucity, of long-term monitoring of both health and environments. Such monitoring can contribute to the "patient science" that slowly evolving natural systems require for their better understanding.

Since the publication of "Late Lessons" we have further explored the second cause of "false negatives" i.e. the issue of bias within the health and environmental sciences. Table 3 lists sixteen common features of methods and culture in the environmental and health sciences and shows their main directions of error. Of these, only three features tend towards generating "false positives" whereas twelve tend towards generating "false negatives". (Clearly, the weighting of these different biases would be the next step but has not yet been tried).

Table 3

ON BEING WRONG:
Environmental and Health Sciences and Their Directions of Error

SCIENTIFIC STUDIES	SOME METHODOLOGICAL FEATURES	MAIN[1] DIRECTIONS OF ERROR-INCREASES CHANCES OF DETECTING A:
Experimental	High doses	False positive
Studies	Short (in biological terms) range of doses	False negative
(Animal	Low genetic variability	False negative
Laboratory)	Few exposures to mixtures	False negative
	Few Foetal-lifetime exposures	False negative
	High fertility strains	False negative (Developmental/reproductive endpoints)
Observational	Confounders	False positive
Studies	Inappropriate controls	False positive/negative
(Wildlife &	Non-differential exposure misclassification	False negative
Humans)	Inadequate follow-up	False negative
	Lost cases	False negative
	Simple models that do not reflect complexity	False negative
Both	Publication bias towards positives	False positive
Experimental And	Scientific cultural pressure to avoid false positives	False negative
Observational Studies	Low statistical power (e.g. From small studies)	False negative
	Use of 5 % probability level to minimise chances of false positives	False negative

Source: Gee, 2006

[1] Some features can go either way (e.g. inappropriate controls) but most of the features mainly err in the direction shown in the table

The general bias towards the null helps to produce robust science, basing it on strong foundations of knowledge, but this bias can encourage poor public health or environmental policy. The goals of science and public policy-making on health and environmental hazards are different: science puts a greater priority on avoiding "false positives" by accepting only very high levels of proof of "causality", whereas public policy tries to prioritize the avoidance of "false negatives" on the basis of a sufficiency of evidence of potential harm.

Table 3 is derived from papers presented to a conference on the precautionary principle organised by the Collegium Ramazzini, the EEA, the WHO and NIEHS in 2002. (Grandjean et al., 2003). It provides a first and tentative step in trying to capture and communicate the main directions of this bias within the environmental and health sciences, a bias which decision makers and the public should be aware of. As they debate the evidence on emerging hazards such as EMF.

The appropriate balance between false negatives and positives was addressed at a JRC/EEA workshop on the precautionary principle and scientific uncertainty which was held during the "Bridging the Gap" Conference, 2001, organised by the Swedish Presidency of the EU, in partnership with the EEA and DG Research. It drew the following conclusion:

> *"Improved scientific methods to achieve a more ethically acceptable and economically efficient balance between the generation of "false negatives" and "false positives" are needed"*. (Swedish EPA 2001).

VIII. SOME CRITERIA FOR ESTABLISHING CAUSATION

Bradford Hill established nine criteria for helping to move from association to causation in environmental health which have been, and still are, widely used in debates on issues such as EMF

Two of the apparently more robust of the "criteria" may not be so robust in the context of multi-causality, complexity and gene/host variability.

For example, ***"consistency"*** of study findings is not always to be expected. As Prof. Needleman, who provided the first of what could be called the second generation of early warnings on lead in petrol in 1979 has observed:

> *"Consistency in nature does not require that all or even a majority of studies find the same effect. If all studies of lead showed the same relationship between variables, one would be startled, perhaps justifiably suspicious"* (Needlemann , 1995).

It follows that the *presence* of consistency of results between studies on the same hazard can provide robust evidence for a causal link, but the *absence* of such consistency may not provide very robust evidence for the absence of a real association. In other words, the "criterion" of consistency is asymmetrical, like most of the other Bradford Hill "criteria".

Similarly, the criterion of ***"temporality",*** which says that the putative cause X of harm Y must come before Y appears, is robust in a simple, uni-causal world. In a multi-causal, complex world of common biological end points that have several chains of causation this may not necessarily be so. For example, falling sperm counts can have multiple, co-causal factors, some of which may have been effective at increasing the incidence of the biological end point in question in advance of the stressors in focus, thereby confusing the analysis of temporality. The resulting overall sperm count trends could then be rising, falling or static, depending on the combined direction and strengths of the co-causal factors and the time lags of their impacts. It follows that say, chlorine chemicals, may or may not be co-causal factors in falling sperm counts: but the use of the "temporality" argument by the WHO, who observed that sperm counts began to fall before chlorine chemistry production took off, does not provide robust evidence that they are not causally involved.

The presence of "temporality", like "consistency" may be robust evidence *for* an association being causal, but its *absence* may not provide robust evidence *against* an association. Bradford Hill was explicitly aware of the asymmetrical nature of his "criteria": his followers have not always been so aware.
During 2005, the 40th anniversary year of the Bradford Hill "criteria", the EEA convened a panel of experts to review the "criteria" and their use in light of advances in knowledge, particularly multi-causality, since 1965. A report will be published in 2007.

How this goal can be achieved without compromising science remains to be explored, (Grandjean 2004; Grandjean et al., 2004). It is clearly necessary, particularly when dealing with EMF, for scientific methods to not only take account of thisfalse negative/positive bias in methodologies but also to more clearly reflect other realities such as multi-causality; thresholds; timing of dose; sensitive sub-populations, such as children, (Jarosinska and Gee, 2007); sex, age, and immune conditions of the host; information physics; effects below the thresholds of "acute" impacts, such as tissue heating; non-linear dose/response relationships; "low dose" effects; and the effects arising from disturbing the balance between opposing elements in complex biological systems. The evidence on EMF needs to take full account of these realities, as well as of the methodological biases of Table 3.

1X. PUBLIC PARTICIPATION IN RISK ANALYSIS

Choosing an appropriate level of proof for a particular case is clearly based, *inter alia*, on value judgements about the acceptability of the costs, and of their distribution, of being wrong in both directions, i.e. of acting or not acting to reduce threatening exposures. This is why it is necessary to involve the public in decisions about serious hazards and their avoidance: and to do so for all stages of the risk analysis process.

Three of the "twelve late lessons" (number 5, number 9 and number 10) explicitly invite early involvement of the public and other stakeholders at all stages of risk analysis, a development which has been actively encouraged in many other influential reports during the last decade. (NRC 1994; US Presidential Commission on Risk Assessment and Risk Management 1997; Royal Commission on Environmental Pollution 1998; CEC Communication on the Precautionary Principle 2000; German Advisory Council on Global Change 2001).

The best available science is therefore only a necessary but not a sufficient condition for sound public policy making on potential threats to health and the environment. Where there is scientific uncertainty and ignorance "it is primarily the task of the risk managers to provide risk assessors with guidance on the science policy to apply in their risk assessments." (Christoforou, 2003). The content of this science policy advice, as well as the nature and scope of the questions to be addressed by the risk

assessors, need to be formulated by the risk managers and relevant stakeholders at the initial stages of the risk analysis.

Involving the public in not only all stages of risk analysis, but also in helping to set research agendas and technological trajectories, (Wilsdon and Willis, 2004) is not easy. Many experiments, in both Europe and the USA, with focus groups, deliberative polling, citizens' juries, and extended peer review, (Funtovicz and Ravetz, 1990/92) are exploring appropriate ways forward.

The issue of time is also a critical issue for risk analysis and application of the precautionary principle. For example, the time from the first scientifically based early warnings (1896 for medical X rays, 1897 for benzene, 1898 for asbestos) to the time of policy action that effectively reduced damage was often 30-100 years. Some consequences of the failures to act in good time (e.g. on CFCs or asbestos) continue to cause damage over even longer time periods. For example, the ozone hole will cause many thousands of extra skin cancers in today's children but the cancers will only peak around the middle of this century because of the long latent period between exposure and effect. Such long-term but foreseeable impacts raise liability and compensation issues, including appropriate discount rates (if any) on future costs and benefits, which being value-laden choices. need also to be discussed by stakeholder groups. Again, experience in the climate change field with these long-term issues may be helpful in managing them with respect to electromagnetic fields (ELF and RF).

The wider involvement of stakeholders has also been recognised more recently by the International Risk Governance Council (IRGC, 2005) and the EU report on Science and Governance, (Wynne et al., 2007). Whether wider involvement of stakeholders results in better and more acceptable decisions needs to studied: early indications (Beierle, 2002), and lessons from history, suggests that is. In many cases several decades will be necessary to confidently judge outcomes, given latencies and complexities.

X. SOME EXAMPLES OF EARLY WARNINGS

The 14 case studies in the Late Lessons Report (EEA 2001) include examples some chemicals (tributylin or TBT, benzene, PCBs, CFCs, MTBE, SO_2 and Great Lakes pollution); two other pharmaceuticals (DES, and beef hormones); two physical agents (asbestos and medical x-rays); one pathogen (BSE); and Fisheries (overfishing).

The main issues discussed so far, such as the contingent nature of knowledge; ignorance and "surprises"; appropriate levels of evidence for policy actions; and public participation in risk analysis are critical to the successful application of both scientific knowledge and the precautionary principle to public policy-making. They are therefore relevant to discussions about the potentially new hazards that are now emerging e.g. from nanotechnology, (Royal Society 2003); from the non-ionising radiations arising from the use of mobile phones, (Stewart Reports 2000, 2004), and from endocrine disrupting substances or EDSs. (WHO, 2002).

With such newly emerging hazards it can be helpful to use historical examples to illustrate what a scientifically based early warning looks like as it is often difficult to properly recognise such warnings at the time they occur. A good example is that provided by the UK Medical Research Council's Swann Committee in 1969. They were asked to assess the evidence for risks of resistance to antibiotics in humans following the prolonged ingestion of trace amounts of antibiotics arising from their use as growth promoters in animal feed. (Edqvist and Pedersen 2001). They concluded that:

> *"Despite the gaps in our knowledge .. we believe … on the basis of evidence presented to us, that this assessment is a sufficiently sound basis for action .. The cry for more research should not be allowed to hold up our recommendations'….'sales/use of AFA should be strictly controlled via tight criteria, despite not knowing mechanisms of action, nor foreseeing all effect"*. (Swann 1969).

A. Antibiotics in Animal Feed

The Swann Committee also concluded that it would be more rewarding and innovative to improve animal husbandry as a means of encouraging disease free animal growth rather than to the cruder approach of diets containing antimicrobials. Despite the gaps in knowledge, the need for much more research, and considerable ignorance about the mechanisms of action, a sufficiency of evidence was identified and described by the Swann Report that justified the need for public authorities to restrict the possibility of exposures to antibiotics from animal growth promoters. This early warning was initially heeded, but was then progressively ignored by the pharmaceutical companies and regulatory authorities, who wanted more scientific justification for restricting anti-microbial growth promoters. However, in 1985 in Sweden, and then in the EU in 1999, the use of antibiotics as growth promoters was finally banned. Pfizer, the main supplier of such antibiotics in Europe, appealed against the European Commission banning decision, pleading, *inter alia*, an insufficiency of scientific evidence. They lost this case at the European Court of Justice (Case T-13/99-Pfizer 2002), a case which further clarified the proper use and application of the precautionary principle in circumstances of scientific uncertainty and of widespread, if low, public exposures to a potentially serious threat.

B. Lead in Gasoline

A US example of an early warning comes from the lead in gasoline story: a warning that was largely ignored for over 50 years, resulting in much damage to the intelligence and behaviour of children in America, Europe and the rest of the motorised world. Yandell Hendersson, Chair of the Medical Research Board, US Aviation Service, who had been asked to look at the scientific evidence on the possible hazards of tetraethyl lead during the temporary ban on lead in petrol, in 1925, concluded:

> *"It seems likely that the development of lead poisoning will come on so insidiously that leaded gasoline will be in nearly universal use … before the public and the government awakens to the situation"*. (Rosner and Markowitz, 2002).

Motorised societies would have gained much in dollars, brainpower and social cohesion had they heeded this foresight.

C. Tributylin (TBR) – A Marine Antifoulant for Ships

The case study on tributylin (TBT) and DES illustrate the surprises that arise from real life complexities and which may carry some lessons for the EMF debate. For example, the unfolding of the TBT story was accompanied by an increased appreciation of scientific complexity arising from the discoveries that adverse impacts were caused by very low doses (i.e. in parts/trillion); that high exposure concentrations were found in unexpected places e.g. in the marine micro-layer; and that bioaccumulation in higher marine animals, including sea-food for human consumption, was greater than expected. The early actions on exposure reduction in France and the UK in 1982-85 were based on a 'strength of evidence' for the 'association' only: knowledge about 'causality', **'**mechanisms of action' and other the complexities above came much later.

We were lucky in some ways with the TBT story: a highly specific, initially uncommon impact (imposex) was quickly linked to one chemical, TBT. This relatively easily identified linkage is not likely to be repeated for the more common and multi-causal impacts where, for example, neurodevelopmental diseases and dysfuntions, or common cancers, are the impacts under suspicion.

D. Diethylstilbestrol (DES)

Key lessons from the DES story are also instructive, as it provides the clearest example of endocrine disruption in humans. Diethylstilbestrol, commonly referred to as DES, is a synthetic estrogen . It was originally prescribed to prevent miscarriage, but did not. Later, sons and daughters of mothers given DES to prevent miscarriage developed cancers, reproductive tract anomalies, and had more pre-term babies themselves as a result. The effects of DES include the absence of visible and immediate teratogenic effects **not** being robust evidence for the absence of reproductive toxicity; and the **'**timing of the dose clearly determining the poison', in contrast to the 'dose determines the poison' dictum of Paracelsus. Timing is also relevant to other biological end points:

> *"the time of life when exposures take place may be critical in defining dose-response relationships of EDSs for breast cancer as well as for other health effects",* (WHO/IPCS, 2002).

Although the exposure levels were higher than the usual environmental levels of other EDSs, the DES story provides a clear warning about the potential dangers of perturbing the endocrine system with synthetic chemicals.

With over 20,000 publications, DES is now a well-studied compound, yet many doubts persist about its mechanisms of action. Since no dose-effect relationship has been found in humans, it cannot be excluded that DES could have been toxic at low doses, and that other less potent xenoestrogens could have similar effects.

If we still have few certainties about DES after so much time and research, what should our attitude be towards emerging hazards, such as other endocrine disrupting substances (EDSs) and EMF?

XI. CONCLUSION

The lessons of history from the EEA report, and subsequent debates and events, indicate that they have much relevance to the EMF issue, as well as to other emerging issues such as nanotechnology, (Royal Society, 2003) and endocrine disrupting substances or EDSs (WHO, 2002). The public health assessment of EMF could apply these lessons, approaches, terms of discussion and interpretations to the precautionary and preventative actions on the different parts of the EMF exposure problem.

There are of course large differences between smoking and EMF. The smoking hazard had at least 10 times the relative risk increase in the exposed population compared to the leukaemia risk from power line exposure; and the size of the smoking exposed population, and its exposure above that needed to generate a doubling of the risk, are both very much greater than with power lines. The larger relative risk for smoking and lung cancer seems to arise from comparing smokers with non, or never, smokers whilst the relative risk of 2 to 3 that arises between moderate and heavy smokers, or between second hand smokers and non smokers, is more relevant to the EMF issue,

where there is an absence of unexposed controls. The lower relative risks of 2 or 3 for EMF are biased towards the null to unknown extent by the absence of such controls (Milham, 1998). However, the parallel between the slow recognition of the smoking hazard and power line EMF hazard is interesting.

The parallel with the history of X rays is also pertinent. The initial discovery, by Alice Stewart in the early 50s, that a few x rays of a pregnant woman in the sensitive period of her pregnancy gave a 2 fold excess of leukaemia, was greeted with much strident disbelief, particularly from the male doctors whose latest toy was under threat. It took another 20 years or so before her result became generally accepted, and only after several negative studies that were conducted in the early response to her study. Many studies of X rays in pregnant women now exist, and, as with the power line studies, the relative risk remains at about 2. (EEA, 2001) What will the history of EMF look like in 2020?

Prepared for the BioInitiative Working Group

December 2012

I. INTRODUCTION

In 2007, the evidence for EMF, and in particular radiofrequency radiation (RFR) from the use of mobile phones, was a focus for discussion in the BioInitiative Report (2007). It arose from growing scientific evidence of possible health risks, with a very large global population that could presumably be affected by the outcome.

Illustrating the importance of observing 'early warnings' of environmental and public health risks arising from emerging scientific studies and direct observation of impacts to peoples' health, this author wrote about the importance of applying 'lessons learned' from the histories of selected public and environmental hazards, from the first scientifically based early warnings about potential harm, to the subsequent precautionary and preventive measures, as reviewed by the European Environment Agency in Late Lessons from Early Warnings: the Precautionary Principle 1896-2000 (EEA, 2001). In considering the evidence on mobile phones and head cancers the EEA concluded that it would be prudent and timely to issue an "early warning" on the issue, in September, 2007. Five years on, this note briefly updates our opinion on this issue.

II. NEED FOR PRECAUTIONARY ACTIONS ON MOBILE PHONES

The communication leaflet for publication of "Late Lessons from Early Warnings 2: Science, Precaution, Innovation." (EEA, 2012) includes this message:

> *"In the context of scientific uncertainty and ignorance, the decision-makers responsible for incentivising and regulating innovation face a significant challenge in balancing opportunities against risks. The precautionary principle can help to better manage such choices. It requires actions to prevent potentially serious harm before the likelihood or severity of an innovation's impacts become all too clear."*

Volume 2 of 'Late Lessons' includes a chapter on mobile phones and brain tumour risk by Hardell, Carlberg and Gee. Inclusion of a full chapter on the science and public health implications of the mobile phone-brain cancer issue underscores the importance to the European Environmental Agency that mobile phone radiation is a possible health threat. This position is supported by the 2011 classification by the World Health

Organization International Agency for Research on Cancer (IARC) of radiofrequency radiation as a Group 2B Possible Human Carcinogen (Baan et al, 2011).

The evidence in 2012 is stronger than in 2007, and based essentially on two large population studies, the Hardell group in Sweden and the Interphone Study Group which involved 13 countries (WHO Interphone Final Report, 2010; Cardis & Radetski 2010? Hansson Mild et al, 2007; Hardell et al, 2006a, 2006b, 2006c; Hardell et al, 2008; Hardell et al, 2009a, 2009b; Hardell et al, 2010; Hardell et al, 2011a, 2011b; Hardell et al, 2012a in press; Hardell et al, 2012b in press). Are all 12 refs from Hardell needed? Looks like overkill…how about those from 2009?

Some researchers have identified in the last five years "*a consistent pattern of increased risk of glioma and acoustic neuroma associated with use of mobile phones and cordless phones.*" (Hardell et al, 2012b in press), a view that is essentially supported by the leader of the Interphone study. (Cardis & Radetski)

The European Environmental Agency's view on the need for precautionary measures on mobile phones is more warranted in 2012, than it was in 2007, or even early 2011, prior to the IARC decision, when we last reviewed the evidence for a presentation to the Council of Europe (EEA, 2011).

Precautionary actions that can be taken to reduce exposures to RFR would be consistent with actions that have been recommended for other emerging environmental and health issues, for example some uses of the common plastic, BPA, some nanotechnologies, and some food chain additives or contaminants, such as antibiotics, beef hormones, and GMOs. The 25 or so more historical case studies in the 'Late Lessons' volumes such as those on the Minamata Bay disaster, asbestos, leaded petrol, and tobacco illustrate the huge costs of not taking robust early warnings seriously.

Precautionary measures are of particular importance in regard to children, who are generally more biologically sensitive, may be unable to protect themselves; and for whom such exposures may carry greater life-time health risks than they do for adults.

The evidence for a brain tumour risk from mobile phones is still not well established

amongst all researchers in the field and there is much scientific controversy about what the current evidence means. The debate is not helped by what might be termed 'trial by media' where some scientific advocates leap into the lay press to argue their own case just as, or even before, their research is published. The effects of this behaviour would be minimized if the results of genuine differences of scientific opinion were made transparent when they were published, with clear explanations about the origins of divergent views, such as the scientific paradigms used ("tissue heating" or "information physics" ?); assumptions made; evidence rejected; and values chosen. This does not tend to happen. Divergent scientific views are often smoothed over with the use of what one respected commentator on the reporting of the Interphone results called "oracular " sentences (Saracci & ?? 2010 ?) which thereby give the media and others the opportunity to report quite opposite conclusions from the same study,as was the case with the Interphone study.

We note that countries including France, Germany, Belgium, Austria, Italy, Russia, India and others have moved toward cautionary warnings and some have revised some target exposure levels for new wireless facilities in line with recommendations issued in 2007. Further actions appear now to be warranted, especially in light of the authoritative 2011 IARC cancer classification.

The IARC, and the EEA , may be wrong to suggest there could be a brain tumour risk from the extensive use of mobile phones, and we dearly hope we are wrong. However, it is worth noting that during over 30 years of classifying cancer risks, covering around 900 agents, IARC very rarely downgrades its judgements: in most cases tentative carcinogens become more certain carcinogens as time since first exposures and further research accumulates. Is it not worth gambling that mobile phones will be one of those very rare cases where IARC has over-classified an agent? We think not. The human cost of getting such a gamble wrong would be too great, especially in light of the relatively low cost of reducing exposures significantly.

I. KEY SCIENTIFIC EVIDENCE

Exposure to electromagnetic fields (EMF) has been linked to a variety of adverse health outcomes. The health endpoints that have been reported to be associated with ELF and/or RF include childhood leukemia, adult brain tumors, childhood brain tumors, genotoxic effects (DNA damage and micronucleation), neurological effects and neurodegenerative disease, immune system disregulation, allergic and inflammatory responses, breast cancer in men and women, miscarriage and some cardiovascular effects.

Effects are not specifically segregated for ELF or RF, since many overlapping exposures occur in daily life; and because this is an artificial division based on frequencies as defined in physics that has little bearing on the biological effects. Both ELF and RF, for example have been shown to cause cells to generate stress proteins, a universal sign of distress in plant, animal and human cells.

The number of people exposed to elevated levels of EMF has been estimated in various studies, and there is general agreement among them. In the United States, few people have chronic or prolonged exposures over 4 mG (0.4 μT) (Kheifets et al, 2005b). Section 20 has information on average residential and occupational ELF levels. The highest exposure category in most all studies is $\geq$ 4 mG ($\geq$ 0.4 μT). Many people have daily exposures to ELF in various ways, some of them up to several hundred milligauss for short periods of time, but relatively few people with the exception of some occupational workers habitually experience ELF exposures greater than 1-2 mG (0.2 – 0.3 μT - App. 20-A).

The exposure of children to EMF has not been studied extensively; in fact, the FCC standards for exposure to radiofrequency radiation are based on the height, weight and stature of a 6-foot tall man, not scaled to children or adults of smaller stature. They do not take into account the unique susceptibility of growing children to exposures (SCENIHR, 2007; Jarosinska and Gee, 2007), nor are there studies of particular relevance to children.

Differences in exposure patterns between infants, children and adults; 2) special susceptibilities of infants and children to the effects of EMF; and 3) interactions between chemical contaminants

and EMF are lacking; as are studies on chronic exposure for both children and adults. There is reason to believe that children may be more susceptible to the effects of EMF exposure since they are growing, their rate of cellular activity and division is more rapid, and they may be more at risk for DNA damage and subsequent cancers. Growth and development of the central nervous system is still occurring well into the teenage years so that neurological changes may be of great importance to normal development, cognition, learning, and behavior. Prenatal exposure to EMF have been identified as possible risk factor for childhood leukemia. Children are largely unable to remove themselves from exposures to harmful substances in their environments. Their exposure is involuntary.

Like second-hand smoke, EMF is a complex mixture, where different frequencies, intensities, durations of exposure(s), modulation, waveform and other factors is known to produce variable effects. Many years of scientific study has produced substantial evidence that EMF may be considered to be both carcinogenic and neurotoxic. The weight of evidence is discussed in this report, including epidemiological evidence and studies on laboratory animals.

Relative risk estimates associated with some of these endpoints are small and the disease is fairly rare (for childhood leukemia, for example), For other diseases, the risk estimates are small but the diseases are common and EMF exposures at levels associated with increased risks are widespread and chronic so the overall public health impacts may be very large.

A. Weight of Evidence Assessment and Criteria for Causality

A weight-of-evidence approach has been used to describe the body of evidence between health endpoints and exposure to electromagnetic fields (ELF and RF).

The number and quality of epidemiological studies, as well as other sources of data on biological plausibility are considered in making scientific and public health policy judgments. Methodological issues that were considered in the review of the epidemiological literature include 1) quality of exposure assessment. 2) sample size of the study, which detects the power to detect an effect, 3) extent to which the analysis or design takes into account potential

confounders or other risk factors, 4) selection bias, 5) the potential for bias in determining exposure. Assessment of the epidemiological literature is consistent with guidelines from Hill (1971), Rothman and Greenland (1998) and the Surgeon General's Reports on Smoking (US DHHS, 2004), and California Air Resources Board (2005). Factors that were considered in reaching conclusions about the weight of evidence overall included strength of the association, consistency of association, temporality, biological plausibility, dose-response and issues with non-linear dose-response, specificity and experimental evidence.

There is a relatively large amount of human epidemiological information with real world exposures, including data from occupational studies. There is less animal data in most cases, except for the genotoxicity studies. Human epidemiological evidence has be given the greatest weight in making judgments about weight-of-evidence, where the results across high quality studies give relatively consistent positive results. Meta-analyses of childhood leukemia, adult leukemia, adult brain tumors, childhood brain tumors, male and female breast cancer and Alzheimer's disease were relied upon in assessing the overall strength of epidemiological study results. Sections 5 – 15 provide analysis of the relevant scientific studies that are key evidence in making public health policy recommendations with respect to exposure to electromagnetic fields (both ELF and RF).

B. Summary of Evidence

1. Childhood Leukemia

Several meta-analyses have been conducted to assess risks of childhood leukemia from exposure to ELF. The results of these studies that combine or pool results of many individual studies (including studies that report both effects and no effects) consistently report increased risks.

Meta-Analysis: Studies of Childhood Leukemia and EMF

Greenland et al., (2000) reported a significantly elevated risk of 1.68 [95% CI 1.23-2.31] based on pooled results from 12 studies using a time-weighted average of exposure greater than 3 mG (0.3 μT). This is a 68% increased risk of childhood leukemia.

Ahlbom et al., (2000) reported a doubling of risk based on a meta-analysis of nine (9) studies. The results reported an elevated risk of 2.0 [95% CI 1.27-3.13] for EMF exposures equal to or greater than 4 mG (0.4 μT) as compared to less than 1 mG (0.1 μT)

Other Relevant Evidence

In 2002, the International Agency for Cancer Research (IARC) designated EMF as a "possible human carcinogen" or Group 2B Carcinogen based on consistent epidemiological evidence. The exposure levels at which increased risks of childhood leukemia are reported in individual studies range from above 1.4 mG or 0.14 μT (Green et al., 1999)for younger children to age six (6) to 4 mG (0.4 μT). Many individual studies with cutpoints of 2 mG or 3 mG (0.2-0.3 μT)) report increased risks. Plausible biological mechanisms exist that may reasonably account for a causal relationship between EMF exposure and childhood leukemia.

Recurrence of Childhood Leukemia and Poorer Survival Rates with Continued EMF Exposure

Foliart reported more than a four-fold (450% increased risk) of adverse outcome (poorer survival rate) for children with acute lymphoblastic leukemia (ALL) who were recovering in EMF environments of 3 mG (0.3 μT) and above (OR 4.5, CI 1.5-13.8). Svendsen reported a poorer survival rate of children with acute lymphoblastic leukemia (ALL) in children exposed to 2 mG (0.2 μT) and above. These children were three times more likely (300% increased risk) to die than children recovering in fields of less than 1 mG (OR 3.0, CI 0.9.8). Children recovering in EMF environments between 1- 2 mG (0.1-0.2 μT) also had poorer survival rates, where the increased risk was 280% (OR 2.8, CI 1.2-6.2).

Higher Lifetime Cancer Risks with Childhood EMF Exposure

Lowenthal (2007) reported that children raised for the first five years in home environments exposed to EMF within 300 meters of a high voltage power line have a five-fold (a 500 percent increased risk of developing some kinds of cancers sometime in later life. For children from newborn to 15 years of age; it is a three-fold risk of developing cancer later in life (Lowenthal et al., 2007). There is suggestive evidence for a link between adult leukemia and EMF exposure.

Attributable Risk

Wartenberg estimates that 8% to 11% of childhood leukemia cases may be related to ELF exposure. This translates into an additional 175 to 240 cases of childhood leukemia based on 2200 US cases per year. The worldwide total of annual childhood leukemias is estimated to be 49,000, giving an estimate of nearly 4000 to 5400 cases per year. Other researchers have estimated higher numbers that could reach to 80% of all cases (Milham, 2001).

2. Childhood Brain Tumors

Childhood Brain Tumors

There is suggestive evidence that other childhood cancers may be related to EMF exposure. The meta-analysis by Wartenberg et al., (1998) reported increased risks for childhood brain tumors. Risks are quite similar whether based on calculated EMF fields (OR = 1.4, 95% CI = 0.8 – 2.3] or based on measured EMF fields (OR = 1.4, 95% CI = 0.8 – 2.4).

3. Adult Brain Tumors

Brain Tumors in Electrical Workers and in Electrical Occupations (Meta-analysis)

A significant excess risk for adult brain tumors in electrical workers and those adults with occupational EMF exposure was reported (Kheifets et al., 1995). This is about the same size risk for lung cancer and second hand smoke (US DHHS, 2006). A total of 29 studies with populations from 12 countries were included in this meta-analysis. The relative risk was reported as 1.16 (CI = 1.08 – 1.24) or a 16% increased risk for all brain tumors. For gliomas, the risk estimate was reported to be 1.39 (1.07 – 1.82) or a 39% increased risk for those in electrical occupations. A second meta-analysis published by Kheifets et al., ((2001) added results of 9 new studies published after 1995. It reported a new pooled estimate (OR = 1.16, 1.08 – 1.01) that showed little change in the risk estimate overall from 1995.

4. Brain Tumors and Acoustic Neuromas in Cell Phone and Cordless Phone Users (Meta-Analysis)

Glioma and Acoustic Neuroma

Hardell et al., (2007) reported in a meta-analysis statistically significant increased risk for glioma with exposure of 10 years or greater in persons using cell phones. Risks were estimated to be 1.2 (0.8 – 1.9) for all use; but when ipsilateral use was assessed (mainly on same side of head) it increased the risk of glioma to 2.0 (1.2 – 3.4) for 10 years and greater use.

For acoustic neuromas, Hardell et al., (2007) reported the increased risk with 10 years or more of exposure to a cell phone at 1.3 (0.6 – 2.8) but this risk increased to 2.4 (1.1 – 5.3) with ipsilateral use (mainly on the same side of the head). There is a consistent pattern of increased risk for brain tumors (glioma) and acoustic neuromas at 10 years and greater exposure to cell phones.

The meta-analysis by Lakhola et al., (2006) reported that brain tumor risk was 1.3 (0.99 – 1.9) for ipsilateral use of a cell phone, but no data was given for exposures at 10 years or greater (all exposures were of shorter duration).

The meta-analysis by Kan et al., (2007) reported "no overall risk" but found elevated risk of brain tumors (RR = 1.25, CI 1.01 – 1.54) $\geq$ 10 years, reinforcing the findings of other pooled

estimates of risk. No estimates of increased risk with ipsilateral use were provided, which would have likely increased reported risks.

5. Neurodegenerative Diseases

Alzheimer's Disease and ALS

Evidence for a relationship between exposure and the neurodegenerative diseases, Alzheimer's and amyotrophic lateral sclerosis (ALS), is strong and relatively consistent. While not every publication shows a statistically significant relationship between exposure and disease, ORs of 2.3 (95% CI = 1.0-5.1 in Qio et al., 2004), of 2.3 (95% CI = 1.6-3.3 in Feychting et al., 2003) and of 4.0 (95% CI = 1.4-11.7 in Hakansson et al., 2003) for Alzheimer's Disease.

Hakansson et al., report more than a doubling of risk for ALS 2.2 (95% CI = 1.0-4.7).

Savitz et al., (1998) reports more than a tripling of risk for ALS (3.1, CI = 1.0 – 9.8).

6. Breast Cancer (Men and Women)

A meta-analysis by Erren (2001) on EMF and breast cancer reported pooled relative risks based on studies of both men and women. A total of 38 publications were reviewed; there were 23 studies on men; 25 studies on women; and 10 studies on both men and women. The pooled relative risk for women exposed to EMF was 1.12 (CI 1.09 – 1.15) or a 12% increased risk, Erren observed that variations between the contributing results are not easily attributable to chance (P = 0.0365). For men and breast cancer, he reported a fairly homogeneous increased risk (a pooled relative risk of 1.37 [CI 1.11 – 1.71]).

This analysis is well conducted. The results were stratified according to measured or assumed intensity of exposure to EMF; and the estimate of risk for the most heavily exposed group was extracted. Independent estimates of RRs were grouped according to gender, type of study (case-control and cohort), country where the study was conducted and method used to assess exposure. Pooled estimates of RRs and their 95% confidence intervals (CI) referring to various combinations of these factors were calculated according to appropriate statistical methods (Greenland, 1987). Misclassification possibilities were thoroughly assessed, and whether the results were sole endpoints or there were multiple endpoints in each study did not affect the RRs.

Erren qualifies his findings by discussing that latencies for cancers can be 20 to 30 years, Further, he notes that studies of total EMF exposures from both home, travel and workplace are rarely available, and these EMF sources are ubiquitous. Both could result in underestimation of risks. Another way in which risks might be masked is by variations in age of study participants. Forssen and colleagues (2000) reported no increased RRs for breast cancer in women of all ages

when they combined residential and occupational EMF exposures (RR = 0.9, CI 0.3 – 2.7). However, when risks for the women younger than 50 years of age were separated out and calculated, the RR increased to 7.3 (CI 0.7 – 78.3) although with wide confidence intervals based on only four cases. Erren notes

"When possibly relevant exposures to EMF in the whole environment are assessed only partially, errors in the categorization of exposure status are likely to occur. If such misclassification is random and thus similar in subrgroups being compared (nondifferential), then the error will tend to introduce bias towards the null. Substantial random misclassification of exposures would then tend to generate spurious reports of 'little or no effect'. Note for example that estimates of smoking-associated lung cancer risks in the early 1950's could have been seriously distorted if exposure assessment had not considered smoking either at work or at home."

"Collectively, the data are consistent with the idea that exposures to EMF, as defined, are associated with some increase in breast cancer risks, albeit the excess risk is small." Erren (2001)

7. Combined Effects of Toxic Agents and ELF

ELF and Toxic Chemical Exposures

There is also the issue of what weight to give the evidence for synergistic effects of toxic chemical exposure and EMF exposure. Juuilainen et al., (2006) reported that the combined effects of toxic agents and ELF magnetic fields together enhances damage as compared to the toxic exposure alone. In a meta-analysis of 65 studies; overall results showed 91% of the *in vivo* studies and 68% of the *in vitro* studies had worse outcomes (were positive for changes indicating synergistic damage) with ELF exposure in combination with toxic agents. The percentage of the 65 studies with positive effects was highest when the EMF exposure preceded the other exposure. The radical pair mechanism (oxidative damage due to free radicals) is cited as a good candidate to explain these results. Reconsideration of exposure limits for ELF is warranted based on this evidence.

II. FALLACIES AND ANSWERS IN THE DEBATE OVER EMF EVIDENCE

There are several arguments (false, in our view) that have been presented by those who minimize the strength of the relationship between exposure to both 50-60Hz ELF and RF EMFs. These are as follows:

A. "Only a small number of children are affected."

This argument is not correct because we do not know precisely how many children are affected. In 1988 Carpenter and Ahlbom attempted to answer this question based on the results of the New York State Powerlines Project and the results of the study of Savitz et al. (1988), and concluded that if the magnetic fields homes in the US were similar to those in Denver, Colorado fully 10 to 15% of US childhood leukemia (about 1,000 cases) could be associated with residential magnetic field exposure. They then concluded that exposure to magnetic fields from non-residential sources (particularly appliances) must be at least equal in magnitude, and that if so these two sources of exposure would account for 20-35% of childhood leukemia.

There have been several meta-analyses of the childhood leukemia data (Wartenberg, 1998; Greenland et al., 2000; Ahlbom et al., 2000). All have concluded that there is a significant association between residential exposure to magnetic fields and elevated risk of leukemia in children. Greenland et al. (2000) performed a meta-analysis of 15 studies of magnetic field or wire code investigations of childhood leukemia, and calculated the attributable fraction of cases of childhood leukemia from residential magnetic field exposure in the US was 3%. Ahlbom et al. (2000) conducted a different meta-analysis that concluded there was a significant 2-fold elevation of risk at exposure levels of 4 mG (0.4 μT) or greater. Kheifets et al. (2006) attempted to calculate the attributable fraction of worldwide childhood leukemia due to EMFs, based on the meta-analyses of Ahlbom et al. (2000) and Greenland et al., (2000). They concluded that the attributable fraction of leukemia was between <1% to 4%. The recent WHO Environmental Health Criteria ELF Monograph #238 (2007) states "(A)ssuming that the association is causal, the number of cases of childhood leukaemia worldwide that might be attributable to exposure can be estimated to range from 100 to 2,400 cases per year. However this represents 0.2 to 4.9% of the total annual incidence of leukaemia cases, estimated to be 49,000 worldwide in 2000. Thus, in a global context, the impact on public health, if any, would be limited and uncertain."

These reports are important, in that they show consistency in there being a clearly elevated risk of leukemia in children with EMF exposure from power line fields in homes. These meta-analyses lead to the conclusion, reflected in the WHO report, that there is an association between childhood cancer and exposure to elevated magnetic fields in homes. We strongly disagree, however, with the overall conclusion that these calculations indicate that the fraction of childhood leukemia attributable to EMFs is so small as to not have serious public health implications.

There are several reasons why the WHO ELF Environmental Health Criteria Monograph conclusion is not justified. These studies all considered either only measured magnetic fields in homes or wire codes from power lines, ignoring exposure from appliances, wireless devices and all exposures outside of the home. Thus these metrics do not come close to accounting for any individual's cumulative exposure to EMFs. If residential magnetic fields cause cancer, then those from other sources will add to the risk. The failure to measure total EMF exposure would tend to obscure the relationship and lead to

gross underestimation of the true relationship between exposure and disease. While the evidence for a relationship between exposure and childhood leukemia may be considered to be definitive at exposure levels of 3 or 4 mG (0.3 or 0.4 μT) or higher; there is evidence from some (but not all) of the other studies for an elevated risk at levels not greater than 2 mG (0.2 μT) (Savitz et al., 1988; Green, 1999). There is absolutely no evidence that exposures at lower levels are "safe", since persons with these exposures are usually the "control" group. Therefore this WHO statement fails to acknowledge the true magnitude of the problem, even when considering only childhood leukemia. The global attributable risk of childhood leukemia as a result of exposure to EMFs must be significantly greater than that calculated from consideration of only residential 50/60 Hz magnetic fields in studies where there is no unexposed control.

As detailed in other chapters in this report (Chapter 10), there is some evidence for a relationship between EMF exposure and brain cancers in children. We have almost no understanding of the mechanisms behind the development of brain cancers, and any cancer in a child is a tragedy. While evidence for a relationship between EMF exposure and childhood brain cancer is not as strong as for leukemia, it is of concern and deserves more study. Of even greater concern, given the clear evidence for elevated risk of childhood leukemia upon exposure to 50/60 Hz EMFs, is the relative lack of a comparable body of information on the effects of radiofrequency EMFs on the health of children. A recent study of South Korean children (1,928 with leukemia, 956 with brain cancer and 3,082 controls) living near to AM radio transmitters reports an OR of 2.15 (95% CI = 1.19-2.11) for risk of leukemia in children living within 2 km of the nearest AM transmitter as compared to those living more than 20 km from it (Ha et al., 2007). No relation was found for brain cancer. This study is consistent with the hypothesis that radiofrequency EMFs have similar effects to 50/60 Hz EMFs, but more study is needed. Since radiofrequency EMFs have higher energy than do power line frequencies, one might expect that they would be even more likely to cause disease. The enormous and very recent increase in use of cell phones by children is particularly worrisome. However there is little information at present on the long-term consequences of cell phone use, especially by children.

B. "There is insufficient evidence that adult diseases are secondary to EMF exposure."

It is correct that the level of evidence definitively proving an association between exposure to EMFs and various adult diseases is less strong that the relationship with childhood leukemia. However there are multiple studies which show statistically significant relationships between occupational exposure and leukemia in adults (see Chapter 11), in spite of major limitations in the exposure assessment. A very recent study by Lowenthal et al. (2007) investigated leukemia in adults in relation to residence near to high-voltage power lines. While they found elevated risk in all adults living near to the high voltage power lines, they found an OR of 3.23 (95% CI = 1.26-8.29) for individuals who spent the first 15 years of life within 300 m of the power line. This study provides support for two important conclusions: adult leukemia is also associated with

EMF exposure, and exposure during childhood increases risk of adult disease. Thus protecting children from exposure should be a priority.

The evidence for a relationship between exposure and breast cancer is relatively strong in men (Erren, 2001), and some (by no means all) studies show female breast cancer also to be elevated with increased exposure (see Chapter 12). Brain tumors and acoustic neuromas are more common in exposed persons (see Chapter 10). There is less published evidence on other cancers, but Charles et al. (2003) report that workers in the highest 10% category for EMF exposure were twice as likely to die of prostate cancer as those exposed at lower levels (OR 2.02, 95% CI = 1.34-3.04). Villeneuve et al. (2000) report statistically significant elevations of non-Hodgkin's lymphoma in electric utility workers in relation to EMF exposure, while Tynes et al. (2003) report elevated rates of malignant melanoma in persons living near to high voltage power lines. While these observations need replication, they suggest a relationship between exposure and cancer in adults beyond leukemia.

Evidence for a relationship between exposure and the neurodegenerative diseases, Alzheimer's and amyotrophic lateral sclerosis (ALS), is strong and relatively consistent (see Chapter 12). While not every publication shows a statistically significant relationship between exposure and disease, ORs of 2.3 (95% CI = 1.0-5.1 in Qio et al., 2004), of 2.3 (95% CI = 1.6-3.3 in Feychting et al., 2003) and of 4.0 (95% CI = 1.4-11.7 in Hakansson et al., 2003) for Alzheimer's Disease, and of 3.1 (95% CI = 1.0-9.8 in Savitz et al., 1998) and 2.2 (95% CI = 1.0-4.7 in Hakansson et al., 2003) for ALS cannot be simply ignored.

In total the scientific evidence for adult disease associated with EMF exposure, given all of the difficulties in exposure assessment, is sufficiently strong that preventive steps are appropriate, even if not all reports have shown exactly the same positive relationship. While there are many possible sources of false positive results in epidemiological studies, there are even more possible reasons for false negative results, depending on sample size, exposure assessment and a variety of other confounders. It is inappropriate to discount the positive studies just because not every investigation shows a positive result. While further research is needed, with better exposure assessment and control of confounders; the evidence for a relationship between EMF exposure and adult cancers and neurodegenerative diseases is sufficiently strong at present to merit preventive actions to reduce EMF exposure.

C. "The risk is low."

This argument is incorrect because at present it is not possible to determine the magnitude of the risk. Clearly as far as EMFs are concerned there is no unexposed population. Therefore one can only compare groups with different levels of exposure. We can perhaps say with confidence that the elevated risk of leukemia from residential exposure of children to magnetic fields is "low" (meaning ORs in the range of 2-4), but this does not consider the child's exposure to appliances, exposure in automobiles and at

daycare or school, exposures in playgrounds and at all of the other places that a child spends time. Even if the risk to one individual is low, the societal impact when everyone is exposed may be very significant.

In addition the exposure assessment is grossly inadequate, even in the best of studies. Most reports deal only with either characterization of the fields within residences or with job titles in occupational settings. Some studies attempt to quantitate other sources of exposure, such as frequency of cell phone usage or use of other appliances, but these studies almost always do not consider residential exposure from power lines. In no investigation has it been possible to follow the exposures of a large number of people over a number of years with accurate monitoring of total exposure to EMFs. This would of course be almost impossible to do for the very good reason that as a person moves through his or her environment the exposures vary from place to place and from moment to moment. However to truly and objectively determine the risk of exposure to EMFs it is essential to consider residential, occupational (or school) and recreational exposures to the full range of the electromagnetic spectrum, including appliances and wireless devices. This has not been accomplished in any study, and without such information it is not possible to determine the overall magnitude of the risk. It is possible, indeed likely, that upon consideration of both childhood and adult diseases that the risk is not low.

D. "There is no animal evidence".

It is correct that there is no adequate animal model system that reproducibly demonstrates the development of cancer in response to exposure to EMFs at the various frequencies of concern. McCann et al. (1997) reviewed the animal studies, and while they found most to be negative there were several that showed suggestive positive results. They also clearly identified issues that need to be improved in further animal carcinogenesis investigations. However Kheifets et al. (2005a) in a policy review noted that "even consistent negative toxicological data cannot completely overcome consistent epidemiological studies. First, a good animal model for childhood leukemia has been lacking. Second, particularly for ELF, the complex exposures that humans encounter on a daily basis and a lack of understanding of the biologically relevant exposure calls into question the relevance of exposures applied in toxicology. Another limitation of toxicologic studies is that animals cannot be exposed to fields that are orders of magnitude more powerful than those encountered by humans, decreasing their power to detect small risks." Further, they conclude that "(A)lthough the body of evidence is always considered as a whole, based on the weight of evidence approach and incorporating different lines of scientific enquiry, epidemiologic evidence, as most relevant, is given the greatest weight."

One positive animal study is that by Rapacholi et al. (1997), who demonstrated that lymphoma-prone transgenic mice developed significantly more lymphoma after exposure to 900 MHz fields (lymphoma being the animal equivalent of human leukemia) than did unexposed animals. More striking is the report from Denver, Colorado using the wire-code characterization originally developed by Wertheimer and Leeper (1979) showing

that pet dogs living in homes characterized as having high or very high wire codes, as compared to those with low or very low wire codes or buried power lines, showed a OR of 1.8 (95% CI = 0.9-3.4) for development of lymphoma after adjustment for potential confounders, whereas dogs that lived in homes with very high wire codes had an OR of 6.8 (95% CI = 1.6-28.5) (Reif et al., 1995). This study is impressive because the exposure of the dogs reflects the environment in which exposure has been associated with elevated risk of human cancer in two independent investigations (Wertheimer and Leeper, 1979: Savitz et al., 1988).

It is curious that in many legal situations the courts are reluctant to accept only evidence that substance X causes cancer in animals without corresponding evidence in humans. In the case of EMFs we have strong evidence that EMFs cause cancer in human, but much less evidence from animal models. The US Supreme Court, in the case of Daubert vs. Merrell Dow Pharmaceuticals, effectively ruled that animal studies were not relevant to human health, and that the only admissible evidence must be from human epidemiological studies! While this is certainly not a justifiable conclusion, the situation with regards to EMF health effects is that we have strong evidence for human cancer from epidemiological studies, but do not have good evidence for cancer in experimental animals. But it is humans that we should be concerned about, not the laboratory rats.

E. "We do not know a mechanism."

We do not know the mechanism of cancer in general, although we know a lot about cancer. It came as a major surprise to most scientists when Lichtenstein et al., (2000) reported that genetic factors play a minor role in causing most types of cancer, since it was commonly assumed that genetics was the major cause. However Lichtenstein et al. concluded from their study of identical twins that environmental factors were the initiating event in the great majority of cancers. This does not, of course, mean that genetic susceptibility to environmental contaminants is unimportant, but only that genetic factors alone do not result in cancer. We know mechanisms of action for some carcinogenic substances, but for most cancers we know neither the environmental trigger nor the mechanism of action. So there is no reason to negate the evidence that EMFs cause cancer just because we do not know a single mechanism to explain it's mode of action.

We do not know the mechanism or cause for development of Alzheimer's Disease or ALS. We do know that both are more common in individuals in certain occupations, and that exposure to certain metals appears to be associated with increased risk (Kamel et al., 2002; Shcherbatykh and Carpenter, 2007). In the case of Alzheimer's Disease there are abnormalities of amyloid β and tau protein (Goedert and Spillantini, 2006), but very limited understanding of why or how they form. Neither the association with metals nor the presence of abnormal proteins constitutes a mechanism for cause of disease. So rather than discounting the relationship between EMF exposure and neurodegenerative diseases we should be using this information as a tool to better understand the etiology of these diseases.

There is clear evidence from animal and cell culture studies that ELF and RFR have biological effects. Furthermore, these effects occur at intensities commonly experienced by humans. We know a number of ways in which EMFs alter cell physiology and function, as detailed in various chapters in this report. EMFs affect gene transcription (Chapter 5 and 6), cause the synthesis of stress proteins (Chapter 7) and cause breakage of DNA, probably through generation of reactive oxygen species (Chapter 6 and 9 - Lai and Singh, 2004). Any one of these actions might be responsible for the carcinogenic and neurodegenerative actions of EMFs. However, as with many environmental agents, it would be a mistake to assume that there is only one target or mechanism of action. It is unlikely, for example, that the effects on the nervous system and behavior are secondary to exactly the same cellular targets and actions that lead to cancer. It is likely that there are multiple mechanisms of action leading to disease. But the lack of complete understanding of basic mechanisms does not alter the importance of the relationships.

F. Vested Interests: How They Shape the Public Health Debate

There is no question but that global implementation of the safety standards proposed in this report has the potential to not only be very expensive but also could be disruptive of life and economy as we know it if implemented abruptly and without careful planning. Action must be a balance of risk to cost to benefit. However, "deny and deploy" strategies by industry should not be rewarded in future risk assessment calculations. For example, if significant economic investments in the roll-out of risky technologies persist beyond the time that there is reasonable suspicion of risk available to all who look, then such costs should not be borne by ratepayers (in the case of new powerlines) or by compensating industry for bad corporate choices. Such investments in the deployment of new sources of exposure for ELF and RF should not count toward the balance sheet when regulatory agencies perform risk assessments. Mistakes may be made, but industry should make mid-course corrections to inform and protect the public, rather than deny effects pending "proof". Whether the costs of remedial action are worth the societal benefits is a formula that should reward precautionary behavior. Prudent corporate policies should be expected to address and avoid future risks and liabilities. Otherwise, there is no market incentive to produce safe (and safer) products.

The deployment of new technologies is running ahead of any reasonable estimation of possible health impacts and estimates of probabilities, let alone a solid assessment of risk. However what has been missing with regard to EMF has been an acknowledgement of the risk that is demonstrated by the scientific studies. As discussed in earlier sections, in this case there is clear evidence of risk, although the magnitude of the risk is uncertain, and the magnitude of doing nothing on the health effects cost to society is similarly uncertain. This situation is very similar to our history of dealing with the hazards of smoking decades ago, where the power of the industry to influence governments and even conflicts of interest within the public health community delayed action for more than a generation, with consequent loss of life and enormous extra health care costs to society.

Just because a problem is difficult to solve is not a reason to deny that a problem exists. In fact solutions to difficult issues usually can't be expected until the issues are known and creative thinking is brought to bear to find a solution.

The most contentious issue regarding public and occupational exposures to ELF and RF involves the resolute adherence to existing ICNIRP and IEEE standards by many countries, in the face of growing scientific evidence of health risks at far lower levels. Furthermore there is widespread belief that governments are ignoring this evidence. There are two obvious factors that work against governments taking action to set exposure guidelines based on current scientific evidence of risk. These are: 1) contemporary societies are very dependent upon electricity usage and RF communications, and anything that restricts current and future usage potentially has serious economic consequences and 2) the electric power and communications industries have enormous political clout and even provide support for a significant fraction of what research is done on EMF. This results in legislation that protects the status quo and scientific publications whose conclusions are not always based on only the observations of the research. It hinders wise public health policy actions and implementation of prevention strategies because of the huge financial investments already made in these technologies.

In 1989, in an editorial for Science Magazine, Philip H. Abelson called for more research into low-frequency electromagnetic fields. At that time, he confirmed that a US Office of Technology Assessment (OTA) study had determined that *"(o)verall, the evidence is too weak to allow firm conclusions either way*" but a policy of prudent avoidance strategy was suggested, Abelson defined this as "*to systematically look for strategies which can keep people out of 60 Hz fields*". Both policy actions were developed in the midst of scientific uncertainty, but rising concern for possible health impacts to the public. At that time, with high level of unknowns, the appropriate level of policy action was prudent avoidance or precautionary action. Nearly two decades later, the level of action warranted is higher – based on many new scientific publications confirming risks may exist – and justifying prevention or preventative action.

III. EMF EXPOSURE AND PRUDENT PUBLIC HEALTH PLANNING

• *The scientific evidence is sufficient to warrant regulatory action for ELF; and it is substantial enough to warrant preventative actions for RF.*

• *The standard of evidence for judging the emerging scientific evidence necessary to take action should be proportionate to the impacts on health and well-being*

• *The exposures are widespread.*

• *Widely accepted standards for judging the science are used in this assessment.*

Public exposure to electromagnetic radiation (power-line frequencies, radiofrequency and microwave) is growing exponentially worldwide. There is a rapid increase in electrification in developing countries, even in rural areas. Most members of society now have and use cordless phones, cellular phones, and pagers. In addition, most populations are also exposed to antennas in communities designed to transmit wireless RF signals. Some developing countries have even given up running land lines because of expense and the easy access to cell phones. Long-term and cumulative exposure to such massively increased RF has no precedent in human history. Furthermore, the most pronounced change is for children, who now routinely spend hours each day on the cell phone. Everyone is exposed to a greater or lesser extent. No one can avoid exposure, since even if they live on a mountain-top without electricity there will likely be exposure to communication-frequency RF exposure. Vulnerable populations (pregnant women, very young children, elderly persons, the poor) are exposed to the same degree as the general population. Therefore it is imperative to consider ways in which to evaluate risk and reduce exposure. Good public health policy requires preventative action proportionate to the potential risk of harm and the public health consequence of taking no action.

IV. RECOMMENDED ACTIONS

A. Defining new exposure standards for ELF

This chapter concludes that new ELF limits are warranted based on a public health analysis of the overall existing scientific evidence. The public health view is that new ELF limits are needed now. They should reflect environmental levels of ELF that have been demonstrated to increase risk for childhood leukemia, and possibly other cancers and neurological diseases. ELF limits should be set below those exposure levels that have been linked in childhood leukemia studies to increased risk of disease, plus an additional safety factor. It is no longer acceptable to build new power lines and electrical facilities that place people in ELF environments that have been determined to be risky. These levels are in the 2 to 4 milligauss* (mG) range (0.2 – 0.4 μT), not in the 10s of mG or 100s of mG. The existing ICNIRP limit is 1000 mG (100 μT) and 904 mG (90.4 μT) in the US for ELF is outdated and based on faulty assumptions. These limits are can no longer be said to be protective of public health and they should be replaced. A safety buffer or safety factor should also be applied to a new, biologically-based ELF limit, and the conventional approach is to add a safety factor lower than the risk level.

While new ELF limits are being developed and implemented, a reasonable approach would be a 1 mG (0.1 μT) planning limit for habitable space adjacent to all new or upgraded power lines and a 2 mG (0.2 μT) limit for all other new construction. It is also recommended for that a 1 mG (0.1 μT) limit be established for existing habitable space for children and/or women who are pregnant (because of the possible link between childhood leukemia and *in utero* exposure to ELF). This recommendation is based on the assumption that a higher burden of protection is required for children who cannot protect themselves, and who are at risk for childhood leukemia at rates that are traditionally high enough to trigger regulatory action. This situation in particular warrants extending the 1 mG (0.1 μT) limit to existing occupied space. "Establish" in this case probably means formal public advisories from relevant health agencies. While it is not realistic to reconstruct all existing electrical distribution systems, in the short term; steps to reduce exposure from these existing systems need to be initiated, especially in places where children spend time, and should be encouraged. These limits should reflect the exposures that are commonly associated with increased risk of child hood leukemia (in the 2 to 5 mG (0.2 to 0.5 μT) range for all children, and over 1.4 mG (0.14 μT) for children age 6 and younger). Nearly all of the occupational studies for adult cancers and neurological diseases report their highest exposure category is

4 mG (0.4 μT) and above, so that new ELF limits should target the exposure ranges of interest, and not necessarily higher ranges.

Avoiding chronic ELF exposure in schools, homes and the workplace above levels associated with increased risk of disease will also avoid most of the possible bioactive parameters of ELF discussed in the relevant literature.

It is not prudent public health policy to wait any longer to adopt new public safety limits for ELF. These limits should reflect the exposures that are commonly associated with increased risk of childhood leukemia (in the 2 to 5 mG (0.2-0.5 μT) range for all children, and over 1.4 mG (0.14 μT) for children age 6 and younger). Avoiding chronic ELF exposure in schools, homes and the workplace above levels associated with increased risk of disease will also avoid most of the possible bioactive parameters of ELF discussed in the relevant literature.

B. Defining preventative actions for reduction in RF exposures

Given the scientific evidence at hand, the rapid deployment of new wireless technologies that chronically expose people to pulsed RF at levels reported to cause bioeffects, whicih in turn, could reasonably be presumed to lead to serious health impacts, is a public health concern. A public health action level that implements preventative action now is warranted, based on the collective evidence. There is suggestive to strongly suggestive evidence that RF exposures may cause changes in cell membrane function, cell communication, metabolism, activation of proto-oncogenes and can trigger the production of stress proteins at exposure levels below current regulatory limits. Resulting effects can include DNA breaks and chromosome aberrations, cell death including death of brain neurons, increased free radical production, activation of the endogenous opioid system, cell stress and premature aging, changes in brain function including memory loss, retarded learning, performance impairment in children, headaches and fatigue, sleep disorders, neurodegenerative conditions, reduction in melatonin secretion and cancers (Chapters 5, 6, 7, 8, 9, 10, and 12).

As early as 2000, some experts in bioelectromagnetics promoted a 0.1 μW/cm2 limit (which is 0.614 Volts per meter) for ambient outdoor exposure to pulsed RF, so generally in cities, the public would have adequate protection against involuntary exposure to pulsed radiofrequency (e.g., from cell towers, and other wireless technologies). The Salzburg Resolution of 2000 set a target of 0.1 μW/cm2 (or 0.614 V/m) for public exposure to pulsed radiofrequency. Since then, there are many credible anecdotal reports of unwellness and illness in the vicinity of wireless transmitters (wireless voice and data communication antennas) at lower levels. Effects include sleep disruption, impairment of memory and concentration, fatigue, headache, skin disorders, visual symptoms (floaters), nausea, loss of appetite, tinnitus, and cardiac problems (racing heartbeat), There are some credible articles from researchers reporting that cell tower -level RF exposures (estimated to be between 0.01 and 0.5 μW/cm2) produce ill-effects in populations living up to several hundred meters from wireless antenna sites,

This information now argues for thresholds or guidelines that are substantially below current FCC and ICNIPR standards for whole body exposure. Uncertainty about how low such standards might have to go to be prudent from a public health standpoint should not prevent reasonable efforts to respond to the information at hand. No lower limit for bioeffects and adverse health effects from RF has been established, so the possible health risks of wireless WLAN and WI-FI systems, for example, will require further research and no assertion of safety at any level of wireless exposure (chronic exposure) can be made at this time. The lower limit for reported human health effects has dropped 100-fold below the safety standard (for mobile phones and PDAs); 1000- to 10,000-fold for other wireless (cell towers at distance; WI-FI and WLAN devices). The entire basis for safety standards is called into question, and it is not unreasonable to question the safety of RF at any level.

A cautionary target level for pulsed RF exposures for ambient wireless that could be applied to RF sources from cell tower antennas, WI-FI, WI-MAX and other similar sources is proposed. The recommended cautionary target level is 0.1 microwatts per centimeter squared (μW/cm2)** (or 0.614 Volts per meter or V/m)** for pulsed RF where these exposures affect the general public; this advisory is proportionate to the evidence and in accord with prudent public health policy. A precautionary limit of 0.1 μW/cm2 should be adopted for outdoor, cumulative RF exposure. This reflects the current RF science and prudent public health response that would reasonably be set for pulsed RF (ambient) exposures where

people live, work and go to school. This level of RF is experienced as whole-body exposure, and can be a chronic exposure where there is wireless coverage present for voice and data transmission for cell phones, pagers and PDAs and other sources of radiofrequency radiation. An outdoor precautionary limit of 0.1 μW/cm2 would mean an even lower exposure level inside buildings, perhaps as low as 0.01 μW/cm2. Some studies and many anecdotal reports on ill health have been reported at lower levels than this; however, for the present time, it could prevent some of the most disproportionate burdens placed on the public nearest to such installations. Although this RF target level does not preclude further rollout of WI-FI technologies, we also recommend that wired alternatives to WI-FI be implemented, particularly in schools and libraries so that children are not subjected to elevated RF levels until more is understood about possible health impacts. This recommendation should be seen as an interim precautionary limit that is intended to guide preventative actions; and more conservative limits may be needed in the future.

Broadcast facilities that chronically expose nearby residents to elevated RF levels from AM, FM and television antenna transmission are also of public health concern given the potential for very high RF exposures near these facilities (antenna farms). RF levels can be in the 10s to several 100's of μW/cm2 in residential areas within half a mile of some broadcast sites (for example, Lookout Mountain, Colorado and Awbrey Butte, Bend, Oregon). Like wireless communication facilities, RF emissions from broadcast facilities that are located in, or expose residential populations and schools to elevated levels of RF will very likely need to be re-evaluated for safety.

For emissions from wireless devices (cell phones, personal digital assistant or PDA devices, etc) there is enough evidence for increased risk of brain tumors and acoustic neuromas now to warrant intervention with respect to their use. Redesign of cell phones and PDAs could prevent direct head and eye exposure, for example, by designing new units so that they work only with a wired headset or on speakerphone mode.

These effects can reasonably be presumed to result in adverse health effects and disease with chronic and uncontrolled exposures, and children may be particularly vulnerable. The young are also largely unable to remove themselves from such environments. Second-hand radiation, like second-hand smoke is an issue of public health concern based on the evidence at hand.

V. CONCLUSIONS

• We cannot afford 'business as usual" any longer. It is time that planning for new power lines and for new homes, schools and other habitable spaces around them is done with routine provision for low-ELF environments . The business-as-usual deployment of new wireless technologies is likely to be risky and harder to change if society does not make some educated decisions about limits soon. Research must continue to define what levels of RF related to new wireless technologies are acceptable; but more research should not prevent or delay substantive changes today that might save money, lives and societal disruption tomorrow.

• New regulatory limits for ELF based on biologically relevant levels of ELF are warranted. ELF limits should be set below those exposure levels that have been linked in childhood leukemia studies to increased risk of disease, plus an additional safety factor. It is no longer acceptable to build new power lines and electrical facilities that place people in ELF environments that have been determined to be risky (at levels generally at 2 mG (0.2 μT) and above).

• While new ELF limits are being developed and implemented, a reasonable approach would be a 1 mG (0.1 μT) planning limit for habitable space adjacent to all new or upgraded power lines and a 2 mG (0.2 μT) limit for all other new construction, It is also recommended for that a 1 mG (0.1 μT) limit be established for existing habitable space for children and/or women who are pregnant . This recommendation is based on the assumption that a higher burden of protection is required for children who cannot protect themselves, and who are at risk for childhood leukemia at rates that are traditionally high enough to trigger regulatory action. This situation in particular warrants extending the 1 mG (0.1 μT) limit to existing occupied space. "Establish" in this case probably means formal public advisories from relevant health agencies.

• While it is not realistic to reconstruct all existing electrical distributions systems, in the short term; steps to reduce exposure from these existing systems need to be initiated, especially in places where children spend time, and should be encouraged.

• A precautionary limit of 0.1 (μW/cm2 (which is also 0.614 Volts per meter) should be adopted for outdoor, cumulative RF exposure. This reflects the current RF science and prudent public health response that would reasonably be set for pulsed RF (ambient) exposures where people live, work and go to school. This level of RF is experienced as whole-body exposure, and can be a chronic exposure where there is wireless coverage present for voice and data transmission for cell phones, pagers and PDAs and other sources of radiofrequency radiation. Some studies and many anecdotal reports on ill health have been reported at lower levels than this; however, for the present time, it could prevent some of the most disproportionate burdens placed on the public nearest to such installations. Although this RF target level does not preclude further rollout of WI-FI technologies, we also recommend that wired alternatives to WI-FI be implemented, particularly in schools and libraries so that children are not subjected to elevated RF levels until more is understood about possible health impacts. This recommendation should be seen as an interim precautionary limit that is intended to guide preventative actions; and more conservative limits may be needed in the future.

I. INTRODUCTION

In public health and environmental policy-making, asking the right questions is a highly evolved art form. It is necessary to periodically look for '*not-so-early-now warnings'* from new science and medical information. At some point it becomes '*old news'* in the real-world process of commercializing new technologies* and is ignored. Precious time is lost if the '*evidence curve'* does not come quickly enough to '*change the rollout curve*' and result in early enough interventions. EMF may be a highly preventable source of disease but not without early enough translation of the science into action. The time for arguing whether EMF health effects exist is over. We know they exist and that they result in human disease.

Asking the right questions and looking for proportionate responses necessarily involves make mid-course corrections guided by new evidence. This is particularly true when the consequences of doing nothing are too great to ignore – because they will affect billions of people in societies around the world. "*While there are many unanswered questions, the cost of doing nothing will result in an increasing number of people, many of them young, developing cancer*." (Carpenter, 2010).

What questions should be asked now, to move forward on the body of evidence? How much evidence do we need to act? Do we have enough? What standard of evidence should be used to judge (purely scientific vs precautionary public health). What is a relevant biological 'dose'? How long does a biological effect last? Are we accounting for differences among individuals or different types of cells?

Which of the studies are truly measuring chronic exposures (is a one-month or a one-year study really revealing chronic effects; if mid-length studies show no effect, does this tell us anything useful)? Why is it still considered reasonable to base safety standards on time-averaged radiofrequency exposures when the technologies today use pulsed RFR?

*Electronics, the internet, cellular telecommunications, wireless medical technologies, and wireless sensors for energy conservation, electric utilities management, transportation, education, banking and national security.

For example, the collective behavior of neurons is established through synchrony. "*Individual neurons have a time window of tens of milliseconds range for single neurons, but oscillatory coalitions of neurons can expand the effect window of synchronization from hundreds of milliseconds to many seconds"* (Buzsaki, 2006). This means the time span a bioeffect can last long enough to overlap with the next environmental provocation (pulsed RFR in this case) so that repetitive exposures may induce an unending cascade of neurological firing that eventually disrupts normal homeostasis and causes chronically abnormal function in cooperative assemblies of cells like neurons. RFR is bioactive and already classified as a Possible Human Carcinogen but the relevant RFR bursts are camouflaged and their relevant metrics are diluted away by time averaging. Why is it reasonable to use safety standards that were developed to guard against induced currents in tissue (ELF-EMF) or that heat or burn tissue (RFR)?

Briefly stated, here is what we knew in 2007.

- Bioeffects and adverse health effects of chronic exposure to low-intensity (non-thermal) non-ionizing radiation are established.
- Existing FCC and ICNIRP public safety limits are not sufficiently protective of public health.
- The World Health Organization has classified ELF-EMF as a Group 2B Possible Human Carcinogen (2001).
- New, biologically-based public exposure standards are critically needed.
- It is not in the public interest to wait.

Here is what we know in 2012. There is more evidence, over a broader range of studies. The levels of biological responses are extraordinarily low (down to the nanowatt and picowatt power density level).

New studies address fertility and reproduction, fetal and neonatal effects, cognitive and behavioral problems in children and neurological damage. There are more mobile phone base station studies with longer testing periods, much more information on genetic damage and confirmation of increased risk of brain cancers from not one or two

studies, but from many studies and many authors including the World Health Organization's massive 13-country INTERPHONE STUDY (Interphone Study Group, 2010).

There are many studies reporting effects of cell phone radiation (even on standby-mode), wireless laptop exposure, cell phone use by mothers resulting in altered fetal brain development in the offspring, and more evidence that the blood-brain barrier and memory are at risk from cell phone use. There is evidence from human and animal studies that key areas of the brain are negatively affected by RFR at legal levels.

There is better understanding of the important physical and biological factors that make ELF-EMF and RFR potent disruptors of living tissues and basic metabolic processes. More and more, EMF devices are being used for medical treatments in cancer, bone and wound healing and re-tuning the nervous system. Increased depth of evidence in many threads is presented in this report by well-regarded scientists and researchers from around the world. The number of good studies has grown. The exposure levels causing effects are documented to be much lower than in the past. The epidemiological evidence is now showing risks for a variety of adverse health outcomes. All this should be taken seriously by governments, and translated quickly into more protective safety standards, and in the interim, into strong preventative actions, warnings and substitution of safer technologies and redesigned devices.

Bioeffects are clearly established and occur at very low levels of exposure to electromagnetic fields and radiofrequency radiation. Bioeffects can occur in the first few minutes at levels associated with cell and cordless phone use. Bioeffects can also occur from just minutes of exposure to mobile phone masts (cell towers), WI-FI, and wireless utility 'smart' meters that produce whole-body exposure. Chronic base station level exposures can result in illness.

Many of these bioeffects can reasonably be expected to result in adverse health effects if the exposures are prolonged or chronic. This is because they interfere with normal body processes (disrupt homeostasis), prevent the body from healing damaged DNA, produce immune system imbalances, metabolic disruption and lower resistance to disease across multiple pathways. Essential body processes can eventually be disabled by incessant external stresses (from system-wide electrophysiological interference) and lead to pervasive impairment of metabolic and reproductive functions.

What does the WHO IARC Classification of ELF-EMF and RFR as Group 2B Possible Human Carcinogens Mean?

The World Health Organization International Agency for Cancer Research (IARC) designated ELF-EMF as a Group 2B (Possible) Carcinogen in 2001. This is the kind of exposure from power lines, battery switching in cell phone devices, laptop computers and appliances. The World Health Organization specifically reaffirmed its finding that EMF is classifiable as a Group 2B Possible Human Carcinogen in 2006 in their Health Criteria Monograph #238 (WHO, 2007).

World Health Organization International Agency for Research on Cancer (IARC) Cancer Classifications

Group 1	Known Carcinogen
Group 2A	Probable Carcinogen
Group 2B	Possible Human Carcinogen
Group 3	Insufficient Information
Group 4	Not a Carcinogen

In 2011, IARC determined that scientific evidence is sufficient now to classify radiofrequency radiation as a Group 2B Possible Human Carcinogen (Baan et al, 2011). This is the kind of exposure coming from cell and cordless phones, cell towers, WI-FI, wireless laptops, electronic baby monitors and wireless 'smart' utility meters.

So, what does this mean? According to the classification categories, it is again clear IARC did NOT find so little clear and consistent evidence that it should support a finding of "Not A Carcinogen". That would be the valid test that RFR is safe, as best public health experts can judge the evidence. Nor did IARC find that the evidence sufficient so as to make a stronger classification (Probably or Known Carcinogen). Rather, IARC found the evidence supports classification as a "Possible" cancer-causing

agent. That is not a weak or reckless judgment made with few facts. It should be a strong warning to governments to reconsider their safety standards, particularly in light of the billions of people at potential health risk from new wireless technologies. Studies of cell and cordless phones and of wireless whole-body RFR exposures consistently show human health impacts that have become 'epidemiologically visible' (Sections 11 and 21).

ELF-EMF AND RFR ARE CLASSIFIED AS POSSIBLE CANCER-CAUSING AGENTS – WHY ARE GOVERNMENTS NOT ACTING?

The World Health Organization International Agency for Research on Cancer has classified wireless radiofrequency as a Possible Human Carcinogen (May, 2011). The designation applies to low-intensity RFR in general, covering all RFR-emitting devices and exposure sources (cell and cordless phones, WI-FI, wireless laptops, wireless hotspots, electronic baby monitors, wireless classroom access points, wireless antenna facilities, etc). The IARC Panel could have chosen to classify RFR as a Group 4 – Not A Carcinogen if the evidence was clear that RFR is not a cancer-causing agent. It could also have found a Group 3 designation was a good interim choice (Insufficient Evidence). IARC did neither.

II. KEY SCIENTIFIC EVIDENCE (2006- 2012)

Many thousand scientific studies over four decades have provided warnings of serious biological effects and potential health harm from EMF and RFR. About 1800 new, scientific papers published in the last five years report more bioeffects and adverse health effects of EMF and RFR, and are presented in great detail in the BioInitiative Report 2012.

These studies since 2006 give critical support to the argument that current safety standards are grossly inadequate. They cannot be protecting public health if they do not prevent harm to a variety of types of human cells, human sperm and the developing fetus *in-utero*. These are all effects reported today due to cell phone radiation exposures that are both legal and common in daily home, business and school environments. These effects are shown to occur at very low-intensity permissible levels that have become 'typical' for pregnant women, the fetus, the infant, the child, and for adults. Such effects are occurring at hundreds to thousands of times lower intensity exposure levels than the current FCC public safety limits allow. These exposure levels are common in the

environment, but worst in close proximity to wireless devices like cell and cordless phones, 'smart' wireless utility meters, wireless routers, wireless classroom access points and laptops, to baby surveillance devices, and in the first few hundred meters of cell towers. WI-FI levels of RFR and cell phones-on-standby mode are sufficient to cause effects that, if chronic, may be damaging to the health of cellular DNA, reproductive germ cells (sperm) and the male reproductive organs.

Overall, these new studies report abnormal gene transcription (Section 5); genotoxicity and single-and double-strand DNA damage (Section 6); stress proteins because of the fractal RF-antenna like nature of DNA (Section 7); chromatin condensation and loss of DNA repair capacity in human stem cells (Sections 6 and 15); reduction in free-radical scavengers - particularly melatonin (Sections 5, 9, 13, 14, 15, 16 and 17); neurotoxicity in humans and animals (Section 9), carcinogenicity in humans (Sections 11, 12, 13, 14, 15, 16 and 17); serious impacts on human and animal sperm morphology and function (Section 18); effects on offspring behavior (Section 18, 19 and 20); and effects on brain and cranial bone development in the offspring of animals that are exposed to cell phone radiation during pregnancy (Sections 5 and 18). This is only a snapshot of the evidence presented in the BioInitiative 2014 updated report.

Many of these bioeffects are associated with disruption of normal biological functioning in the genes, and in the physiology of the nervous and cardiac systems of the body (brain, blood-brain barrier, heart, vascular system). Sleep disruption (insomnia) is a hallmark bioeffect of RFR. Hypersensitivity disorders like allergies and asthma are reported from exposure to environmental chemicals and to EMF. A pregnant woman's exposure to EMF has been linked to increased asthma and behavioral problems in the human child after *in-utero* exposure. Pregnant mice exposed to cell phone radiation give birth to baby mice with attention disorders, hyperactivity and impaired memory function, similar to effects seen in human babies as reported by Divan et al (2008).

A. Stress, Stress Proteins and DNA as a Fractal Antenna: The word stress invokes different concepts for people, but needs to be understood as a physiological response. BioInitiative author Martin Blank has described how both ELF-EMF and RFR produce stress proteins at very low exposure levels, and why this is only adaptive in the short-

term. Chronic exposures that trigger stress responses (stress proteins) regardless of their environmental cause are mal-adaptive if they go on too long. Any agent (EMF, ionizing radiation, chemicals, heavy metals, etc) that continuously generates stress proteins is not adaptive, and is harmful, if it is a constant provocation.

The work of Martin Blank and Reba Goodman of Columbia University has established that stress proteins are produced by ELF-EMF and RFR at levels far below current safety standards allow. Further, they think DNA is actually a very good fractal RF-antenna which is very sensitive to low doses of EMF, and may induce the cellular processes that result in chronic 'unrelenting' stress. That daily environmental levels of ELF-EMF and RFR can and do throw the human body into stress protein response mode (out of homeostasis) is a fundamental and continuous insult. Chronic exposures can then result in chronic ill-health**.**

B. Fetal Effects and Fetal Development Studies: Effects on the developing fetus from *in-utero* exposure to cell phone radiation have been observed in both human and animal studies since 2006. Divan et al (2008) found that children born of mothers who used cell phones during pregnancy develop more behavioral problems by the time they have reached school age than children whose mothers did not use cell phones during pregnancy. The July 2008 issue of Epidemiology reports that children whose mothers used cell phones during pregnancy had 25% more emotional problems, 35% more hyperactivity, 49% more conduct problems and 34% more peer problems (Divan et al, 2008).

Aldad et al (2012) showed that cell phone radiation significantly altered fetal brain development and produced ADHD-like behavior in the offspring of pregnant mice. Exposed mice had a dose-dependent impaired glutamatergic synaptic transmission onto Layer V pyramidal neurons of the prefrontal cortex. The authors conclude the behavioral changes were the result of altered neuronal developmental programming *in utero*. Offspring mice were hyperactive and had impaired memory function and behavior problems, much like the human children in Divan et al (2008).

A new study from Greece reports altered development of the cranial bones of the mouse fetus from low intensity (0.6 to 0.9 W/kg) *in-utero* 900 MHz cell phone radiation (Fragopoulou et al, 2009). They report *"our results clearly show that even modest exposure (e.g., 6-min daily for 21 days) is sufficient to interfere with the normal mouse developmental process."*

Other new studies by Fragopoulou et al report that brain astrocyte development followed by proteomic studies is adversely affected by DECT (cordless phone radiation) and mobile phone radiation (Fragopoulou et al, 2012); and that whole body exposure with GSM 900MHz affects spatial memory in mice (Fragopoulou et al, 2010).

FETAL BRAIN DEVELOPMENT MAY BE ALTERED

There is increasing evidence that fetal (*in-utero*) and early childhood exposures to cell phone radiation and wireless technologies in general is a risk factor for hyperactivity, learning disorders and behavioral problems in school.

Neonatal physician Carlo Bellieni of Italy found that heart rate variability is adversely affected in infants hospitalized in isolettes or incubators where ELF-EMF levels are in the 0.8 to 0.9 μT range (8 to 9 mG) (Bellieni, 2008). Infants suffer adverse changes in heart rate variability, similar to adults. He also reported that newborns cared for in the high ELF-EMF environments of isolettes have disrupted melatonin levels (Bellieni et al, 2012a).

C. Studies of Sperm: Several international laboratories have replicated studies showing adverse effects on sperm quality, motility and pathology in men who use and particularly those who wear a cell phone, PDA or pager on their belt or in a pocket (Agarwal et al, 2008; Agarwal et al, 2009; Wdowiak et al, 2007; De Iuliis et al, 2009; Fejes et al, 2005; Aitken et al, 2005; Kumar, 2012). Other studies conclude that usage of cell phones, exposure to cell phone radiation, or storage of a mobile phone close to the testes of human males affect sperm counts, motility, viability and structure (Aitken et al, 2004; Agarwal et al, 2007; Erogul et al., 2006). Animal studies have demonstrated oxidative and DNA damage, pathological changes in the testes of animals, decreased sperm mobility and viability, and other measures of deleterious damage to the male germ line

(Dasdag et al, 1999; Yan et al, 2007; Otitoloju et al, 2010; Salama et al, 2008; Behari et al, 2006; Kumar et al, 2012). There are fewer animal studies that have studied effects of cell phone radiation on female fertility parameters. Panagopoulous et al. 2012 report decreased ovarian development and size of ovaries, and premature cell death of ovarian follicles and nurse cells in *Drosophila melanogaster.* Gul et al (2009) report rats exposed to stand-by level RFR (phones on but not transmitting calls) caused decrease in the number of ovarian follicles in pups born to these exposed dams. Magras and Xenos (1997) reported irreversible infertility in mice after five (5) generations of exposure to RFR at cell phone tower exposure levels of less than one microwatt per centimeter squared (μW/cm2).

Agarwal et al (2009) evaluated the effect of cell phone radiation during talk mode on human sperm samples. The authors found "*radiofrequency electromagnetic waves emitted from cell phones may lead to oxidative stress in human semen. We speculate that keeping the cell phone in a trouser pocket in talk mode may negatively affect spermatozoa and impair male fertility.*"

Aitken et al (2005) studied the effect of 900 MHz cell phone radiation on mice (7 days, 12-hr per day at 0.09 W/kg). The authors found statistically significant damage to the mitochondrial genome of epididymal spermatozoa ($p<0.05$).

Avendano et al, 2012 provided evidence that a 4-hr exposure to WI-FI at exceeding low levels (0.5-1.0 μW/cm2) near a laptop computer caused decreased sperm viability and DNA fragmentation in human sperm samples. Avendado says "(*T)o our knowledge, this is the first study to evaluate the direct impact of a laptop use on human spermatozoa. Ex vivo exposure of human spermatozoa to a wireless internet-connected laptop decreased motility and induced DNA fragmentation by a nonthermal effect. We speculate that keeping a laptop connected wirelessly to the internet on the lap near the testes may result in decreased male fertility.*"

De Iuliis et al (2009) reported that "*RF-EMR in both the power density and frequency range of mobile phones enhances mitochondrial reactive oxygen species generation by human spermatozoa, decreasing the motility and vitality of these cells*

while stimulating DNA base adduct formation, and ultimately DNA fragmentation." They warned their findings *"have clear implications for the safety of extensive mobile phone use by males of reproductive age, potentially affecting both their fertility and the health and wellbeing of their offspring"* based on damage from a 6-hr exposure to 1800 MHz cell phone radiation in human sperm cells. This 6-hr exposure caused reduced sperm motility and viability and caused a significant increase in reactive oxygen species (free radicals that are associated with oxidative damage to DNA), and the effects were worse with more exposure (a significant dose-response was observed). Atasoy (2012) also questioned the safety of 2400 MHz exposure to those of reproductive age. This study reports that WI-FI internet access devices can damage DNA and reduce DNA repair when the exposures are very low(exposure level of 0.091 W/kg) and chronic; damage can occur even at levels that comply with 802.11 g WI-FI public safety limits.

Behari et al (2006) reported that chronic exposure of rats to cell phone radiation caused double-strand DNA breaks in sperm cells (35 days, 2-hr per day). This study also showed that the mobile radiation exposure at 900 MHz (at 0.9 W/kg) and at 2.45 GHz (at 0.1 W/kg) caused a statistically significant decrease in sperm count and the weight of testes.

Otitoloju et al., (2010) graphically describe sperm head abnormalities in mice exposed for six months to base-station level RF/MW at 70 to 100 nanowatts/cm2 (0.07 – 0.1 μW/cm2). Only 2% of controls but a stunning 39% to 46% of exposed mice had damaged sperm.

> *"The major abnormalities observed were knobbed hook, pin-head and banana-shaped sperm head. The occurrence of sperm head abnormalities was also found to be dose dependent. The implications of the observed increased occurrence of sperm head abnormalities on the reproductive health of humans living in close proximity to GSM base stations were discussed.*"

These studies taken together should provide a strong warning that 'normal' use of a cell phone presents risks that warrant strong preventative actions to protect the integrity of the human genome from de novo mutations and loss of fertility across entire male populations of cell phone users. Further, even the much lower exposure levels associated with mobile phone base station (cell tower) RFR levels are deleterious over time.

HUMAN SPERM AND THEIR DNA ARE DAMAGED

Human sperm are damaged by cell phone radiation at very low intensities (0.00034 – 0.07 μW/cm2). There is a veritable flood of new studies reporting sperm damage in humans and animals, leading to substantial concerns for fertility, reproduction and health of the offspring (unrepaired de novo mutations in sperm). Exposure levels are similar to those resulting from wearing a cell phone on the belt, or in the pants pocket, or using a wireless laptop computer on the lap. Sperm lack the ability to repair DNA damage.

D. Human Stem Cell Studies: Markova et al (2010) reported that 915 MHz microwave exposure significantly affects human stem cells. They found that very low-intensity microwave radiation from mobile phones can inhibit DNA repair processes in human stem cells. By placing a mobile phone at one meter distance from human stem cells in petri dishes (SAR = 0.037 W/Kg), they found a significant reduction in 53BP1 foci. These foci are a measure of DNA repair in cells with double strand DNA damage. The damage was greater to stem cells (derived from adipose tissue in humans) than in fibroblasts. Stem cells did not repair over time - and the damage was done within one hour of microwave exposure. Fibroblasts were similarly affected (inhibited 53BP1 foci) but repaired over time. The effects are carrier-frequency dependent. The effects occurred with GSM exposure at 915 MHz, but not at 905 MHz. The failure of DNA repair also occurred at the mobile phone UTMS carrier frequency of 1947 MHz. Analysis of the 53BP1 foci is a sensitive technique to measure double-strand DNA breaks in both unexposed cells and in cells exposed to cytotoxic agents. In the authors' words, *"this represents a direct mechanistic link to epidemiological data showing an association of MW exposure with increased cancer risk*." The data obtained from human stem cells is of "*utmost relevance for assessment of possible health risks of MW exposure from mobile phones."* Most, if not all adult tissues and organs including blood, skin and brain contain stem cells. Therefore, "*stem cells like blood cells and fibroblasts are always subjected to exposure from mobile phones*." With respect to children, because "*almost all organs and tissues possess stem cells and stem cells are more active in children, the possible relationship of chronic MW exposure and various types of tumors and leukemia especially in children should be investigated."*

Czyz et al (2004) reported that GSM cell phone exposure affected gene expression levels in embryonic stem cells (p53-deficient); and significantly increased heat shock protein HSP 70 production.

HUMAN STEM CELL DNA DOES NOT ADAPT OR REPAIR

Human adipose tissue stem cells lack the ability to repair DNA damage caused by chronic exposure to non-thermal microwaves. Damage to DNA in some other cells may be incompletely repaired.

E. Mobile Phone Base Station (Cell Tower) Studies

Human Studies: Hutter et al (2006) reported that short-term exposure to GSM cell phone radiation resulted in complaints of headache, neurological problems, sleep and concentration problems in adults with 0.01 - 0.05 μW/cm2 exposure levels. Kundi and Hutter (2009) reviewed human effects in fourteen (14) mobile phone base station studies and reported *"(F)rom available evidence it is impossible to delineate a threshold below which no effect occurs, however, given the fact that studies reporting low exposure were invariably negative it is suggested that power densities around 0.5–1 mW/m2 [*0.05 – 0.1 uW/cm2*] must be exceeded in order to observe an effect."*

Buchner and Eger (2012) conducted an eighteen (18) month study to assess changes in stress hormones in 60 persons exposed before and after a mobile phone base station went into operation in the Rimbach village in Germany. The study showed that chronic exposure to base station RF (whole-body) at 0.006 - 0.01 μW/cm2 in humans had significant impacts on stress hormones over time. In the beginning months, adrenaline levels first increased in a dose-dependent fashion according to exposure level ($p < 0.002$) and then decreased below normal levels ($p < 0.005$). Both the average as well as the median adrenaline values increased after the activation of the transmitter and decreased again after one year with exposure levels >0.006 μW/cm2. Chronically ill subjects and children showed especially strong responses; except for some "outliers," no effect was observed in healthy adults (Buchner and Eger, 2012). For dopamine, inverse effects to

those for adrenaline and noradrenaline were observed. The median dopamine levels decreased from 199 to 115 μg/g creatinine between January and July 2004. The fact that the dopamine levels of the study subjects decreased during this period is highly significant ($p<0.0002$). Thereafter, the median increased again: In January 2005, it was at 131 μg/g creatinine, in July of 2005. This increase is also significant between July 2004 and July 2005 ($p<0.05$).

Buchner (2012) indicates that the RFR transmitter induced changes in stress hormones that follow the classic stress syndrome of adaptation, then exhaustion established by Hans Seyle in the 1950's. *"After the stages of alarm and resistance, the last stage of exhaustion sets in. The parameters investigated in the Rimbach study follow this pattern"*.

A long-term 6-yr study assessed the role of exposure to radio frequency radiation (RFR) emitted either from mobiles or base stations and its relations with human's hormone profiles. The study revealed significant RFR effects on pituitary–adrenal axis, resulting in reduction of ACTH, cortisol, thyroid hormones, prolactin in young females, and testosterone levels in males (Eskander et al, 2012). But no direct measurements of RFR power density levels were made, only categories of distance from transmitter.

Oberfeld et al (2004) reported that populations exposed to base stations transmitting cell phone frequencies had more fatigue, depressive tendency, sleeping disorders, concentration difficulties, and cardio-vascular problems reported with exposure to GSM 900/1800 MHz cell phone signal.

Navarro et al (2003) reported that exposure levels of 0.01 - 0.11 μW/cm2 resulted in fatigue, headaches, sleeping problems in populations around mobile phone base stations.

Thomas et al (2008) reported an increase in adult complaints of headaches and concentration difficulties with short-term cell phone use at 0.005 to 0.04 μW/cm2 exposure levels.

Heinrich et al (2010) reported that children and adolescents (8-17 years old) with short-term exposure to base-station level RFR experienced headache, irritation, and concentration difficulties in school. RFR levels were 0.003 - 0.02 μW/cm2.

Thomas et al (2010) reported that RFR levels of 0.003 - 0.02 μW/cm2 resulted in conduct and behavioral problems in children and adolescents (8-17 years old) exposed to short-term cell phone radiation in school.

Mohler et al (2010) reported that adults exposed to 0.005 μW/cm2 cell phone radiation (base-station exposure levels) had sleep disturbances with chronic exposure, but this effect was not significantly increased across the entire population.

Human Studies at Base Station Exposure Levels (Cell Towers)

At least five new cell tower studies with base-station level RFR at levels ranging from 0.003 μW/cm2 to 0.05 uW/cm2 published since 2007 report headaches, concentration difficulties and behavioral problems in children and adolescents; and sleep disturbances, headaches and concentration problems in adults. This is highly consistent with studies done prior to 2007, but the 'effect levels' are significantly lower (dropping from the microwatt to the nanowatt range per square centimeter).

Public safety standards are 1,000 – 10,000 or more times higher than levels now commonly reported in mobile phone base station studies to cause bioeffects.

Sperm studies are showing DNA damage, impaired sperm quality, motility and viability from cell phones on standby mode and wireless laptop use at exposures of 0.00034 μW/cm2 to 0.07 μW/cm2. Several studies report sperm damage effects at 'standby model' cell phone emission levels, which are in the low nanowatt to picowatt per square centimeter range.

F. Electrohypersensitivity (EHS) Studies: McCarty et al (2011) studied electrohypersensitivity in a patient (a female physician). The patient was unable to detect the presence or absence of EMF exposure, largely ruling out the possibility of bias. In multiple trials with the fields either on or not on, the subject experienced and reported temporal pain, feeling of usease, skipped heartbeats, muscle twitches and/or strong headache when the pulsed field (100 ms, duration at 10 Hz) was on, but no or mild symptoms when it was off. Symptoms from continuous fields were less severe than with pulsed fields. The differences between field on and sham exposure were significant at the $p < 0.05$ level. The authors conclude that electromagnetic hypersensitivity is a neurological syndrome, and statistically reliable somatic reactions could be provoked in this patient by exposure to 60-Hz electric fields at 300 volts per meter (V/m). They

conclude *"EMF hypersensitivity can occur as a bona fide environmentally inducible neurological syndrome*." In their response to a letter to the editor of the journal, the authors say: *"(W)e followed an empirical approach and demonstrated a cause-and-effect relationship ($p < 0.05$) under conditions that permitted us to infer the existence of electromagnetic hypersensitivity (EHS), a novel neurological syndrome*." (Marino et al., 2012)

Further, the authors explain the significance of detecting EHS effects by non-linear methods.

> *"The important issue at this point is not whether EMF can produce symptoms (we empirically demonstrated that it can) but rather why this effect historically has been difficult to detect. It occurred to us that EHS has remained elusive because of the way it was studied. The experiments designed to detect EHS had been based on the assumption that if it existed, it was a linear phenomenon, whereas EHS is actually a nonlinear phenomenon." "Our study was designed to detect whether EHS was a linear or nonlinear phenomenon, and we were successful in showing a link between acute EMF exposure and somatic responses ($p < 0.05$). This finding – taken together with the unfailingly negative results of the linear studies – is good evidence that EHS is a nonlinear phenomenon, as we suspected."*

With the exception of the McCarty study there have not been clear demonstrations in controlled circumstances showing that persons reporting to be electrophypersensitive can distinguish whether or not RFR is being applied. There are, however, multiple reports of symptoms experienced by individuals exposed to EMFs in uncontrolled circumstances.

A. Johansson et al (2010) studied symptoms, personality traits and stress in people with mobile phone-related symptoms and electromagnetic hypersensitivity. They reported there is support for a difference between people with symptoms related to specific EMF sources and people with general EHS. The symptoms are anxiety, depression, somatization, exhaustion and stress. The EHS group reported more neurasthenic symptoms.

Two publications on electrohypersensitivity by O. Johansson (2007, 2009) provide an extensive overview of the relevant literature on electrohypersensitivity. Both

publications document symptoms and conditions giving rise to increased sensitivity to ELF-EMF and RFR. The need for new, biologically-based public exposure standards is recommended in both publications, in order to address electrohypersensitivity.

Landgrebe et al (2007) reported that their study of electrosensitive patients showed participants had a reduced intracortical facilitation as compared to two control groups. The EHS group of patients showed altered central nervous system function. In a follow-up study, the authors reported that EHS patients but not controls "*demonstrated significant cognitive and neurobiological alterations pointing to a higher genuine individual vulnerability of electromagnetic hypersensitive patients." (Landgrebe et al, 2008).*

The team of Sandstrom, Hansson Mild and Lyskov produced numerous papers between 1994 and 2003 involving people who are electrosensitive (Lyskov et al, 1995; Lyskov et al, 1998; Sandstrom et al, 1994; Sandstrom et al, 1995; Sandstrom et al, 1997; Sandstrom et al, 2003). Sandstrom et al (2003) presented evidence that heart rate variability is impaired in people with electrical hypersensitivity and showed a dysbalance of the autonomic nervous system. *"EHS patients had a disturbed pattern of circadian rhythms of HRF and showed a relatively 'flat' representation of hourly-recorded spectral power of the HF component of HRV"*. This research team also found that *"EHS patients have a dysbalance of the autonomic nervous system (ANS) regulation with a trend to hyper-sympathotonia, as measured by heart rate (HR) and electrodermal activity, and a hyperreactivity to different external physical factors, as measured by brain evoked potentials and sympathetic skin responses to visual and audio stimulation*." (Lyskov et al, 2001 a,b; Sandstrom et al, 1997). The reports referenced above provide evidence that persons who report being electrosensitive differ from others in having some abnormalities in the autonomic nervous system, reflected in measures such as heart rate variability. At present it remains unclear whether EHS is actually caused by RF/EMF exposure, or rather is a self-identifying syndrome of excessive responsiveness to a variety of stimuli. But given the relatively high percentage of persons reported to be electrosensitive (5% of the general population of Switzerland according to Schreier et al,

2006), with some being severely disabled as a consequence, it is critical that there be more study of this syndrome.

Tuengler and von Klitzing et al (2012) reported EHS people that were tested showed significant changes in regulation of the autonomic nervous system, including changes in capillary blood flow (microcirculation), heart rate variability, and electric skin potentials. The continuous detection of capillary blood flow is an important tool in analyzing the capacity of the autonomic nervous system. In EHS patients, von Klitzing finds that intestinal motility may also be disregulated and show no activity at all for some time after exposure.

G. Effects on the Blood-brain Barrier (BBB): The Lund University (Sweden) team of Leif Salford, Bertil Persson and Henrietta Nittby has done pioneering work on effects of very low level RFR on the human brain's protective lining – the barrier that protects the brain from large molecules and toxins that are in the blood.

THE BLOOD-BRAIN BARRIER IS AT RISK

The BBB is a protective barrier that prevents the flow of toxins into sensitive brain tissue. Increased permeability of the BBB caused by cell phone RFR may result in neuronal damage. Many research studies show that very low intensity exposures to RFR can affect the blood-brain barrier (BBB) (mostly animal studies). Summing up the research, it is more probable than unlikely that non-thermal EMF from cell phones and base stations do have effects upon biology. A single 2-hr exposure to cell phone radiation can result in increased leakage of the BBB, and 50 days after exposure, neuronal damage can be seen, and at the later time point also albumin leakage is demonstrated. *The levels of RFR needed to affect the BBB have been shown to be as low as 0.001 W/kg, or less than holding a mobile phone at arm's length. The US FCC standard is 1.6 W/kg; the ICNIRP standard is 2 W/kg of energy (SAR) into brain tissue from cell/cordless phone use. Thus, BBB effects occur at about 1000 times lower RFR exposure levels than the US and ICNIRP limits allow.* *(Salford, 2012)*

The consequence to modern life is that cell and cordless phone use may cause a pathological leakage of the BBB with very short use periods, and the damage may be long-lasting. Harmful substances may enter the brain. If the damage is ongoing (if cell and cordless phone use continues to occur over months and years), the potential for

harmful effects increases. There is already 'epidemiologically visible' evidence of increased brain cancer risk in humans (Section 11).

Volkow et al (2011a, b) reported increased glucose metabolism in the brain with cell phone use in humans. This important investigation of 47 human subjects used a randomized crossover design and labeled fluorodeoxyglucose to measure the metabolisms of the brain when the cell phone was activated but muted for 50 minutes as compared to not being activated. "*Our study showed that cell phone activation was associated with metabolic increases in brain regions closest to the antenna and that the increases showed a negative linear correlation with distance from the antenna. While the effect was small, the negative correlation of the effect with distance was statistically significant (R = −0.91; P <.001).* This study is particularly important in that it demonstrates definitively that an active cell phone, placed on the ear as one would normally be used, alters brain metabolic activity, but only in the region close to the cell phone.

H. Brain Cancer Studies: The Orebro University (Sweden) team led by Lennart Hardell, MD, an oncologist and medical researcher, has produced an extraordinary body of work on environmental toxins of several kinds, including the effects of radiofrequency/microwave radiation and cancer. Their 2012 work concludes:

> *"Based on epidemiological studies there is a consistent pattern of increased risk for glioma and acoustic neuroma associated with use of mobile phones and cordless phones. The evidence comes mainly from two study centres, the Hardell group in Sweden and the Interphone Study Group. No consistent pattern of an increased risk is seen for meningioma. A systematic bias in the studies that explains the results would also have been the case for meningioma. The different risk pattern for tumor type strengthens the findings regarding glioma and acoustic neuroma. Meta-analyses of the Hardell group and Interphone studies show an increased risk for glioma and acoustic neuroma. Supportive evidence comes also from anatomical localisation of the tumor to the most exposed area of the brain, cumulative exposure in hours and latency time that all add to the biological relevance of an increased risk. In addition risk calculations based on estimated absorbed dose give strength to the findings.*

In summary:

- *There is reasonable basis to conclude that RF-EMFs are bioactive and have a potential to cause health impacts.*

- *There is a consistent pattern of increased risk for glioma and acoustic neuroma associated with use of wireless phones (mobile phones and cordless phones) mainly based on results from case-control studies from the Hardell group and Interphone Final Study results.*
- *Epidemiological evidence gives that RF-EMF should be classified as a human carcinogen.*
- *Based on our own research and review of other evidence the existing FCC/IEE and ICNIRP public safety limits and reference levels are not adequate to protect public health.*
- *New public health standards and limits are needed.* (Hardell et al, 2012)

I**. Genetic Damage (Genotoxicity Studies):** There are at least several hundred published papers that report EMF affects cellular oxidative processes (oxidative damage). Increased free radical activity and changes in enzymes involved in cellular oxidative processes are the most consistent effects observed in cells and animals after EMF exposure. Aging may make an individual more susceptible to the detrimental effects of ELF EMF from oxidative damage, since anti-oxidants may decline with age. Clearly, the preponderance of genetic studies report DNA damage and failure to repair DNA damage.

Eighty six (86) new papers on genotoxic effects of RFR published between 2007 and mid-2012 are profiled. Of these, 54 (63%) showed effects and 32 (37%) showed no effects (Lai, 2012)

Forty three (43) new ELF-EMF papers and two static magnetic field papers that report on genotoxic effects of ELF-EMF published between 2007 and mid-2012 are profiled. Of these, 35 (81%) show effects and 8 (19%) show no effect (Lai, 2012).

J. Nervous System Damage: Factors that act directly or indirectly on the nervous system can cause morphological, chemical, or electrical changes in the nervous system that can lead to neurological effects. Both RF and ELF EMF affect neurological functions and behavior in animals and humans.

One hundred fifty five (155) new papers that report on neurological effects of RFR published between 2007 and mid-2012 are profiled. Of these, 98 (63%) showed effects and 57 (37%) showed no effects.

Sixty nine (69) new ELF-EMF papers (including two static field papers) that report on genotoxic effects of ELF-EMF published between 2007 and mid-2012 are profiled. Of these, 64 (93%) show effects and 5 (7%) show no effect. (Lai, 2012)

L. Children are More Vulnerable: Many studies demonstrate that children are more sensitive to environmental toxins of various kinds (Barouki et al, 2012; Preston, 2004; WHO, 2002; Gee, 2009; Sly and Carpenter, 2012).

> The Presidential Cancer Panel (2010) found that children '*are at special risk due to their smaller body mass and rapid physical development, both of which magnify their vulnerability to known carcinogens, including radiation.*'

> The American Academy of Pediatrics, in a letter to Congressman Dennis Kucinich dated 12 December 2012 states "*Children are disproportionately affected by environmental exposures, including cell phone radiation. The differences in bone density and the amount of fluid in a child's brain compared to an adult's brain could allow children to absorb greater quantities of RF energy deeper into their brains than adults. It is essential that any new standards for cell phones or other wireless devices be based on protecting the youngest and most vulnerable populations to ensure thay are safeguarded through their lifetimes."*

II. ISSUES AND ANSWERS IN THE EMF DEBATE

Much of the emphasis in the 2007 Bioinititative Report focused on cancer, which is still the best documented disease of concern from exposure to EMF/RF. The evidence that exposure to EMF/RF increases the risk of cancer has only gotten significantly stronger since then, and we have a better, albeit still incomplete, understanding of the mechanisms involved. However, in terms of threshold exposures that result in human disease, new research on male reproduction and neurobehavioral alterations provide evidence for harm at even lower exposure levels. RFR has been shown in this Report to act as an external synchronizer of neural activity, capable of disrupting sleep, circadian rhythms, diurnal hormone fluctuations, brain wave activity and heart rate variability by exposure to artificial electromagnetic signals (as opposed to natural evolutionary frequencies) and to do so at exceedingly low intensities.

Much of the debate over the body of EMF science ignores simple questions that would help to discriminate among studies with apparently conflicting results. Section 15 by Dr. Belyaev is helpful in identifying key factors which must be known and controlled for in experiments (biological variables and physical parameters include bandwidth, frequency, modulation, polarization, intermittence and coherence time of exposure, static

magnetic field, electromagnetic stray fields, sex, age, individual traits, and cell density during exposure). Dr. Andrew Marino emphasizes that detection of EMF/RFR effects require investigation of non-linear phenomena, a critical difference that if ignored, may miss important biological effects (Marino, 2012).

A unifying hypothesis for a plausible biological mechanism to account for very weak field EMF bioeffects other than cancer may lie with weak field interactions of pulsed RFR and ELF-modulated RFR as disrupters of synchronized neural activity. Electrical rhythms in our brains can be influenced by external signals. This is consistent with established weak field effects on coupled biological oscillators in living tissues. Biological systems of the heart, brain and gut are dependent on the cooperative actions of cells that function according to principles of non-linear, coupled biological oscillations for their synchrony, and are dependent on exquisitely timed cues from the environment at vanishingly small levels (Buzsaki, 2006; Strogatz, 2003). The key to synchronization is the joint actions of cells that co-operate electrically - linking populations of biological oscillators that couple together in large arrays and synchronize spontaneously according to the mathematics described for Josephson junctions (Brian Josephson, the 1993 Nobel prize winner for this concept). This concept has been professionally presented in journal articles and also popularized in print by Prof. Steven Strogatz, a mathematician at Cornell University who has written about 'sync' as a fundamental organizing principle for biological systems (Strogatz, 2001; 2003).

> *"Organisms are biochemically dynamic. They are continuously subjected to time-varying conditions in the form of both extrinsic driving from the environment and intrinsic rhythms generated by specialized cellular clocks within the organism itself. Relevant examples of the latter are the cardiac pacemaker located at the sinoatrial node in mammalian hearts and the circadian clock residing at the suprachiasmatic nuclei in mammalian brains. These rhythm generators are composed of thousands of clock cells that are intrinsically diverse but nevertheless manage to function in a coherent oscillatory state. This is the case, for instance, of the circadian oscillations exhibited by the suprachiasmatic nuclei, the period of which is known to be determined by the mean period of the individual neurons making up the circadian clock. The mechanisms by which this collective behavior arises remain to be understood."(Strogatz, 2003)*

Synchronous biological oscillations in cells (pacemaker cells) can be disrupted by artificial, exogenous environmental signals, resulting in desynchronization of neural

activity that regulates critical functions (including metabolism) in the brain, gut and heart and circadian rhythms governing sleep and hormone cycles (Strogatz, 1987). The brain contains a population of oscillators with distributed natural frequencies, which pull one another into synchrony (the circadian pacemaker cells). Strogatz has addressed the unifying mathematics of biological cycles and external factors disrupt these cycles. Buzsaki (2006) says "*rhythms can be altered by a wide variety of agents and that these perturbations must seriously alter brain performance. Rhythms are a robust phenomenon.*"

The heart's natural pacemaker center is the sinoatrial node, a cluster of about 10,000 cells that generate electrical rhythm that commands the rest of the heart to beat. Diseases related to disruption of that synchronization include epilepsy, chronic insomnia, and cardiac arrhythmias (Strogatz, 2003). Some EMF diseases are those where desynchronization of neural activity results in physiological changes that, if chronic, result in chronically disrupted homeostasis, and eventually ill-health and chronic diseases. Such a future burdens health care systems in an irreversible way.

The late Dr. Ross Adey in his last publication in Bioelectromagnetic Medicine (P. Roche and M. Markov, eds. 2004) concluded:

> "*There are major unanswered questions about possible health risks that may arise from exposures to various man-made electromagnetic fields where these human exposures are intermittent, recurrent, and may extend over a significant portion of the lifetime of the individual."*
>
> *"Epidemiological studies have evaluated ELF and radiofrequency fields as possible risk factors for human health, with historical evidence relating rising risks of such factors as progressive rural electrification, and more recently, to methods of electrical power distribution and utilization in commercial buildings. Appropriate models describing these bioeffects are based in nonequilibrium thermodynamics, with nonlinear electrodynamics as an integral feature. Heating models, based in equilibrium thermodynamics, fail to explain an impressive new frontier of much greater significance. Though incompletely understood, tissue free radical interactions with magnetic fields may extend to zero field levels."*

Our society appears determined to make everything wireless, and the consequence is to increase cumulative exposure to RFR. Many homes and almost every Starbucks or McDonalds has WiFi. Smart phones, tablets, video iPods and other wireless devices are even given to children as playthings. The result is a significant increase in cumulative RFR exposure of the whole population, but particularly of those who have and use wireless devices for prolonged periods of time. No national or international standard of RFR exposure considers cumulative effects, all being developed to avoid local tissue heating from acute exposures.

The issues around exposure of children to RFR is of critical importance. There is overwhelming evidence that children are more vulnerable than adults to many different exposures (Sly and Carpenter, 2012), including RFR, and that the diseases of greatest concern are cancer and effects on neurodevelopment. Yet parents place RFR baby monitors in cribs, provide very young children with wireless toys, and give cell phones to young children, usually without any knowledge of the potential dangers. A growing concern is the movement to make all student computer laboratories in schools wireless. A wired computer laboratory will not increase RFR exposure, and will provide safe access to the internet.

An urgent example for the need to address the lack of adequate public protection from inadequate safety standards for pulsed RFR exposures is the rapid, global rollout of wireless utility meters (‘smart’ meters for electricity, gas and water meters). Current safety standard calculations that rely on time-averaging of RFR almost entirely dilute out the power density of RFR levels that are delivered in millisecond bursts, but occur at intervals of every second, or multiple times per second when in use within a wireless mesh network. Said differently, the RFR power density levels are usually legal. While there have been no long term studies of adverse effects of smart meters on human health (primarily because they are so new), there are increasing reports from electrosensitive individuals of harm. Added together, these RFR pulses that now appear to be a highly bioactive agent but are essentially erased or made energetically invisible by time-averaging the pulses as current FCC safety rules mandate.

The wireless meters transmit RF signals like a mini-cell tower antennas in the cell phone radiation frequencies. Currently, they are being deployed in the US and are on the drawing boards around the world including many European countries. The 'smart meter' infrastructure represents the largest single commercial saturation of living space with pulsed RFR yet rolled out by industry. This program places a wireless device (like a mini-mobile phone base station) on the wall, replacing the electromechanical (spinning dial) meter. They will be installed on every home and classroom (every building with an electric meter). Utilities from California to Maine have installed tens of millions already, despite health concerns of experts who already are seeing thousands of health complaints. The wireless meters produce spikes of pulsed radiofrequency radiation on a continuous basis (24/7), and in typical operation, will saturate living space at levels that can be much higher than already reported to cause bioeffects and adverse health effects for some people. These meters, depending on where they are placed relative to occupied space in the home or classroom, can produce RFR exposure levels similar to that within the first 100 feet to 600 feet of a mobile phone base station (cell tower). In the not-so-distant future the plan is to have a wireless device implanted in every household appliance, which will communicate with the smart meter whenever electricity is being used. This will likely make the kitchen a major source of exposure to RFR.

The cumulative RFR burden within any community is largely unknown. Both involuntary sources (like cell towers, smart meters and second-hand radiation from the use of wireless devices by others) plus voluntary exposures from ones' personal use of cell and cordless phones, wireless routers, electronic baby surveillance monitors, wireless security systems, wireless hearing aids, and wireless medical devices like implanted insulin pumps all add up. No one is tallying up the combined exposure levels. Billions of new RFR transmitters from a global smart meter rollout will significantly add to the existing RFR body-burden of pulsed RFR for millions of people. The health concerns are the same as with all other sources of EMF/RFR. Cancer is a serious adverse effect, but damage to male reproduction and central nervous system effects may results from even lower levels of exposure. The work by Strogatz (2001, 2003) and Buzsaki (2006) on weak-field effects on non-linear biological oscillators (brain waves and synchronization of neural activities that regulate body processes) is directly relevant to an understanding

of the profound biological disruptions and health symptoms that continued exposures of pulsed RFR may produce.

The Commons of the Air

Turning to questions of social equity and the individuals' choice not to be exposed to harmful levels of environmental toxins, there has been little inclusion of the public in discussions of wireless radiofrequency exposure. Wireless technologies have become infused in daily habits of billions of people; often choices for wired equivalents are lacking (or those that exist are disappearing). Involuntary exposure to EMF and RFR is becoming more the norm, even where it runs counter to individual choice (second-hand radiation, like second-hand smoke is difficult to avoid).

> *"Wireless technologies drive electromagnetic energy through our air, into and through virtually all indoor and outdoor living environments. The protective air cushion around our planet holds breathable air, buffers us from space radiation, and supports and sustains life in tandem with the natural electromagnetic signature of the earth itself. We are changing this 'commons of the air' in major ways. Wireless signals from broadcast and communications technologies are crowding out and overpowering the natural background. The 'commons of the air' is being altered in unprecedented ways that have enormous consequences for life on earth."(Sage, 2010).*

The rush to 'buy the airwaves' and to market them for commercial purposes is loading '*the commons of the air*' with unsustainable levels of exposure (Sage, 2010). Commercial markets for wireless spectrum successfully lobby government regulators to allocate even more spectrum, once the existing frequencies are allocated. Sage (2010) asks:

> *"Who owns the 'commons of the air'? Who should be allowed to pollute it? What are the limits? On what basis should carrying capacity be defined? Who defines the limits? Do these limits conserve the resource for the future? Do they protect public health and welfare, and the health and well-being of other living things on earth? Who bears the burden of proof of safety or of harm? How should the 'new commons' be managed for the greater good? Do we know enough to act responsibly? Who decides? When should limits be placed on utilization?"*

With no regard to cumulative harm, this commercial rush to buy up wireless spectrum territorial rights has vast implications for public health and well-being. Environmental protections afforded to other natural resources under the National Environmental Policy Act have been ignored. The cumulative impacts and irretrievable commitments on humans, wildlife, and natural resources have never been assessed.

> *"Societies must now define carrying capacity for chronic electromagnetic and wireless exposures. Taking into account the large individual variability to withstand it, new limits must conserve and sustain the 'commons of the air' so that is sustainable for all—and this includes sensitive populations, the young, the elderly, and those with existing sensitivity. Some countries of the world already have surpassed sustainable wireless exposure levels as demonstrated by significant percentages that have already become electrosensitive." (Sage, 2010)*

Homeostasis and Human Health Rights

Chronic exposure to low-intensity RFR and to ELF-modulated RFR at today's environmental levels in many cities will exceed thresholds for increased risk of many diseases and causes of death (Sage and Huttunen, 2012). RFR exposures in daily life alter homeostasis in human beings. These exposures can alter and damage genes, trigger epigenetic changes to gene expression and cause de novo mutations that prevent genetic recovery and healing mechanisms. These exposures may interfere with normal cardiac and brain function; alter circadian rhythms that regulate sleep, healing, and hormone balance ; impair short-term memory, concentration, learning and behavior; provoke aberrant immune, allergic and inflammatory responses in tissues; alter brain metabolism; increase risks for reproductive failure (damage sperm and increase miscarriage risk); and cause cells to produce stress proteins. Exposures now common in home and school environments are likely to be physiologically addictive and the effects are particularly serious in the young (Sage and Huttunen, 2012). This declaration of human health rights below (Sage and Huttunen, 2012) is based on specific reference to health impacts of EMF and RFR that are reasonably well established to occur (Sage and Carpenter, 2009).

Human Health Rights Declaration
Fundamental Human Health Rights (Sage and Huttunen, 2012)

The right to homeostasis in our own bodies.
The right to normal central nervous system function.
The right to natural environmental cues that synchronize our circadian rhythms.
The right to sleep.
The right to heal.
The right to hear.
The right to reproduce.
The right to learn and retain memories.
The right to an intact genome.

If even one of these rights is compromised – placed at risk from involuntary wireless exposures in daily life, it is a breach of human health rights. When many of these human health rights are compromised without the consent of the individual, then the deployment of wireless technologies should be halted and existing exposures reduced or eliminated, in accord with the scientific and public health findings on chronic exposure to low-intensity radiofrequency radiation, and other forms of potentially harmful electromagnetic fields (Sage and Huttunen, 2012)

V. CONCLUSIONS FOR PRUDENT PUBLIC HEALTH PLANNING

Methodology and Approach for Precautionary Action Limits

In 2007, the BioInititive Report chapter on Key Scientific Evidence and Public Health Policy Implications, proposed a specific, interim radiofrequency radiation target level of 0.1 μW/cm2 for cumulative, outdoor RFR exposure (for AM, FM, TV and wireless). It was based on best-available scientific studies to that date. There were few studies prior to 2006 that reported effects at less than 0.1 to 1 μW/cm2 chronic RFR exposures.

In 2009, the journal Pathophysiology produced many peer-reviewed articles in a special two-volume edition on EMF (both ELF-EMF and RFR) essentially publishing the contents of the BioInitiative Report and updating some information. One of these 2009 Pathophysiology papers presented a review of mobile phone base station studies (Kundi and Hutter, 2009). It concluded that the overall studies did not detect effects (headache,

fatigue, tinnitus, concentration difficulties, sleep disruption, etc) at levels of RFR exposure below 0.05 to 0.1 μW/cm2.

New base station-level RFR studies are available in 2012 that can be analyzed to determine if new (and lower) RFR recommendations are warranted. The approach in this chapter relies on "lowest levels at which effects are not seen" akin to the “no observed effect level (NOEL)” used for chemical exposures, as a sufficient basis to establish scientific benchmarks for harm (or alternately, the lowest observed effects level of exposure). It is the province of the science and public health evaluation we do here to report the evidence regardless of what political or strategic complications it may create. An objective presentation of what the studies reveal for ‘effects levels’ is our goal; not to pre-judge or dilute the evidence because it may present strategic or political hurdles to achieve consensus on policy and regulatory changes. What this report does not intend to do is take into account“how could we do this” or “what would it mean”. The purpose is to lay out the science, and make some defensible reductions for factors that studies cannot or do not yet test for, and compensate with deductions for them (safety margins). As interim targets for precautionary action, they will serve as guides for decision-makers who will take up the issues of health, the quality of the future gene pool, social equity and cost.

There is no one study alone that meets impeccable standards for exposure assessment or totally eliminates all possibility for bias, but the constellation of studies together gives adequate support to delineate a ‘lowest observed effects level’, that in turn, with added safety margins, can serve as a guideline for precautionary action.

A reduction from the BioInitiative 2007 recommendation of 0.1 uW/cm2 (or one-tenth of a microwatt per square centimeter which is the same as 100 nanowatts/cm2) for cumulative outdoor RFR down to something three orders of magnitude lower (in the low nanowatt per square centimeter range) is justified on a public health basis. We use the new scientific evidence documented in this Report to identify ‘effect levels’ and then apply one or more reduction factors to provide a safety margin. We do note however, even a precautionary action level of several tenths of a nanowatt per square centimeter (or

several hundred picowatts per square centimeter) would still allow for cell phone transmissions (that can operate down to about 0.00003 V/m).

Even so, these levels may need to go lower in the future, as new and better studies are completed. This is what the authors said in 2007 (Carpenter and Sage, 2007, BioInitiative Report) and it remains true today in 2012. We leave room for future studies that may lower today's observed 'effects levels' and should be prepared to accept new information as a guide for new precautionary actions.

Establishing A Scientific Benchmark for 'Lowest Observed Effect Levels'

Studies that provide information at 'new levels of observed effect' have been identified. These serve as scientific benchmarks for possible risk to health and well-being. Next, we indentify reduction factors to compensate for sensitive subpopulations and apply them to the scientific benchmarks (lowest observed effect levels).

A ten-fold reduction factor is warranted (or higher) for studies that report effects from only short-term (i.e., acute) rather than chronic (i.e., long-term) exposures. Longer duration of exposure can cause bioeffects at lower exposures where these effects are NOT seen with shorter (acute) exposures (Belyaev, 1997; Belyaev, 2012). Chronic exposures with longer durations of weeks, months or years is what most populations face with respect to wireless classrooms, wireless offices and locations near base stations.

A second ten-fold reduction (or higher) is justified as a buffer for sensitive populations including children, the elderly and other adult groups that may be ill, already sensitized, in remission or suffer from ailments made worse by physiological stress and insomnia.

Studies which contribute together can reasonably contribute to delineating a new RFR lower effects level are primarily mobile phone (cell phone) base station studies of healthy human populations and studies of sperm damage in men who use and/or wear their wireless devices on or around the belt or pants pocket.

Power Density Studies (Mobile Phone Base Stations and Sperm/Fertility Studies)

A scientific benchmark of 0.003 uW/cm2 or three nanowatts per centimeter squared for 'lowest observed effect level' for RFR is based on mobile phone base station-level studies. The Thomas et al, (2008) study shows effects at a LOEL of 0.005 uW/cm2 on adults exposed to short-term cell phone radiation only (it is not a chronic exposure study). Other studies that are relevant are Thomas et al (2010) with a LOEL of 0.003 uW/cm2 and Heinrich et al (2010) with a LOEL of 0.003 uW/cm2. Both studied mixed child/adolescent populations of students, but have short-term test periods (are not chronic exposure studies) and have LOELs of 0.003 uW/cm2. Buchner et al (2012) shows a 0.006 uW/cm2 'effect level' and tests adult populations, but achieves 'chronic' exposure testing criterion (over 18 months). Applying a ten-fold reduction to compensate for the lack of long-term exposure (to provide a safety buffer for chronic exposure) or for children as a sensitive subpopulation yields a 300 to 600 picowatts per square centimeter precautionary action level. This is also equal to a 0.3 nanowatts to 0.6 nanowatts per square centimeter as a reasonable, precautionary action level.

Of the studies that deal with children and base-station level RFR exposures, none studied children exclusively, so the results may dilute out any apparent effects accruing to the younger test subjects. Thomas et al (2010) is a short-term exposure study of children and adolescents 8 to 17 years in age. Heinrich et al (2010) is a further study of the same population of 8 to 17 year olds over the short-term. A 100-fold reduction could be defended as reasonably conservative in this instance.

Behari et al (2006) provides the one sperm study expressed in power density units with a LOEL of 0.00034 uW/cm2. It is a chronic exposure study. The majority of sperm studies with good exposure information are expressed in SARs (W/kg). These range from LOELs of 0.014 (Kumar et al, 2012) to 0.091 W/kg (Atasoy et al, 2012) to 0.43 W/kg (Salama et al, 2008) to 0.795 W/kg (Panagopoulous et al, 2012) to 0.9 W/kg (Kesari et al, 2012). All the other sperm damage or ovarian damage studies have SARs

of greater than 1.0 W/kg (7 more studies). All are short-term studies. There are more sperm damage studies but without any measurements or other specific exposure information. These are studies that place sperm, or mice, or give prenatal exposures to animals close to sources of cell phone radiation. Such studies give weight to the argument that low-intensity RFR exposures can cause damage, but do not help in delineating LOELs because they have no specific exposure numbers, just distances.

Most of the sperm studies and base station studies which have exposures expressed power density (microwatts per square centimeter) have 'effect' levels in the nanowatt range (0.34 nanowatt/cm2 to 100 nanowatt/cm2)*. They include Behari and Kesari, 2006; Buchner and Eger, 2012; Oberfeld et al, 2004; Thomas et al, 2008, 2010; Heinrich et al, 2010; Navarro et al, 2003; and Otitoloju et al 2010. Avendano et al (2012) report that WI-FI exposure from a 4-hr laptop exposure decreased sperm viability and caused DNA fragmentation in human sperm samples (exposure in petri dishes) at 0.5 to 1.0 uW/cm2. The Kundi-Hutter 2009 Pathophysiology Journal review paper of base station studies through 2006 reports an overall NOEL below 0.05 to 0.1 uW/cm2. Overall, the new 2007-2012 power density studies are reporting 'lowest effects levels' two or three orders of magnitude lower than in 2006, down from the microwatt/cm2 range to the nanowatt/cm2 range.

SAR Studies (Sperm Studies and Ovarian Damage with Cell Phone Radiation Exposures)

Studies on male fertility (adverse effects on sperm, on the testes size and morphology, etc) coming from cell phone-in-the-pocket-on-stand-by-mode and wireless laptop studies provide us with a flood of new data showing very low-intensity effects to guide precautionary actions and to educate the public about potential risks to health, fertility and reproduction.

*The RF Color Charts in this Report are a guide to reported biological effects and those RFR levels reported to cause them.

Sperm and fertility studies with 'effects levels' in the 9 microwatt/kg to 80 milliwatt/kg range are Kumar et al (2012) (male infertility) and Aitken et al (2005) (sperm DNA damage). Sperm studies with 'effect levels' in the 90 to 900 milliwatt/kg range are De Iuliis et al (2009) (human sperm cell damage), Salama et al (2008) (decrease in sperm mobility and concentration), Panagopoulous et al (2012) (ovarian damage) and Kesari et al (2012) (sperm damage). Studies from 1 W/kg to 1.8 W/kg that report sperm or reproductive damage are Gul et al (2009) (toxic effect on ovaries), Agarwal et al (2008) (sperm damage), Agarwal et al (2009) (sperm damage) and Yan et al (2007) (deformed sperm cells, disabled for swimming).

The WI-FI laptop study by Atasoy et al (2012) reports that exposures to laptops estimated at 0.091 W/kg increase DNA damage and reduce DNA repair in damaged sperm, and "*raise questions about safety of radiofrequency exposure from WI-FI internet access dvices for growing organisms of reproductive age, with a potential effect on fertility and integrity of germ lines*."

Altered fetal development in mice exposed to RFR at SARs of 0.3 to 60 milliwatt/kg is reported to result in consequent adverse effects on learning and behavior (Aldad et al, 2012). Fragopoulou et al (2009) reported changes at 600 to 900 milliwatts/kg in mouse embryos.

General Approach to Delineating a Precautionary Action Level

As a methodology, is not necessary or wise to use an averaging approach among studies. The technique itself is too vulnerable to weighting problems by the older studies that did not test for effects at the lowest range of exposures to RFR (or did not have the power to assess effects). Averaging also is insensitive in giving proper visibility to important NEW results at the very low-intensity (nanowatt, picowatt and femtowatt/cm2 range). Even when they are averaged together, these studies contribute vanishingly small influence when averaged together with studies of much higher power density to determine a scientific benchmark for harm.

One limitation of the sperm studies using base station-level RFR exposures is that good estimates of exposure are available if sperm are tested outside the body (in petri dishes), but that does not reflect the more realistic situation of sperm exposed in humans themselves (using or carrying a mobile phone near the testes) where exposure estimates are more difficult to determine. So, it is useful and informative to observe the combined results of both in-vivo and ex-vivo studies as a guide. For base station studies on human populations, the quality of exposure assessments is variable, and in some cases inadequate. Further, very few base station studies are conducted so that test subjects do not know if/when they are subjected to elevated RFR (blinded studies), so that some bias may influence results. People often report more ill effects because they are aware of the exposure (from a nearby base station, for example). These variations in quality across the studies, however, do not offset their usefulness in the aggregate for delineating what the lowest observable effect exposures are, and helping to guide decision-making for public health and precautionary actions.

A further concern is that time-averaging of RFR to give a single numeric recommendation for a precautionary action guideline does not address the critical difference between peak power levels (RFR spikes that occur intermittently) and measurements that hide how high peak power spikes are by dilution. Biological responses can last over seconds of time, or have even longer effects on proteins and enzymes, while the RFR pulses may be in microseconds or milliseconds in duration. It is entirely possible that what causes bioeffects is the high, intermittent RFR spikes that the body perceives and responds to as one continuous, high-power assault. For example, the DECT phone peak power is about 100 times larger than what RFR is measured with time-averaging. A person near a cell tower that produces an RFR measurement of 0.1 microwatts/cm2 is probably getting RFR power density spikes of eight times higher, if one could measure the spikes individually. None of the studies profiled in this section deal with peak power pulses and biological response times that are longer than the 'intermission' between RFR spikes. Thus, precautionary action levels should err on the side of being conservative.

The planning of base stations, and other site evaluations needs to have a scientific benchmark below which effects have not (not yet) been characterized, published or vetted. Then, a reasonable safety buffer should be added - remembering that the design life of such facilities may be 30-50 years long. This is standard procedure for environmental planning constraints.

Health Agencies Should Act Now

Health agencies and regulatory agencies that set public safety standards for ELF-EMF and RFR should act now to adopt new, biologically-relevant safety limits that key to the lowest scientific benchmarks for harm coming from the recent studies, plus a lower safety margin. Existing public safety limits are too high by several orders of magnitude, if prevention of bioeffects and resulting adverse health effects are to be minimized or eliminated. Most safety standards are a thousand times or more too high for healthy populations, and even less effective in protecting sensitive subpopulations.

New, biologically-based public exposure standards are critically needed now and should key to scientific benchmarks for harm, plus a safety margin below that level.

Standard of Evidence for Judging the Science

The standard of evidence for judging the scientific evidence should be based on good public health principles rather than demanding scientific certainty before actions are taken.

Sensitive Populations Require Special Protections

Safety standards for sensitive populations will need to be set at lower levels than for healthy adult populations to protect the developing fetus, the infant and young child, school-age children, the elderly, those with pre-existing chronic diseases, and those with

developed electrical sensitivity (EHS). Men of child-bearing age should not wear wireless devices on their body in order to protect the integrity of sperm DNA. Sperm should be considered a 'sensitive population'. Scientific benchmarks for lowest effect levels should be identified, and applied with additional safety margin reductions to safeguard populations against excessively high exposure to chronic ELF-EMF and RFR.

Protect Children Against Chronic Exposure to Wireless Devices

Strong precautionary action and clear public health warnings are universally warranted for use of cordless and cell phones to help prevent a global epidemic of brain tumors. This is especially important for children, adolescents and young adults, while new safety standards are established and implemented. Children should not use wireless devices except in the case of emergencies, or be exposed on an involuntary and chronic basis to wireless in their living, sleeping or learning environments.

Common Sense Precautionary Measurees are Warranted Now

Common sense measures to limit both ELF-EMF and RFR in the fetus and newborn infant are needed, especially with respect to avoidable exposures like baby monitors in the crib and baby isolettes (incubators) in hospitals that can be modified; and where education of the pregnant mother with respect to laptop computers, mobile phones and other sources of ELF-EMF and RFR are easily instituted.

Wireless laptops and other wireless devices should be strongly discouraged in schools for children of all ages, and wireless systems already installed should be replaced with wired (cable) alternatives. While without question it is important for children to have access to the internet, wired computer laboratories will have no elevated exposure to RFR. What might be lost in flexibility of moving rooms arounds will be more than gained by reducing exposure to RFR if wired connections, rather than wireless, are used. Pregnant women should be strongly cautioned not to use wireless devices during pregnancy. If a school already has wireless facilities, classrooms without wireless should

be made available to students, teachers and staff during the transition if sensitivities to EMF are reported by the individual. Special education classroom teaching environments should offer wired teaching environments (not wireless), nor should they be exposed to off-site wireless radiofrequency radiation from other sources that elevate interior levels for children.

Special Protections for the Integrity of the Genome and Reproduction

Reducing life-long health risks should begin in the earliest stages of embryonic and fetal development. Development pace is accelerated for the infant and very young child compared to adults, and is not complete in young people (as far as brain and nervous system maturation) until the early 20's. Windows of critical development mean that risk factors once laid down in the cells, or in epigenetic changes in the genome may have grave and life-long consequences for health or illness for every individual, and furthermore these genetic and epigenetic changes may be passed to the next generation. All relevant environmental conditions, including biologically active exposures to EMF and RFR that can degrade the human genome, and impair normal health and development of all species including humans - should be given weight in defining and implementing strong precautionary actions now to protect public health. The consequence of ignoring clear evidence of large-scale health risks to global populations, when the risk factors are largely avoidable or preventable is too high a risk to take.

SECTION 26

Glossary of Terms and Abbreviations

Prepared for the BioInitiative Working Group

July 2007

Absorption. In radio wave propagation, attenuation of a radio wave due to dissipation of its energy, i.e., conversion of its energy into another form, such as heat.

Athermal effect. Any effect of electromagnetic energy on a body that is not a heat-related effect.

Blood–brain barrier. A functional concept developed to explain why many substances that are transported by blood readily enter other tissues but do not enter the brain; the "barrier" functions as if it were a continuous membrane lining the vasculature of the brain. These brain capillary endothelial cells form a nearly continuous barrier to entry of substances into the brain from the vasculature.

Conductance. The reciprocal of resistance. Expressed in siemens (S).

Conductivity: A property of materials that determines the magnitude of the electric current density when an electric field is impressed on the material.

Continuous wave. A wave whose successive oscillations are identical under steady-state conditions.

Current density. A vector of which the integral over a given surface is equal to the current flowing through the surface; the mean density in a linear conductor is equal to the current divided by the cross-sectional area of the conductor. Expressed in ampere per square metre (A $m^{!2}$).

Depth of penetration. For a plane wave electromagnetic field (EMF), incident on the boundary of a good conductor, depth of penetration of the wave is the depth at which the field strength of the wave has been reduced to 1/e, or to approximately 37% of its original value.

Dielectric properties: In the context of this document the properties of materials conductivity and permeability.

Dosimetry. Measurement, or determination by calculation, of internal electric field strength or induced current density, of the specific energy absorption, or specific energy absorption rate distribution, in humans or animals exposed to electromagnetic fields.

Electric field strength. The force (**E**) on a stationary unit positive charge at a point in an electric field; measured in volt per metre (V $m^{!1}$).

Electrosensitivity (Electrohypersensitivity): A working definition of EHS from Bergqvist et al. (1997) is "a phenomenon where individuals experience adverse health effects while using or being in the vicinity of devices emanating electric, magnetic or electromagnetic fields (EMFs)".

Electromagnetic energy. The energy stored in an electromagnetic field. Expressed in joule (J).

Electric field strength (E): The magnitude of a field vector at a point that represents the force (F) on a charge (q). E is defined as E = F/q and is expressed in units of Volt per meter (V/m).

Electromagnetic field: Electromagnetic phenomena expressed in vector functions of space and time.

Electromagnetic radiation: The propagation of energy in the form of electromagnetic waves through space.

EMF. Electric, magnetic, and electromagnetic fields.

Exposure: Exposure occurs wherever a person is subjected to electric, magnetic or electromagnetic fields or contact currents other than those originating from physiological processes in the body.

Extra low frequency (ELF): Extra low frequency fields include, in this document, electromagnetic fields from 1 to 300 Hz. Alternately, **ELF-** Extremely low frequency where the European convention is extremely low frequncy, US is extra-low frequency.

Frequency modulation (FM): Frequency Modulation is a type of modulation representing information as variations in the frequency of a carrier wave. FM is often used at VHF frequencies (30 to 300 MHz) for broadcasting music and speech.

Far field. The region where the distance from a radiating antenna exceeds the wavelength of the radiated EMF; in the far-field, field components (**E** and **H**) and the direction of propagation are mutually perpendicular, and the shape of the field pattern is independent of the distance from the source at which it is taken.

Frequency. The number of sinusoidal cycles completed by electromagnetic waves in 1 second; usually expressed in hertz (Hz).

Impedance, wave. The ratio of the complex number (vector) representing the transverse electric field at a point to that representing the transverse magnetic field at that point. Expressed in ohm (S).

Magnetic flux density (B): The magnitude of a field vector at a point that results in a force (F) on a charge (q) moving with the velocity (v). The force F is defined by F = q*(v x B) and is expressed in units of Tesla (T).

Magnetic field strength (H): The magnitude of a field vector that is equal to the magnetic flux density (B) divided by the permeability (μ) of the medium. H is defined as H = B/μ and is expressed in units of Ampere per metre (A/m).

Magnetic permeability. The scalar or vector quantity which, when multiplied by the magnetic field strength, yields magnetic flux density; expressed in henry per metre ($H\ m^{-1}$). *Note:* For isotropic media, magnetic permeability is a scalar; for anisotropic media, it is a tensor quantity.

Microwaves: Microwaves are defined in the frame of this expertise as electromagnetic waves with wavelengths of approximately 30 cm (1 GHz) to 1 mm (300 GHz).

Milligauss (mG): A milligauss is a measure of ELF intensity and is abbreviated mG. This is used to describe electromagnetic fields from appliances, power lines, interior electrical wiring.

Milliwatt (mW): A unit of power equal to 10^{-3}.

Microwatt (uW): A unit of power equal to 10^{-6}

Microwatts per centimeter squared (µW/cm2)

Radiofrequency radiation in terms of power density is measured in microwatts per centimeter squared and abbreviated (µW/cm2). It is used when talking about emissions from wireless facilities, and when describing ambient RF in the environment. The amount of allowable RF near a cell tower is 1000 µW/cm2 for some cell phone frequencies, for example.

Nanowatt (nW): A unit of power equal to 10^{-9} Watt.

Non – thermal effects (or athermal effects): An effect which can only be explained in terms of mechanisms other than increased molecular motion (i.e. heating), or occurs at absorbed power levels so low, that a thermal mechanism seems unlikely, or displays so unexpected a dependence upon some experimental variable that it is difficult to see how heating could be the cause.

Near field. The region where the distance from a radiating antenna is less than the wavelength of the radiated EMF. *Note:* The magnetic field strength (multiplied by the impedance of space) and the electric field strength are unequal and, at distances less than one-tenth of a wavelength from an antenna, vary inversely as the square or cube of the distance if the antenna is small compared with this distance. Near field exposures are unreliable for estimation of exposures by calculation. The can zero out or be additive and nearly infinite, thus creating problems for exposure assessment.

Non-ionizing electromagnetic radiation (NIER). Includes all radiations and fields of the electromagnetic spectrum that do not normally have sufficient energy to produce ionization in matter; characterized by energy per photon less than about 12 eV, wavelengths greater than 100 nm, and frequencies lower than 3×10^{15} Hz.

Occupational exposure. All exposure to EMF experienced by individuals in the course of performing their work. Safety limits are five times higher for allowable occupational exposures than for general public exposures in the US.

Permeability (µ): A property of materials that indicates how much polarisation occurs when an electric field is applied.

Permittivity. A constant defining the influence of an isotropic medium on the forces of attraction or repulsion between electrified bodies, and expressed in farad per metre ($F\ m^{!1}$); *relative permittivity* is the permittivity of a material or medium divided by the permittivity of vacuum.

Public Exposure. All exposure to EMF experienced by the general public excluding exposure during medical procedures and occupational work environments. Public exposure limits in the US are five times lower than for occupational exposures, where informed consent by employees is required.

Power Density. The power as measured in free space (ambient) as opposed to measured by SAR or specific absorption rate (within tissues or the body). The unit of measurement can be watts per square meter, milliwatts per square meter or microwatts per centimeter squared. Radiofrequency (RF). Any frequency at which electromagnetic radiation is useful for telecommunications, or broadcasting for radio and television. Frequency range is usually defined as 300 Hz (300 hertz) to 300 GHz (300 gigahertz).

Radiofrequency (RF): The frequencies between 100 kHz and 300 GHz of the electromagnetic spectrum.

Reasonance. The change in amplitude occurring as the frequency of the wave approaches or coincides with a natural frequency of the medium; whole body absorption of electromagnetic waves presents its highest value, i.e., the reasonance. for frequencies (in MHz or megahertz) corresponding to approximately 114/L where L is the height of the individual in meters. Reasonance can also be applicable to organs, tissues, or other body parts.

Specific Absorption Rate (SAR is measured in watts per kilogram or W/Kg)
SAR stands for specific absorption rate. It is a calculation of how much RF energy is absorbed into the body, for example when a cell phone or cordless phone is pressed to the head. SAR is expressed in watts per kilogram of tissue (W/Kg). The amount of allowable energy into 1 gram of brain tissue from a cell phone is 1.6 W/Kg in the US. For whole body exposure, the exposure is 0.8 W/Kg averaged over 30 minutes for the general public. International standards in most countries are similar, but not exactly the same.

Static electric field: Static fields produced by fixed potential differences.

Static magnetic fields: Static fields established by permanent magnets and by steady currents.

VDU: Video display units for computers, videos, TV and some measurement devices using cathode ray tubes

WI-FI: Stands for wireless fidelity. WI-FI systems create zones of wireless RF that allow access to wireless internet for computers, internet phone access and other wireless services. Access points that provide WI-FI to access Land Area Networks (LANs) can be installed on streets (for city-wide coverage) or indoors in buildings, Restaurants, hotels, coffee shops, airports, malls and other commercial enterprises are widely installing WI-FI. The range of typical WI-FI systems is about 300 feet.

WI-MAX: Stands for "Wireless interoperability for Microwave Access" and is a telecommunications technology aimed at providing wireless data over long distances. Like WI-FI, WI-MAX systems are designed to provide wireless access but over much broader geographic areas, with some systems transmitting signal up to 10 miles. Higher levels of RF are produced at the wireless transmission facilities than for WI-FI.s

Section 20 LIST OF ABBREVIATIONS

µT	microtesla
µW	microwatt
AC	Alternating current
ALS	Amyotrophic Lateral Sclerosis
AM	Amplitude modulation
B	Magnetic flux density
BBB	Blood-Brain-Barrier
CENELEC	European Committee for Electrotechnical Standardization
CI	Confidence Interval
CNS	Central Nervous System
CW	Continuous wave
DC	Direct current
DECT	Digital Enhanced Cordless Telephone
DMBA	7,12-dimethylbenz[a]anthracene
DNA	Deoxyribonucleic acid
EEG	Electroencephalogram
EHS	Electromagnetic hypersensitivity
ELF	Extra low frequency (also ELF-EMF)
EMF	Electromagnetic field
FM	Frequency Modulation
GSM	Global System for Mobile Communication
H	Magnetic field strength
HSP	Heat-shock proteins (stress proteins)
Hz	Frequency in Hertz
IARC	International Agency for Research on Cancer
IL	Interleukin
kg	Kilogram
kHz	Kilohertz
kV	Kilovolt
MF	Magnetic Field (sometimes MF-ELF)
MHz	Megahertz
ms	Milliseconds
mT	Millitesla
mG	Milligauss
mW	Milliwatt
nT	Nanotesla

nW Nanowatt

NRPB National Radiation Protection Board (HPA)

OR Odds Ratio (measure of increased risk of disease)

REFLEX European Research Program for Radiofrequency Hazards

RF Radiofrequency Radiation (also written as RFR or RF-EMF)

SCENIHR Scientific Committee on Emerging and Newly Identified Health Risks

TNO Nederlandse Onderzoek (Netherlands Organisation Applied Scientific Research

UMTS Universal Mobile Telephony System **UNEP** United Nations Environmental

VDT Video display terminal (VDU – for computers, videos, TV, that use cathode ray tubes).

Wi-Fi Short for wireless fidelity – wireless internet access - works for short- distances for cell phone and laptop computer access without wires.

WLAN Wireless Local Area Network (wireless internet coverage usually up to 300' provided by access points that create elevated radiofrequency radiation for that service zone

WiMAX Worldwide Interoperability for Microwave Access (wireless service up to 10 miles in comparison to Wi-Fi that may serve 300' area)

WHO World Health Organisation

FCC The Federal Communications Commission (FCC) is an independent United States government agency, created, directed, and empowered by Congressional statute to oversee the regulation of radio and TV broadcasting and wireless technologies. It is not a health agency.

HPA Health Protection Agency (UK) that was formerly the National Radiation Protection Division Board). The Health Protection Agency (HPA) is an independent body that protects the health and well-being of the population. The Agency plays a critical role in protecting people from infectious diseases and in preventing harm when hazards involving chemicals, poisons or radiation occur.

DNA Deoxyribonucleic acid, or DNA is a nucleic acid molecule that contains the genetic instructions used in the development and functioning of all living things.

Melatonin Melatonin is a hormone produced in the brain by the pineal gland, It is a potent anti-oxidant that protects against oxidative damage from free radicals that can cause DNA damage.

Alzheimer's Alzheimer's disease is a progressive brain disorder that gradually destroys a person's memory and ability to learn, reason, make judgments, communicate and carry out daily activities. As Alzheimer's progresses, individuals may also experience changes in personality and behavior, such as anxiety, suspiciousness or agitation, as well as delusions or hallucinations.

RFIAWG Radiofrequency Interagency Working Group (US) composed of members from federal agencies with some interest in radiofrequency radiation issues. This Working Group was made up of representatives from the US government's National Institute for Occupational Safety and Health (NIOSH), the Federal Communications Commission (FCC), Occupational Health and Safety Administration (OSHA), the Environmental Protection Agency (US EPA), the National Telecommunication and Information Administration, and the US Food and Drug Administration (FDA).

ICNIRP International Commission on Non-Ionizing Radiation. It is a body of independent scientific experts consisting of a main Commission of 14 members, 4 Scientific Standing Committees covering Epidemiology, Biology, Dosimetry and Optical Radiation and a number of consulting experts. This expertise is brought to bear on addressing the important issues of possible adverse effects on human health of exposure to non-ionising radiation.

SECTION 27

Appendix 20-A Average Residential Exposures to ELF (Power Frequency Fields)

Prepared for the BioInitiative Working Group

July 2007

What are Ambient ELF and RF Levels?

A nation-wide survey in the United States by Zaffanella et al (1993) collected engineering data on sources and levels of 60 Hz electric power magnetic fields that exist inside residences in the United States.

Approximately 1000 residences were randomly selected for the survey. The goals were to 1) identify all significant sources of magnetic field, 2) estimate for each source the percentage of residences where magnetic fields exceeded specified levels, 3) to determine the relation between magnetic field and sources and 4) to characterize the field varations in time.

The median field was identified as 0.5 mG and the average field was 0.9 mG. Thus, this confirms that average residential magnetic fields based on the 1000-home study is less than 1 mG.

Appliances produce magnetic fields but these diminish rapidly with distance (at $1/R^3$),

Power lines generally produce the largest average residential magnetic field when the entire living space of a residence and a 24-hour period are considered. Power line magnetic field exceeds 1 mG in 17%, exceed 2.5 mG in 9.5% and exceed 5 mG in 0.3% of all the residences surveyed.

Zaffanella (1998) conducted measurements to characterize typical EMF exposure levels in persons living in the United States - a study called the 1000-Person Study. Table A-S.2 shows that about half of all people in the US have EMF exposures at home under 0.75 mG; in bed are 0.48 mg; at school 0.60 mG; at work 0.99 mG; and 0.87 mG is the median EMF exposure for an average 24-hour day.

Table A-S.2

Table S.2 Descriptive Statistics for Different Activity Periods

Parameter	Home not in Bed	In Bed	Work	School	Travel	24-Hour
Number of Valid Data Sets	1011	996	525	139	765	1012
1st Percentile	0.10 mG	0.01 mG	0.14 mG	0.13 mG	0.13 mG	0.18 mG
5th Percentile	0.20 mG	0.08 mG	0.24 mG	0.18 mG	0.29 mG	0.27 mG
10th Percentile	0.27 mG	0.12 mG	0.30 mG	0.29 mG	0.41 mG	0.35 mG
25th Percentile	0.44 mG	0.24 mG	0.60 mG	0.35 mG	0.66 mG	0.51 mG
50th Percentile	0.75 mG	0.48 mG	0.99 mG	0.60 mG	0.98 mG	0.87 mG
75th Percentile	1.39 mG	1.24 mG	1.78 mG	1.01 mG	1.46 mG	1.41 mG
90th Percentile	2.49 mG	2.44 mG	3.32 mG	1.64 mG	2.18 mG	2.38 mG
95th Percentile	3.89 mG	3.63 mG	5.00 mG	1.77 mG	2.73 mG	3.38 mG
99th Percentile	9.50 mG	9.19 mG	13.5 mG	3.55 mG	5.43 mG	6.16 mG
Mean	1.29 mG	1.11 mG	1.73 mG	0.82 mG	1.22 mG	1.25 mG
Standard Deviation	2.54 mG	2.06 mG	3.09 mG	0.70 mG	0.99 mG	1.51 mG
Geometric Mean	0.80 mG	0.52 mG	1.03 mG	0.64 mG	0.96 mG	0.89 mG
Geometric Standard Deviation	2.50	3.52	2.57	2.06	2.03	2.18

In Sweden, Mild et al (1996) report that overall mean residential ELF exposures are 0.4 mG, and in Norway are 0.13 mG.

Average Occupational Exposures to ELF

Average occupational exposures in commercial office buildings are 1-2 mG or less and have been reported fairly consistently across numerous studies of exposure assessment (Table 1). Powerline and electrical workers have higher average occupational exposures from 10 mG to 16.6 mG.

Table A-2: Average Occupational Exposures to ELF

EMF RAPID Program – Questions and Answers, NIEHS, June 2002	
Office buildings (median)	0.6 mG
Support staff	0.5 mG
Professional staff	0.6 mG
Maintenance staff	0.6 mG
Visitors	0.6 mG
EMF RAPID Program Engineering Project #3 Executive Summary, May 1996	
Office building (average)	0.7 mG
Office building (median)	0.4 mG
Electric and Magnetic Field Fundamentals (EPRI Resource Paper, March 1994)	
Typical magnetic fields in offices	1 – 2 mG
Power line workers	10 mG
Occupational EMF Exposure Assessment (EPRI Resource Paper, February 1994)	
Office Worker Comparison Group	1.6 mG
All Occupationally Exposed Utility Workers	16.6 mG
Table 7 – Other Studies Cited	
Bracken Study (1990)	1.0 mG
Deadman Study (1988)	1.6 mG
Bowman Study (1992)	0.9 – 1.8 mG

Limits on Operation of Sensitive Electronic Equipment

Companies that manufacture or use equipment in nanotechnology and biotechnology and found 1.0 mG is generally the limit for proper operation of electron beam devices (mass spectrometers, scanning electron microscopes, lithography, etc) used in these technologies. Ten (10) milligauss (mG) is the EMF limit for normal computers – above 10 mG can introduce "computer jitter" and other problems.

What are Ambient Radiofrequency Radiation/Microwave Levels?

Prior to the rapid development of wireless communications for personal and business usage, RF power density levels were primarily related to AM, FM and television broadcasting signal in both urban and rural areas of the United States. Microwave frequencies used for wireless communications were negligible.

Original extra-planetary sources of microwave radiation were infinitesimally small, on the order of a billionth of a microwatt per centimeter squared (10^{-12} uW/cm^2). Human evolution took place without any appreciable exposure to microwave radiation from background sources. The human body has no evolutionary protection against microwave radiation, as it does for ultraviolet radiation from the sun (Johannson, 2000). Wireless voice and communications have introduced unprecedented levels of public exposure in the last decade.

Mantiply (1997) measured and reported common sources and levels of RF in the environment. He identified areas near cellular base stations on the ground near towers to be from 0.003 to 0.3 μW/cm2. Background level ambient RF exposures in cities and suburbs in the 1990's were generally reported to be below 0.003 μW/cm2.

Hamnerius (2000) reported that ambient RF power density measurements in twelve (12) large cities in Sweden were roughly ten times higher than in the United States for equivalent measurement locations by Mantiply in 1978 (when no cellular phone service existed in the US). He reported a total mean value of 26 measured sites in the study was 0.05 μW/cm2 and the median value was 40 μW/cm2. An office location with a base station nearby at about 300 feet distance tested 150 μW/cm2. A train station with antennas mounted indoors tested at about 3 μW/cm2. Both indoor and outdoor ambient RF power density measurements showed high variability depending on proximity to transmitting antennas.

Sage Associates reported on microwave frequency RF power density levels at outdoor locations both near and far from wireless antenna sites in the United States (Sage, 2000). Within the first 100-300 feet, power density levels have been measured at 0.01 to 3.0 μW/cm2. Elevated RF power density levels from a major wireless antenna site can often be detected at 1000 feet or more. Power density levels away from wireless antenna sites measure between 0.001 μW/cm2 to 0.000001 μW/cm2. Vegetation often reduces signal (and therefore the reach of elevated RF exposures) but dry building materials used to visually screen wireless sites do not appreciably diminish signal transmission. Therefore, many sites that are "out-of-sight" because of stealth design can still produce elevated RF levels in nearby areas where people live, work and go to

school. For purposes of this evaluation, a 10 dB attenuation has been incorporated to take building material shielding effects into account.

APPENDIX 20-B

STANDARDS OF EVIDENCE FOR DECISIONMAKING DIFFERS AMONG PROFESSIONS

There is a large difference between what constitutes causal evidence for purposes of achieving scientific consensus, what constitutes sufficient evidence for purposes of interim public health policy, and what constitutes "a more likely than not" case. A central confusion in this debate is whether prudent policy and public health decisions necessarily require conclusive scientific evidence first. This is not the case. The state of the science needs to be presented in an understandable and scientifically accurate manner, but prudent public health actions do not and should not require 100% proof of harm. In fact, precautionary and preventative actions are specifically justified at a point in time before scientific proof is established. If the growing weight of evidence is positive (although all studies need not report positive effects) then it may be essential to take preventative actions and implement policies that are protective of public health, safety and welfare rather than wait for absolute certainty. The following discussion is presented to highlight some of the main differences in professional approach and traditional ways of viewing and interpreting scientific evidence. In reality, the basis for taking action (preventative or precautionary action) is a continuum – there are no hard and fast rules. The bar for Public Health Policy may be higher or lower than shown in Figure 2; based on many factors, including how widespread the risk, how dread the disease, the cost of inaction (doing nothing until there is proof, but many may be harmed), etc.

A. Scientific Standard of Evidence

There are several levels of proof for adverse effects of environmental exposures. The most rigorous is a scientific standard, where virtual proof of causation is typically required by scientists to arrive at consensus about an effect. This approach works best in physics and chemistry. In biological systems this is rarely possible.

In this case, the 'scientific standard' refers to the overall evidence that the science community typically requires before rendering opinions on the strength of evidence, and what evidence they believe is necessary to establish a causal link (proof).

Figure 1 shows Standards of Evidence that are routinely employed by various interest groups in the EMF debate (Sage, 1997). It can be used to focus on various accepted standards for evidence that are legitimately used by scientific and professional groups to determine when an action is appropriate. The varying levels of certainty about an outcome will dictate different decision-making among different groups that may all be appropriate given their professional charge. Even though the evidence required to make a scientific determination about causality has a far higher standard than a legal determination on the 'weight of the evidence' or 'preponderance of evidence' (a legal standard), neither negates the correctness of the other in its proper jurisdiction. Scientists typically want all possible evidence (animal, cell and epidemiological studies, with replications) showing a high degree of consistency. This can generally be described as a 95% to

99% degree of certainty before drawing conclusions (it does not refer to the 95% confidence interval in epidemiology, except as a part of the overall proof).

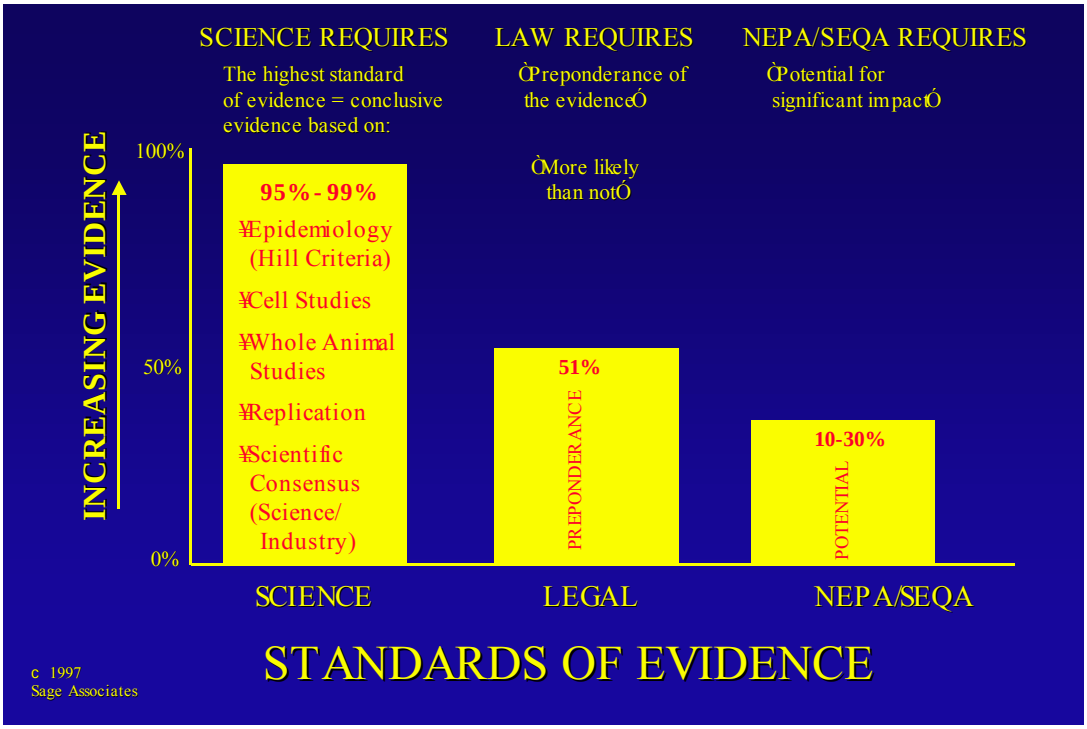

Figure 1 Variable Standards of Evidence (By Profession)

B. Legal Standard of Evidence

The second level of proof is the standard applied in legal proceedings, which is 'more likely than not' or 'preponderance of the evidence' (Figure 1). This is to say if there is a 50%+ likelihood of harm, this is taken as evidence for a relationship (Sage, 1997). At least this level of evidence is reached for the studies of adult cancer and neurodegenerative diseases and 50/60 Hz magnetic field exposures. As with childhood leukemia, while we have documented associations, this does not necessarily indicate causation. Failure to meet either the scientific or the legal standard of proof does not mean that there is no relationship between exposure and disease. In the case of EMF exposure, where everyone is exposed, the societal implications may be huge if there is a real risk whose magnitude has simply just not yet been clarified. Public policies are needed to address this issue of decision-making in the face of this scientific uncertainty.

C. Environmental Protection Standard of Evidence

National and state environmental quality acts (The National Environmental Policy Act) and various state environmental quality acts (SEQA) require that assessments use a standard of "potential for a significant impact on the environment which is a relatively low level of certainty (10% to 30%). The potential for a significant impact requires that mitigation strategies be developed, i.e, require precautionary or preventative actions when only the potential for risk is present (Figure 1).

For example, the potential for risk to humans from building on an active earthquake fault will require a finding of potentially significant impact, and will require mitigative action; even when there is no certainty (no causal evidence) that the fault will rupture and cause damage within the design lifetime of the building. Proof of harm is not a pre-condition for taking action, and the level of certainty is low in comparison to a scientific or legal standard of certainty. Nonetheless, each standard has validity, and will have a different level of evidence required to take action. What decision-makers need to address is what standard of evidence is appropriate now to guide them with respect to EMF exposures that are clearly of environmental and public health concern.

D. Public Health Standard of Evidence

The prudent approach from a public health point of view is to take preventive actions as if causation had been proven, while at the same time to continue to search for mechanisms of action. In the case of childhood leukemia and ELF exposure there is a consistent and statistically significant association in most studies, while for many of the other diseases the results are less consistent although strong associations are found in some studies (Figure 2). This bar graph should be considered illustrative only, since the level of certainty may be higher or lower (above or below 50%) depending on the circumstances of the potential risk, and costs of those risks to society.

Whether magnetic fields actually cause childhood leukemia and the other cancers and neurological diseases documented in this Report; or whether it is some other component in the electromagnetic environment that is responsible for the association is a subject of debate within the scientific community, but from a public health point of view it doesn't matter. The fact that there are unknowns does not negate or override the ultimate public health responsibility, which is to protect the population from exposures which cause disease. Those who make public health decisions, as well as policymakers who rely on them and who approve construction of new schools and homes near power lines, those who provide insurance or financing of new construction, those who must choose siting routes for new electrical facilities all face making decisions with some uncertainty about the potential health risks from EMF exposure. Important social issues must often be decided on the basis of incomplete or uncertain scientific information.

Acknowledgements

The BioInitiative Working Group gratefully acknowledges the many independent scientists, researchers and experts who have labored, some for decades - many of whom are no longer with us - to bring this body of science into the public arena. There would be no BioInitiative without their perseverance and generous contributions of intellect and resources.

We deeply appreciate the Santa Barbara Foundation for serving as our fiscal agent. Thanks go to Jan Campbell, Senior Vice President of Philanthropic Services, Communications and Marketing, and to Cheri Savage. Assistant Treasurer of the Santa Barbara Foundation for making this relationship possible. In addition, Mr. Nick Munday gave us brilliant technical help in refining our graphic products.

Web designer Julie Faber of Mountain Studio has our gratitude for her artful guidance in the redesign and layout of the BioInitiative 2012 website. She is both professional and intuitive, helping us communicate complex ideas with precision and flair.

Personally, I am indebted to my husband Dr. Orrin Sage and our family for their encouragement and understanding during the long months of immersion and irregular hours this project demanded. Working with colleagues in time zones spanning Russia, Sweden, Canada, Austria, the Slovak Republic, Italy, Greece, and India makes a 24-hr workday seem normal. Finally, gratitude to Avery, Drake, Ford, Jenner, Luke, Solei, and all the children whose trusting faces remind us that we hold their future in our hands. (Cindy Sage).

Preface

We are honored to have been asked to carry on the tradition established by Dr. Postow and the late Dr. Polk in the first two editions of the *Handbook of Biological Effects of Electromagnetic Fields*. Their editions of this handbook were each recognized as the authoritative standards of their time for scientists working in bioelectromagnetics, the science of electromagnetic field effects on biological systems, and for others seeking information about this field of research.

In revising and updating this edition of the *Handbook of Biological Effects of Electromagnetic Fields*, we have expanded the coverage to include more material on diagnostic and therapeutic applications. At the same time, in updating and expanding the previous editions' coverage of the basic science and studies related to the possible biological effects of the electromagnetic fields, we have added new material on the related physics and chemistry as well as reviews of the recent developments in the setting standards for exposure limits. Following the previous edition's lead, we have charged the authors of the individual chapters with providing the reader, whom we imagine is fairly well founded in one or more of the sciences underlying bioelectromagnetics but perhaps not in the others or in the interdisciplinary subject of bioelectromagnetics itself, with both an introduction to their topic and a basis for further reading. We asked the chapter authors to write what they would like to be the first thing they would ask a new graduate student in their laboratory to read. We hope that this edition, like its two predecessors, will be useful to many as a reference book and to others as a text for a graduate course that introduces bioelectromagnetics or some of its aspects.

As a ''handbook'' and not an encyclopedia, this work does not intend to cover all aspects of bioelectromagnetics. Nevertheless, taking into account the breadth of topics and growth of research in this field since the last edition, we have expanded the number of topics and the number of chapters. Unavoidably, some ideas are duplicated in chapters, sometimes from different viewpoints that could be instructive to the reader; and different aspects of others are presented in different chapters. The increased amount of material has led to the publication of the handbook as two separate, but inter-related volumes: *Biological and Medical Aspects of Electromagnetic Fields (BMA)* and *Bioengineering and Biophysical Aspects of Electromagnetic Fields (BBA)*. Because there is no sharp dividing line, some topics are dealt with in parts of both volumes. The reader should be particularly aware that various theoretical models, which are proposed for explaining how fields interact with biological systems at a biophysical level, are distributed among a number of chapters. No one model has become widely accepted, and it is quite possible that more than one will in fact be needed to explain all observed phenomena. Most of these discussions are in the *Biological and Medical* volume, but the *Bioengineering and Biophysics* volume's chapters on electroporation and on mechanisms and therapeutic applications, for example, also have relevant material. Similarly, the chapters on biological effects of static magnetic fields and on endogenous electric fields in animals could equally well have been in the *Biological and Medical* volume. We have tried to use the index and cross-references in the chapters to direct the reader to the most relevant linkages, and we apologize for those we have missed.

Research in bioelectromagnetics stems from three sources, all of which are important; and various chapters treat both basic physical science and engineering aspects and the biological and medical aspects of these three. Bioelectromagnetics first emerged as a

separate scientific subject because of interest in studying possible hazards from exposure to electromagnetic fields and setting exposure limits. A second interest is in the beneficial use of fields to advance health, both in diagnostics and in treatment, an interest that is as old as the discovery of electricity itself. Finally, the interactions between electromagnetic fields and biological systems raise some fundamental, unanswered scientific questions and may also lead to fields being used as tools to probe basic biology and biophysics. Answering basic bioelectromagnetic questions will not only lead to answers about potential electromagnetic hazards and to better beneficial applications, but they should also contribute significantly to our basic understanding of biological processes. Both strong fields and those on the order of the fields generated within biological systems may become tools to perturb the systems, either for experiments seeking to understand how the systems operate or simply to change the systems, such as by injecting a plasmid containing genes whose effects are to be investigated. These three threads are intertwined throughout bioelectromagnetics. Although any specific chapter in this work will emphasize one or another of these threads, the reader should be aware that each aspect of the research is relevant to a greater or lesser extent to all three.

The reader should note that the chapter authors have a wide variety of interests and backgrounds and have concentrated their work in areas ranging from safety standards and possible health effects of low-level fields to therapy through biology and medicine to the fundamental physics and chemistry underlying the biology. It is therefore not surprising that they have different and sometimes conflicting points of view on the significance of various results and their potential applications. Thus authors should only be held responsible for the viewpoints expressed in their chapters and not in others. We have tried to select the authors and topics so as to cover the scientific results to date that are likely to serve as a starting point for future work that will lead to the further development of the field. Each chapter's extensive reference section should be helpful for those needing to obtain a more extensive background than is possible from a book of this type.

Some of the material, as well as various authors' viewpoints, are controversial, and their importance is likely to change as the field develops and our understanding of the underlying science improves. We hope that this volume will serve as a starting point for both students and practitioners to come up-to-date with the state of understanding of the various parts of the field as of late 2004 or mid-2005, when authors contributing to this volume finished their literature reviews.

The editors would like to express their appreciation to all the authors for the extensive time and effort they have put into preparing this edition, and it is our wish that it will prove to be of value to the readers and lead to advancing our understanding of this challenging field.

Editors

Frank Barnes received his B.S. in electrical engineering in 1954 from Princeton University and his M.S., engineering, and Ph.D. degrees from Stanford University in 1955, 1956, and 1958, respectively. He was a Fulbright scholar in Baghdad, Iraq, in 1958 and joined the University of Colorado in 1959, where he is currently a distinguished professor. He has served as chairman of the Department of Electrical Engineering, acting dean of the College of Engineering, and in 1971 as cofounder/director with Professor George Codding of the Political Science Department of the Interdisciplinary Telecommunications Program (ITP).

He has served as chair of the IEEE Electron Device Society, president of the Electrical Engineering Department Heads Association, vice president of IEEE for Publications, editor of the *IEEE Student Journal* and the *IEEE Transactions on Education*, as well as president of the Bioelectromagnetics Society and U.S. Chair of Commission K—International Union of Radio Science (URSI). He is a fellow of the AAAS, IEEE, International Engineering Consortium, and a member of the National Academy of Engineering.

Dr. Barnes has been awarded the Curtis McGraw Research Award from ASEE, the Leon Montgomery Award from the International Communications Association, the 2003 IEEE Education Society Achievement Award, Distinguished Lecturer for IEEE Electron Device Society, the 2002 ECE Distinguished Educator Award from ASEE, The Colorado Institute of Technology Catalyst Award 2004, and the Bernard M. Gordon Prize from National Academy of Engineering for Innovations in Engineering Education 2004. He was born in Pasadena, CA, in 1932 and attended numerous elementary schools throughout the country. He and his wife, Gay, have two children and two grandchildren.

Ben Greenebaum retired as professor of physics at the University of Wisconsin–Parkside, Kenosha, WI, in May 2001, but was appointed as emeritus professor and adjunct professor to continue research, journal editing, and university outreach projects. He received his Ph.D. in physics from Harvard University in 1965. He joined the faculty of UW–Parkside as assistant professor in 1970 following postdoctoral positions at Harvard and Princeton Universities. He was promoted to associate professor in 1972 and to professor in 1980. Greenebaum is author or coauthor of more than 50 scientific papers. Since 1992, he has been editor in chief of *Bioelectromagnetics*, an international peer-reviewed scientific journal and the most cited specialized journal in this field. He spent 1997–1998 as consultant in the World Health Organization's International EMF Project in Geneva, Switzerland. Between 1971 and 2000, he was part of an interdisciplinary research team investigating the biological effects of electromagnetic fields on biological cell cultures. From his graduate student days through 1975, his research studied the spins and moments of radioactive nuclei. In 1977 he became a special assistant to the chancellor and in 1978, associate dean of faculty (equivalent to the present associate vice chancellor position). He served 2 years as acting vice chancellor (1984–1985 and 1986–1987). In 1989, he was appointed as dean of the School of Science and Technology, serving until the school was abolished in 1996.

On the personal side, he was born in Chicago and has lived in Racine, WI, since 1970. Married since 1965, he and his wife have three adult sons.

Table of Contents

Introduction

Charles Polk*

Revised for the 3rd Edition by Ben Greenebaum

Much has been learned since this handbook's first edition, but a full understanding of biological effects of electromagnetic fields has is to be achieved. The broad range of what must be studied has to be a factor in the apparent slow progress toward this ultimate end. The broad range of disciplines involved includes basic biology, medical science and clinical practice, biological and electrical engineering, basic chemistry and biochemistry, and fundamental physics and biophysics. The subject matter ranges over characteristic lengths and timescales from, at one extreme, direct current (dc) or $\sim 10^4$ km-wavelengths, multimillisecond ac fields and large, long-lived organisms to, at the other extreme, submillimeter wavelength fields with periods below 10^{-12} s and subcellular structures and molecules with subnanometer dimensions and characteristic times as short as the 10^{-15} s or less of biochemical reactions.

This chapter provides an introduction and overview of the research and the contents of this handbook.

0.1 Near Fields and Radiation Fields

In recent years it has become, unfortunately, a fairly common practice—particularly in nontechnical literature—to refer to the entire subject of interaction of electric (E) and magnetic (H) fields with organic matter as biological effects of nonionizing radiation, although fields that do not vary with time and, for most practical purposes, slowly time-varying fields do not involve radiation at all. The terminology had its origin in an effort to differentiate between relatively low-energy microwave radiation and high-energy radiation, such as UV and x-rays, capable of imparting enough energy to a molecule or an atom to disrupt its structure by removing one or more electron\s with a single photon. However, when applied to dc or extremely low-frequency (ELF), the term ''nonionizing radiation'' is inappropriate and misleading.

A structure is capable of efficiently radiating electromagnetic waves only when its dimensions are significant in comparison with the wavelength λ. But in free space $\lambda = c/f$, where c is the velocity of light in vacuum (3×10^8 m/s) and f is the frequency in hertz (cycles/s); therefore the wavelength at the power distribution frequency of 60 Hz, e.g., is 5000 km, guaranteeing that most available human-made structures are much smaller than one wavelength.

The poor radiation efficiency of electrically small structures (i.e., structures whose largest linear dimension $L \ll \lambda$ can be illustrated easily for linear antennas. In free space the radiation resistance, R_r of a current element, i.e., an electrically short wire of length ℓ carrying uniform current along its length [1], is

$$R_r = 80\pi^2 \left(\frac{\ell}{\lambda}\right)^2 \tag{0.1}$$

*Deceased.

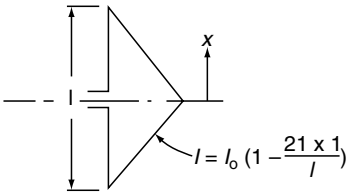

FIGURE 0.1
Current distribution on short, thin, center-fed antenna.

whereas the R_r of an actual center-fed radiator of total length ℓ with current going to zero at its ends, as illustrated in Figure 0.1, is

$$R_r = 20\pi^2 \left(\frac{\ell}{\lambda}\right)^2 \tag{0.2}$$

Thus, the R_r of a 0.01 λ antenna, 50 km long at 60 Hz, would be 0.0197 Ω. As the radiated power $P_r = I^2 R_r$ where I is the antenna terminal current, whereas the power dissipated as heat in the antenna wire is $I^2 R_d$; when I is uniform, the P_r will be very much less than the power used to heat the antenna, given that the ohmic resistance R_d of any practical wire at room temperature will be very much larger and R_r. For example, the resistance of a 50-km long, 1/2-in. diameter solid copper wire could be 6.65 Ω. At dc, of course, no radiation of any sort takes place, as acceleration of charges is a condition for radiation of electromagnetic waves.

The second set of circumstances, which guarantees that any object subjected to low-frequency E and H fields usually does not experience effects of radiation, is that any configuration that carries electric currents sets up E and H field components which store energy without contributing to radiation. A short, linear antenna in free space (short electric dipole) generates, in addition to the radiation field E_r, an electrostatic field E_s and an induction field E_i. Neither E_s nor E_i contribute to the P_r [2,3]. Whereas E_r varies as $1/r$, where r is the distance from the antenna, E_i varies as $1/r^2$, and E_s as $1/r^3$. At a distance from the antenna of approximately one sixth of the wavelength ($r = \lambda/2\pi$), the E_i equals the E_r, and when $r \ll \lambda/6$ the E_r quickly becomes negligible in comparison with E_i and E_s. Similar results are obtained for other antenna configurations [4]. At 60 Hz the distance $\lambda/2\pi$ corresponds to about 800 km and objects at distances of a few kilometers or less from a 60-Hz system are exposed to nonradiating field components, which are orders of magnitude larger than the part of the field that contributes to radiation.

A living organism exposed to a static (dc) field or to a nonradiating near field may extract energy from it, but the quantitative description of the mechanism by which this extraction takes place is very different than at higher frequencies, where energy is transferred by radiation:

1. In the near field the relative magnitudes of E and H are a function of the current or charge configuration and the distance from the electric system. The E field may be much larger than the H field or vice versa (see Figure 0.2).
2. In the radiation field the ratio the E to H is fixed and equal to 377 in free space, if E is given in volt per meter and H in ampere per meter.
3. In the vicinity of most presently available human-made devices or systems carrying static electric charges, dc, or low-frequency (<1000 Hz) currents, the E and H fields will only under very exceptional circumstances be large enough to produce heating effects inside a living object, as illustrated by Figure 0.3. (This statement assumes that the living object does not form part of a conducting path

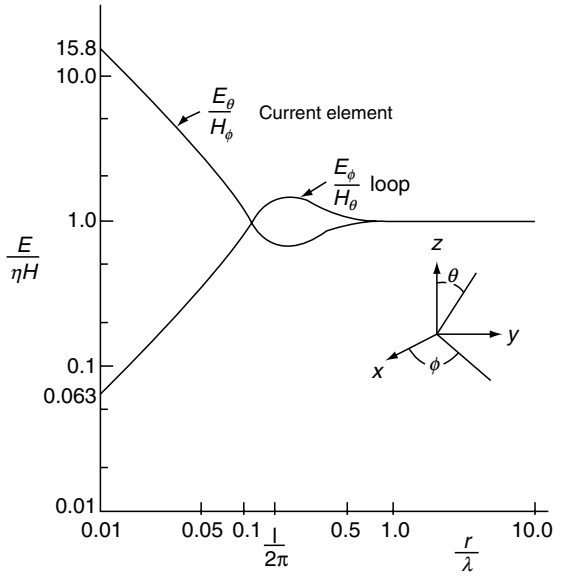

FIGURE 0.2
Ratio of E to H field (divided by wave impedance of free space $\eta = 377\ \Omega$) at $\theta = 90°$; for electric current element at origin along z-axis and for electrically small loop centered at the origin in x–y plane.

that permits direct entrance of current from a wire or conducting ground.) However, nonthermal effects are possible; thus an E field of sufficient magnitude may orient dipoles, or translate ions or polarizable neutral particles (see Chapter 3 and Chapter 4 in *BBA**).

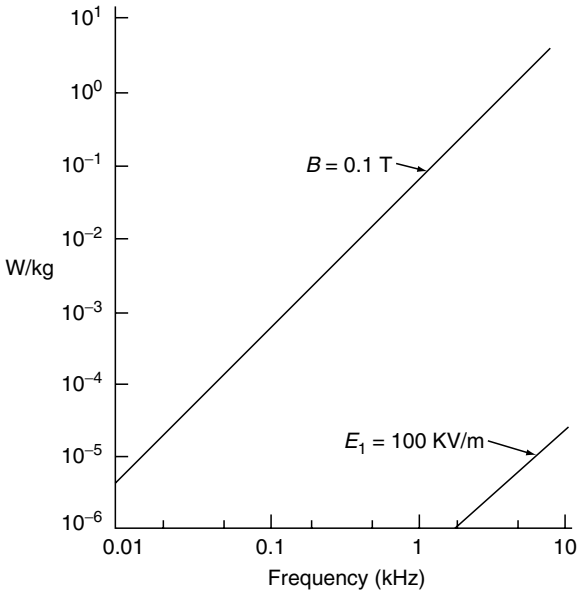

FIGURE 0.3
Top line: Eddy current loss produced in cylinder by sinusoidally time-varying axial H field. Cylinder parameters are conductivity $\sigma = 0.1\,\mathrm{S/m}$, radius 0.1 m, density $D = 1100\,\mathrm{kg/m^3}$, RMS magnetic flux density $0.1\,\mathrm{T} = 1000\,\mathrm{G}$. Watt per kilogram $= \sigma B^2 r^2 w^2 / 8D$; see Equation 0.15 and use power per volume $= J^2/\sigma$, *Lower line:* Loss produced by 60-Hz E field in Watt per kilogram $= \sigma\, E_{\mathrm{int}}{}^2/D$, where external field E_1 is related to E_{int} by Equation 0.9 with $\varepsilon_2 = \varepsilon_0 \times 10^5$ at 1 kHz and $\varepsilon_0 = 8 \times 10^4$ at 10 kHz.

**BBA*: *Bioengineering and Biophysical Aspects of Electromagnetic Fields* (ISBN 0-8493-9539-9); *BMA*: *Biological and Medical Aspects of Electromagnetic Fields* (ISBN 0-8493-9538-0).

4. With radiated power it is relatively easy to produce heating effects in living objects with presently available human-made devices (see Chapter 10 in *BBA* and Chapter 5 in *BMA*). This does not imply, of course, that all biological effects of radiated radio frequency (RF) power necessarily arise from temperature changes.

The results of experiments involving exposure of organic materials and entire living organisms to static E and ELF E fields are described in *BBA*, Chapter 3. Various mechanisms for the interaction of such fields with living tissue are also discussed there and in *BBA*, Chapter 5. In the present introduction, we shall only point out that one salient feature of static (dc) and ELF E field interaction with living organisms is that the external or applied E field is always larger by several orders of magnitude than the resultant average internal E field [5,6]. This is a direct consequence of boundary conditions derived from Maxwell's equations [1–3].

0.2 Penetration of Direct Current and Low-Frequency Electric Fields into Tissue

Assuming that the two materials illustrated schematically in Figure 0.4 are characterized, respectively, by conductivities σ_1 and σ_2 and dielectric permittivities ε_1 and ε_2, we write E-field components parallel to the boundary as E_{P} and components perpendicular to the boundary as $E_{\perp}$. For both static and time-varying fields

$$E_{\mathrm{P1}} = E_{\mathrm{P2}} \tag{0.3}$$

and for static (dc) fields

$$\sigma_1 E_{\perp 1} = \sigma_2 E_{\perp 2} \tag{0.4}$$

as a consequence of the continuity of current (or conservation of charge). The orientations of the total E fields in media 1 and 2 can be represented by the tangents of the angles between the total fields and the boundary line

$$\tan\theta_1 = \frac{E_{\perp 1}}{E_{\mathrm{P1}}}, \quad \tan\theta_2 = \frac{E_{\perp 2}}{E_{\mathrm{P2}}} \tag{0.5}$$

From these equations it follows that

$$\tan\theta_1 = \frac{\sigma_2}{\sigma_1}\frac{E_{\perp 1}}{E_{\mathrm{P1}}} = \frac{\sigma_2}{\sigma_1}\frac{E_{\perp 2}}{E_{\mathrm{P2}}} = \frac{\sigma_2}{\sigma_1}\tan\theta_2 \tag{0.6}$$

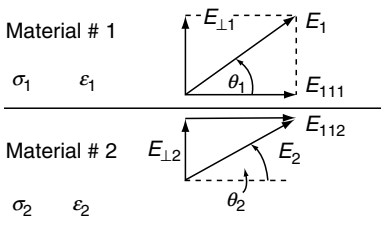

FIGURE 0.4
Symbols used in description of boundary conditions for E-field components.

If material 1 is air with conductivity [7] $\sigma_1 = 10^{-13}$ S/m and material 2 a typical living tissue with $\sigma_2 \approx 10^{-1}$ S/m (compare Chapter 3 in *BBA*), $\tan\theta_1 = 10^{12}\tan\theta_2$, and therefore even if the field in material 2 (the inside field) is almost parallel to the boundary so that $\theta_2 \cong 0.5^\circ$ or $\tan\theta_2 \approx (1/100)$, $\tan\theta_1 = 10^{10}$ or $\theta_1 = (\pi/2 - 10)^{-10}$ radians. Thus an electrostatic field in air, at the boundary between air and living tissue, must be practically perpendicular to the boundary. The situation is virtually the same at ELF although Equation 0.4 must be replaced by

$$\sigma_1 E_{\perp 1} - \sigma_2 E_{\perp 2} = -\mathrm{j}\omega\rho_s \tag{0.7}$$

and

$$\varepsilon_1 E_{\perp 1} - \varepsilon_2 E_{\perp 2} = \rho_s \tag{0.8}$$

where $\mathrm{j} = \sqrt{-1}$, ω is the radian frequency ($= 2\pi \times$ frequency), and ρ_s is the surface charge density. In Chapter 3 in *BBA* it is shown that at ELF the relative dielectric permittivity of living tissue may be as high as 10^6 so that $\varepsilon_2 = 10^6\ \varepsilon_0$, where ε_0 is the dielectric permittivity of free space $(1/36\ \pi)\ 10^{-9}$ F/m; however, it is still valid to assume that $\varepsilon_2 \leq 0^{-5}$. Then from Equation 0.7 and Equation 0.8

$$E_{\perp 1} = \frac{\sigma_2 + \mathrm{j}\omega\varepsilon_2}{\sigma_1 + \mathrm{j}\omega\varepsilon_1} E_{\perp 2} \tag{0.9}$$

which gives at 60 Hz with $\sigma_2 = 10^1$ S/m, $\sigma_1 = 10^{-13}$ S/m, $\varepsilon_2 \approx 10^{-5}$ F/m, and $\varepsilon_1 \approx 10^{-11}$ F/m

$$E_{\perp 1} = \frac{10^{-1} + \mathrm{j}_4 10^{-3}}{10^{-13} + \mathrm{j}_4 10^{-9}} E_{\perp 2} \approx \frac{\sigma_2}{\mathrm{j}\omega\varepsilon_1} = -\mathrm{j}\,(2.5 \times 10^7) E_{\perp 2} \tag{0.10}$$

This result, together with Equation 0.3 and Equation 0.5, shows that for the given material properties, the field in air must still be practically perpendicular to the boundary of a living organism: $\tan\theta_1$: $2.5(10^7)\tan\theta_2$.

Knowing now that the living organism will distort the E field in its vicinity in such a way that the external field will be nearly perpendicular to the boundary surface, we can calculate the internal field by substituting the total field for the perpendicular field in Equation 0.4 (dc) and Equation 0.9 (ELF). For the assumed typical material parameters we find that in the static (dc) case

$$\frac{E_{\text{internal}}}{E_{\text{external}}} \approx 10^{-12} \tag{0.11}$$

$$\rho_f = \frac{3(\sigma_2\varepsilon_1 - \sigma_1\varepsilon_2)E_0}{2\sigma_1 + \sigma_2} \cos\vartheta\ \text{C/m}^2$$

and for 60 Hz

$$\frac{E_{\text{internal}}}{E_{\text{external}}} \approx 4(10^{-8}) \tag{0.12}$$

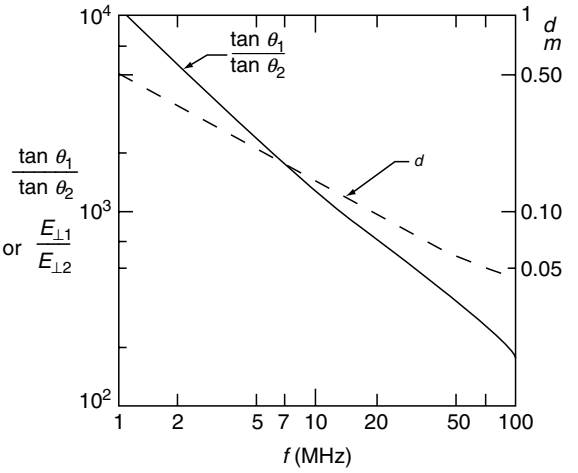

FIGURE 0.5
Orientation of *E*-field components at air–muscle boundary (or ratio of fields perpendicular to boundary); depth (d) at which field component parallel to boundary surface decreases by approximately 50% ($d = 0.6938$).

Thus, a 60-Hz external field of 100 kV/m will produce an average E_{internal} field of the order of 4 mV/m.

If the boundary between air and the organic material consists of curved surfaces instead of infinite planes, the results will be modified only slightly. Thus, for a finite sphere (with ε and σ as assumed here) embedded in air, the ratios of the internal field to the undisturbed external field will vary with the angle θ and distance r as indicated in Figure 0.5, but will not deviate from the results indicated by Equation 0.7 and Equation 0.8 by more than a factor of 3 [3,8]. Long cylinders ($L \ll r$) aligned parallel to the external field will have interior fields essentially equal to the unperturbed external field, except near the ends where the field component perpendicular to the membrane surface will be intensified approximately as above (see Chapter 9 and Chapter 10 in this volume).

0.3 Direct Current and Low-Frequency Magnetic Fields

Direct current H fields are considered in more detail in the Chapter 3, Chapter 5, and Chapter 8 in *BBA*. ELF H fields are considered in various places, including Chapter 5 and Chapter 7 in *BBA* and Chapter 2 and Chapter 11 in *BMA*. As the magnetic permeability μ of most biological materials is practically equal to the magnetic permeability μ_0 of free space, $4\pi(10^{-7})$ H/m, the dc or ELF H field ''inside'' will be practically equal to the H field ''outside.'' The only exceptions are organisms such as the magnetotactic bacteria, which synthesize ferromagnetic material, discussed in Chapter 8 of *BBA*. The known and suggested mechanisms of interaction of dc H fields with living matter are:

1. Orientation of ferromagnetic particles, including biologically synthesized particles of magnetite.
2. Orientation of diamagnetically or paramagnetically anisotropic molecules and cellular elements [9].
3. Generation of potential differences at right angles to a stream of moving ions (Hall effect, also sometimes called a magnetohydrodynamic effect) as a result of the magnetic force $F_{\text{m}} = qvB \sin \theta$, where q is the the electric charge, v is the

velocity of the charge, B is the magnetic flux density, and sin θ is the sine of the angle θ between the directions v and B. One well-documented result of this mechanism is a ''spike'' in the electrocardiograms of vertebrates subjected to large dc H fields.

4. Changes in intermediate products or structural arrangements in the course of light-induced chemical (electron transfer) reactions, brought about by Zeeman splitting of molecular energy levels or effects upon hyperfine structure. (The Zeeman effect is the splitting of spectral lines, characteristic of electronic transitions, under the influence of an external H field; hyperfine splitting of electronic transition lines in the absence of an external H field is due to the magnetic moment of the nucleus; such hyperfine splitting can be modified by an externally applied H field.) The magnetic flux densities involved not only depend upon the particular system and can be as high as 0.2 T (2000 G) but also $<$0.01 mT (100 G). Bacterial photosynthesis and effects upon the visual system are prime candidates for this mechanism [10,11].
5. Induction of E fields with resulting electrical potential differences and currents within an organism by rapid motion through a large static H field. Some magnetic phosphenes are due to such motion [12].

Relatively slow time-varying H fields, which are discussed in the basic mechanisms and therapeutic uses chapters (Chapter 5 of *BBA* and Chapter 11 in *BMA*), among others, may interact with living organisms through the same mechanisms that can be triggered by static H fields, provided the variation with time is slow enough to allow particles of finite size and mass, located in a viscous medium, to change orientation or position where required (mechanism 1 and 2) and provided the field intensity is sufficient to produce the particular effect. However, time-varying H fields, including ELF H fields, can also induce electric currents into stationary conducting objects. Thus, all modes of interaction of time-varying E fields with living matter may be triggered by time-varying, but not by static, H fields.

In view of Faraday's law, a time-varying magnetic flux will induce E fields with resulting electrical potential differences and ''eddy'' currents through available conducting paths. As very large external ELF E fields are required (as indicated by Equation 0.9 through Equation 0.12) to generate even small internal E fields, many human-made devices and systems generating both ELF E and H fields are more likely to produce physiologically significant internal E fields through the mechanism of *magnetic* induction.

The induced voltage V around some closed path is given by

$$V = \oint E \cdot \mathrm{d}\ell = -\int\int \frac{\partial B}{\partial t}\mathrm{d}s \tag{0.13}$$

where E is the induced E field. The integration $\oint E\ \mathrm{d}\ell$ is over the appropriate conducting path, $\partial B/\partial t$ is the time derivative of the magnetic flux density, and the ''dot'' product with the surface element, ds, indicates that only the component of $\partial B/\partial t$ perpendicular to the surface, i.e., parallel to the direction of the vector ds, enclosed by the conducting path, induces an E field. To obtain an order-of-magnitude indication of the induced current that can be expected as a result of an ELF H field, we consider the circular path of radius r, illustrated by Figure 0.6. Equation 0.13 then gives the magnitude of the E field as

$$E = \frac{\omega B r}{2} \tag{0.14}$$

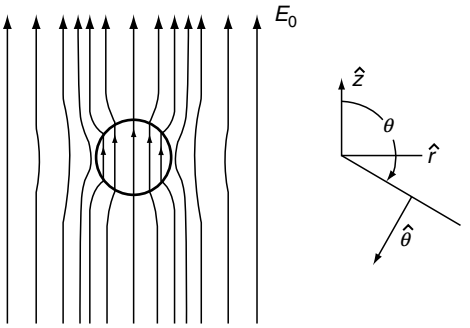

FIGURE 0.6
E field when sphere of radius R, conductivity σ_2, and dielectric permittivity ε_2 is placed into an initially uniform static field ($E = 2E_0$) within a medium with conductivity σ_1 and permittivity ε_1. The surface charge density is $\rho_r = \dfrac{3(\sigma_2\varepsilon_1 - \sigma_1\varepsilon_2)E_0}{2\sigma_1 + \sigma_2}\cos\theta$ C/m^2.

$$r < R \quad \bar{E} = \frac{3\sigma_1 E_0}{2\sigma_1 + \sigma_2}\hat{z} \qquad \varepsilon_2, \sigma_2$$

$$r < R \quad \bar{E} = E_0\cos\theta\left[1 + \frac{2R^3(\sigma_2 \propto \sigma_1)}{r^3(2\sigma_1 + \sigma_2)}\right]\hat{r} \qquad \varepsilon_1, \sigma_1$$

$$- E\sin\theta\left[1 - \frac{R^3(\sigma_2 \propto \sigma_1)}{r^3(2\sigma_1 + \sigma_2)}\right]\hat{\theta}$$

where ω is the $2\pi f$ and f is the frequency. The magnitude of the resulting electric current density J in ampere per square meter is*

$$J = \sigma E = \frac{\sigma\omega B r}{2} \tag{0.15}$$

where σ is the conductivity along the path in Siemens per meter. In the SI (Systeme Internationale) units used throughout this book, B is measured in tesla ($T = 10^4$ G) and r in meters. Choosing for illustration a circular path of 0.1 m radius, a frequency of 60 Hz, and a conductivity of 0.1 S/m, Equation 0.14 and Equation 0.15 give $E = 18.85$ B and $J = 1.885$ B. The magnetic flux density required to obtain a current density of 1 mA/m^2 is 0.53 mT or about 5 G. The E field induced by that flux density along the circular path is 10 mV/m. To produce this same 10 mV/m E_{internal} field by an external 60 Hz E_{external} field would require, by Equation 0.12, a field intensity of 250 kV/m.

As the induced voltage is proportional to the time rate of change of the H field (Equation 0.13), implying a linear increase with frequency (Equation 0.14), one would expect that the ability of a time-varying H field to induce currents deep inside a conductive object would increase indefinitely as the frequency increases; or conversely, that the magnetic flux density required to induce a specified E field would decrease linearly with frequency, as indicated in Figure 0.7. This is not true however, because the displacement current density $\partial D/\partial t$, where $D = \varepsilon E$, must also be considered as the frequency increases. This leads to the wave behavior discussed in Part III, implying that at sufficiently high frequencies the effects of both external E and H fields are limited

*Equation 0.15 neglects the H field generated by the induced eddy currents. If this field is taken into account, it can be shown that the induced current density in a cylindrical shell of radius r and thickness Δ is given by $\Delta r < 0.01$ m$^2/[1 + j\Delta r/\delta^2]$, where $H_0 = B_0/\mu_0$ and δ is the skin depth defined by Equation 0.17 below. However, for conductivities of biological materials ($\sigma < 5$ s/m) one obtains at audio frequencies $\delta > 1$ m and as for most dimensions of interest $\Delta r < 0.01$ m^2 the term $j\Delta r/\delta^2$ becomes negligible. The result $-jrH_0/\delta^2$ is then identical with Equation 0.15.

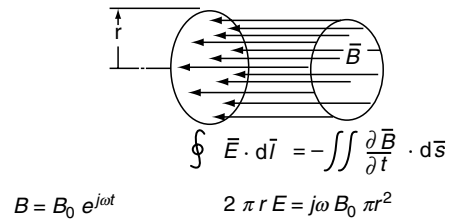

FIGURE 0.7

by reflection losses (Figure 0.8 through Figure 0.10) as well as by skin effect [13], i.e., limited depth of penetration d in Figure 0.5.

0.4 RF Fields

At frequencies well below those where most animals and many field-generating systems have dimensions of the order of one free space wavelength, e.g., at 10 MHz where $\lambda = 30$ m, the skin effect limits penetration of the external field. This phenomenon is fundamentally different from the small ratio of internal to external E fields described in Equation 0.4 (applicable to dc) and Equation 0.9.

Equation 0.9 expresses a ''boundary condition'' applicable at all frequencies, but as the angular frequency ω increases (and in view of the rapid decrease with frequency of the dielectric permittivity ε_2 in biological materials—see Chapter 3 of *BBA*, the ratio of the normal component of the external to the internal E field at the boundary decreases

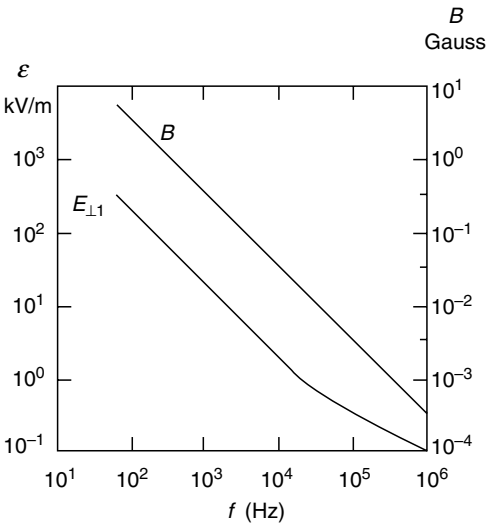

FIGURE 0.8
External E and H field required to obtain an internal E field of 10 mV/m (conductivity and dielectric permittivity for skeletal muscle from Foster, K.R., Schepps, J.L., and Schwan, H.P. 1980. *Biophys. J.*, 29:271–281. H-field calculation assumes a circular path of 0.1-m radius perpendicular to magnetic flux).

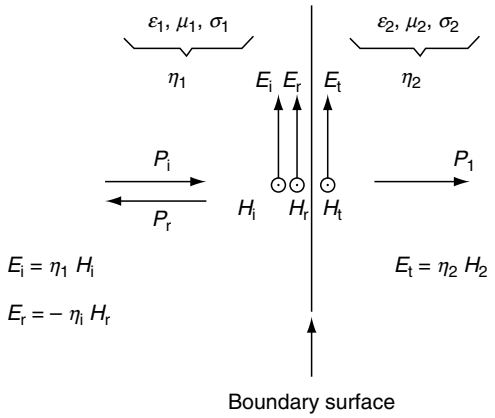

FIGURE 0.9
Reflection and transmission of an electromagnetic wave at the boundary between two different media, perpendicular incidence; P_i = incident power, P_r = reflected power, P_t = transmitted power.

with increasing frequency. This is illustrated by Figure 0.10 where $\tan\theta_1/\tan\theta_2$ is also equal to $E_{\perp 1}/E_{\perp 2}$ in view of Equation 0.3, Equation 0.5, and Equation 0.9. However, at low frequencies the total field inside the boundary can be somewhat larger than the perpendicular field at the boundary; and any field variation with distance from the boundary is not primarily due to energy dissipation, but in a homogeneous body is a consequence of shape. At RF, on the other hand, the E and H fields of the incoming

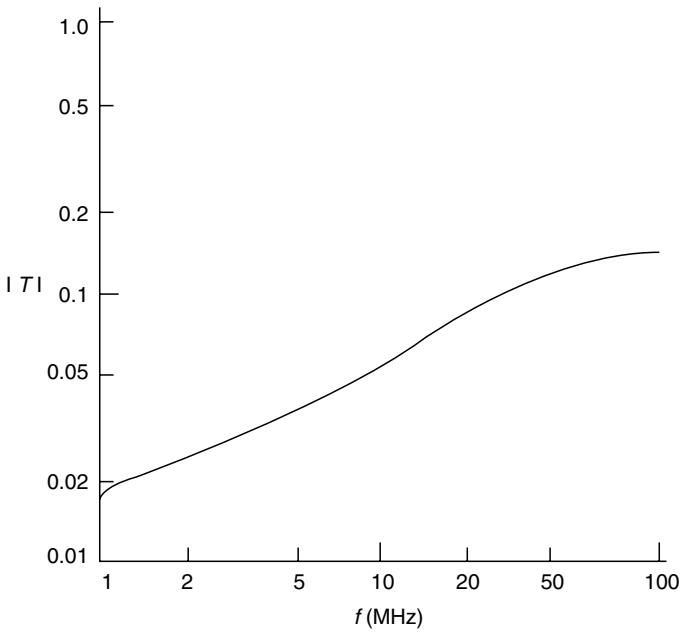

FIGURE 0.10
Magnitude of transmission coefficient T for incident E field parallel to boundary surface. $T = E_t/E_i$: reflection coefficient $r = E_r/E_i = T\text{-}1$. Γ and T are complex numbers; ε_r and σ for skeletal muscle from Chapter 3 in *BBA*.

electromagnetic wave, after reflection at the boundary, are further decreased due to energy dissipation. Both E and H fields decrease exponentially with distance from the boundary

$$g(z) = Ae^{-\frac{z}{\delta}} \tag{0.16}$$

where $g(z)$ is the field at the distance z and A is the magnitude of the field just *inside* the boundary.

As defined by Equation 0.16 the skin depth δ is the distance over which the field decreases to $1/e$ ($= 0.368$) of its value just *inside* the boundary. (Due to reflection, the field A just inside the boundary can already be very much smaller than the incident external field; see Figure 0.8 and Figure 0.9.)

Expressions for δ given below were derived [2,3,13,14] for plane boundaries between infinite media. They are reasonable accurate for cylindrical structures if the ratio of radius of curvature to skin depth (r_0/δ) is larger than about five [13]. For a good conductor

$$\delta = \frac{1}{\sqrt{\pi f \mu \sigma}} \tag{0.17}$$

where a good conductor is one for which the ratio p of conduction current, $J = \sigma E$, to displacement current, $\partial D/\partial t = \varepsilon\,(\partial E/\partial t) = j\omega\varepsilon E$ is large:

$$p = \frac{\sigma}{\omega\varepsilon} \gg 1 \tag{0.18}$$

Since for most biological materials p is of the order of one ($0.1 < p < 10$) over a very wide frequency range (see Chapter 3 of *BBA*), it is frequently necessary to use the more general expression [13]

$$\delta = \frac{1}{\omega\left[\frac{\mu\varepsilon}{2}(\sqrt{1+p^2}-1\right]^{1/2}} \tag{0.19}$$

The decrease of field intensity with distance from the boundary surface indicated by Equation 0.16 becomes significant for many biological objects at frequencies where $r_0/\delta \geq 5$ is not satisfied. However, the error resulting from the use of Equation 0.16 and Equation 0.17 or Equation 0.19 with curved objects is less when $z < \delta$. Thus at $z = 0.693\,\delta$, where $g(z) = 0.5$ A from Equation 0.16 and Equation 0.17, the correct values of $g(z)$, obtained by solving the wave equation in cylindrical coordinates, differs only by 20% (it is 0.6 A) even when r_0/δ is as small as 2.39 [14]. Therefore, Figure 0.10 shows the distance $d = 0.693\,\delta$, at which the field decreases to half of its value just inside the boundary surface, using Equation 0.19 with typical values for σ and ε for muscle from Figure 0.11. It is apparent that the skin effect becomes significant for humans and larger vertebrates at frequencies >10 MHz.

Directly related to skin depth, which is defined for fields varying sinusoidally with time, is the fact that a rapid transient variation of an applied magnetic flux density constitutes an exception to the statement that the dc H field inside the boundary is equal to the H field outside. Thus, from one viewpoint one may consider the rapid application or removal of a dc H field as equivalent to applying a high-frequency field during the switching period, with the highest frequencies present of the order of $1/\tau$, where τ is the rise time of the applied step function. Thus, if $\tau < 10^{-8}$ s, the skin effect will be important during the transient period, as d in Figure 0.5 is <5 cm above 100 MHz. It is also possible to calculate directly the magnetic flux density inside a conducting cylinder as a function of radial position r and time t when a magnetic pulse is applied in the axial

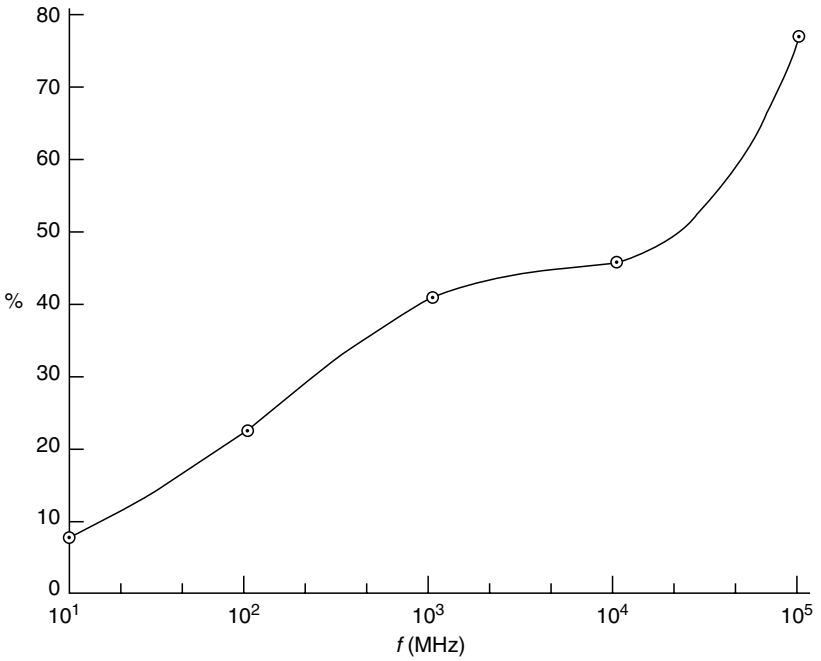

FIGURE 0.11
Ratio of transmitted to incident power expressed as percent of incident power. Air–muscle interface, perpendicular incidence (Equation 0.31, Table 0.1).

direction [15,16]. Assuming zero rise time of the applied field B_0, i.e., a true step function, one finds that the field inside a cylinder of radius a is

$$B = B_0\left[1 - \sum_{k=1}^{\infty} J_0\left(r\frac{v_k}{a}\right)\mathrm{e}^{-t/T_k}\right] \tag{0.20}$$

where $J_0\,(r\,v_k/a)$ is the zero-order Bessel function of argument $r\,v_k/a$ and the summation is over the nulls of J_0 designated v_k (the first four values of v_k are 2.405, 5.520, 8.654, and 11.792).* T_k is the rise time of the kth term in the series and is given by

$$T_k = \frac{\mu_0 \sigma a^2}{v_k} \tag{0.21}$$

As v_k increases, the rise time decreases and therefore the longest delay is due to the first term in the summation with $k = 1$

$$T_1 = \frac{\mu_0 \sigma a^2}{2.405} \tag{0.22}$$

For a cylinder with 0.1 m radius and a conductivity $\sigma \approx 1$ S/m, which is a typical value for muscle between 100 and 1000 MHz, Equation 0.22 gives $T_1 = 2.6 \times 10^{-8}$ s. This finite rise time (or decay time in case of field removal) of the internal H field may be of some importance when pulsed H fields are used therapeutically [17]. It might also be used

*This result is based on solution of $\partial B/\partial t = (1/\mu_0)\nabla^2 B$, which is a consequence of Ampere's and Farraday's laws when displacement is disregarded. Equations 0.20 to 0.22 are therefore only correct when $\mathrm{p} \gg 1$.

to measure noninvasively the conductivity of biological substances *in vivo* through determination of the final decay rate of the voltage induced into a probe coil by the slowly decaying internal field after the applied field is removed [16].

The properties of biological substances in the intermediate frequency range, above ELF (>300 Hz), and below the higher RFs, where wave behavior and skin effect begin to be important (~20 MHz), are discussed in Chapter 3 of *BBA*. However, many subsequent chapters are concerned with biological effects at dc and ELF frequencies below a few kilohertz, while others deal primarily with the higher RFs, >50 MHz. One reason for this limited treatment of the intermediate frequency range is that very little animal data are available for this spectral region in comparison with the large number of experiments performed at ELF and microwave frequencies in recent years.* Another reason is that most electrical processes known to occur naturally in biological systems—action potentials, EKG, EEG, ERG, etc.—occur at dc and ELF frequencies. Therefore, one might expect some physiological effects from external fields of appropriate intensity in the same frequency range, even if the magnitude of such fields is not large enough to produce thermal effects. As illustrated by Figure 0.3 and Figure 0.7, most *E* fields below 100 kHz set up by currently used human-made devices, and most *H* fields below 10 kHz except the very strongest, are incapable of producing thermal effects in living organisms, excluding, of course, fields accompanying currents directly introduced into the organism via electrodes. Thus, the frequencies between about 10 and 100 kHz have been of relatively little interest because they are not very likely to produce thermal or other biological effects. On the other hand, the higher RFs are frequently generated at power levels where enough energy may be introduced into living organisms to produce local or general heating. In addition, despite skin effect and the reflection loss to be discussed in more detail below, microwaves modulated at an ELF rate may serve as a vehicle for introducing ELF fields into a living organism of at least the same order of magnitude as would be introduced by direct exposure to ELF. Any effect of such ELF-modulated microwaves would, of course, require the existence of some amplitude-dependent demodulation mechanism to extract the ELF from the microwave carrier.

Among the chapters dealing with RF, Chapter 10 and Chapter 11 of *BBA* give the necessary information for establishing the magnitude of the fields present in biological objects: (1) experimental techniques and (2) analytical methods for predicting field intensities without construction of physical models made with ''phantom'' materials, i.e., dielectric materials with properties similar to those of living objects which are to be exposed. As thermal effects at microwave frequencies are certainly important, although one cannot assume *a priori* that they are the only biological effects of this part of the spectrum, and as some (but not all) thermal effects occur at levels where the thermoregulatory system of animals is activated, thermoregulation in the presence of microwave fields is discussed in Chapter 5 of *BMA*, as well as in Chapter 10 of *BBA*. Not only are the therapeutic applications of microwaves based upon their thermal effects, but also the experimental establishment of possible nonthermal effects at the threshold of large scale tissue heating in particular living systems and also requires thorough understanding of thermoregulatory mechanisms. The vast amount of experimental data obtained on animal systems exposed to microwave is discussed in Chapter 3 and Chapter 4 in *BMA*. Both nonmodulated fields and modulated fields, where the type of modulation had no apparent effect other than modification of the average power level, are considered. These chapters and the Chapter 9 in *BMA* are considered to be very new extension of experiments into exposures to ultra-short and to ultra-high power pulses.

*Though this statement was written in for the second edition in 1995, it continues to be true in 2005—Ben Greenebaum.

At the higher RFs, the external E field is not necessarily perpendicular to the boundary of biological materials (see Figure 0.4 and Figure 0.10), and the ratio of the total external E field to the total internal field is not given by Equation 0.9. However, the skin effect (Equation 0.16 through Equation 0.19) and reflection losses still reduce the E field within any biological object below the value of the external field. As pointed out in Chapter 3, dielectric permittivity and electrical conductivity of organic substances both vary with frequency. At RF, most biological substances are neither very good electrical conductors nor very good insulators, with the exception of cell membranes, which are good dielectrics at RF but at ELF can act as intermittent conductors or as dielectrics and are ion-selective [18–20]). The ratio p (Equation 0.18) is neither much smaller nor very much larger than values shown for typical muscle tissue [21,22] in Table 0.1.

Reflection loss at the surface of an organism is a consequence of the difference between its electrical properties and those of air. Whenever an electromagnetic wave travels, from one material to another with different electrical properties, the boundary conditions (Equation 0.3 and Equation 0.8) and similar relations for the H field require the existence of a reflected wave. The expressions for the reflection coefficient

$$\Gamma = \frac{E_r}{E_i} \tag{0.23}$$

and the transmission coefficient

$$T = \frac{E_t}{E_i} \tag{0.24}$$

become rather simple for loss-free dielectrics ($p \ll 1$) and for good conductors ($p \gg 1$). As biological substances are neither the most general expressions for Γ and T, applicable at plane boundaries, are needed [3,13]. For perpendicular incidence, illustrated by Figure 0.8,

$$\Gamma = \frac{\eta_2 - \eta_1}{\eta_2 + \eta_1} \tag{0.25}$$

$$T = \frac{2\eta_2}{\eta_2 + \eta_1} = 1 + \Gamma \tag{0.26}$$

TABLE 0.1

Ratio p of Conduction Current to Displacement as a Function of Frequency

f (MHz)	σ	ε_r	$p = \frac{\sigma}{\omega\varepsilon_0\varepsilon_r}$
1	0.40	2000	3.6
10	0.63	160	7.1
100	0.89	72	2.2
10^3	1.65	50	0.59
10^4	10.3	40	0.46
10^5	80	6	2.4

where η_1 and η_2 are the wave impedances, respectively, of mediums 1 and 2. The wave impedance of a medium is the ration of the E to the H field in a plane wave traveling through that medium; it is given by [13]

$$\eta = \left(\frac{j\omega\mu}{\sigma + j\omega\varepsilon}\right)^{1/2} \tag{0.27}$$

Clearly Γ and T are in general complex numbers, even when medium 1 is air for which Equation 0.27 reduces to the real quantity $\eta_0 = \sqrt{\mu_0/\varepsilon_0}$, because medium 2, which here is living matter, usually has a complex wave impedance at RFs.

The incident, reflected, and transmitted powers are given by [13]

$$P_i = R_1|E_i|^2\frac{1}{\eta_1^*} = \frac{|E_i|^2}{|\eta_1|^2}R_1 \tag{0.28}$$

$$P_r = R_1|E_r|^2\frac{1}{\eta_1^*} = \frac{|E_r|^2}{|\eta_1|^2}R_1 \tag{0.29}$$

$$P_t = R_1|E_t|^2\frac{1}{\eta_2^*} = \frac{|E_t|^2}{|\eta_2|^2}R_2 \tag{0.30}$$

where the E fields are effective values ($E_{\text{eff}} = E_{\text{peak}}/\sqrt{2}$) of sinusoidal quantities, R_1 signifies ''real part of,'' η^* is the complex conjugate of η, and R_1 and R_2 are the real parts of η_1 and η_2. If medium 1 is air, $\eta_1 = R_1 = 377\ \Omega$, it follows from Equation 0.23, Equation 0.24, and Equation 0.28 through Equation 0.30 and conservation of energy that the ratio of the transmitted to the incident real power is given by

$$\frac{P}{P_1} = |T|^2\frac{\eta_1\eta_2^* + \eta_1^*\eta_2}{2|\eta_2|^2} = 1 - \frac{P_r}{P_i} = 1 - |\Gamma|^2 \tag{0.31}$$

The magnitude of the transmission coefficient T for the air–muscle interface over the 1- to 100-MHz frequency range is plotted in Figure 0.9, which shows that the magnitude of the transmitted E field in muscle tissue is considerably smaller than the E field in air. The fraction of the total incident power that is transmitted (Equation 0.31) is shown in Figure 0.11, indicating clearly that reflection loss at the interface decreases with frequency. However, for deeper lying tissue this effect is offset by the fact that the skin depth δ (Equation 0.19) also decreases with frequency (Figure 0.12) so that the total power penetrating beyond the surface decreases rapidly.

In addition to reflection at the air–tissue boundary, further reflections take place at each boundary between dissimilar materials. For example, the magnitude of the reflection coefficient at the boundary surface between muscle and organic materials with low-water content, such as fat or bone, is shown in Table 0.2.

The situation is actually more complicated than indicated by Figure 0.9 and Figure 0.11, because the wave front of the incident electromagnetic wave may not be parallel to the air–tissue boundary. Two situations are possible: the incident E field may be polarized perpendicular to the plane of incidence defined in Figure 0.13 (perpendicular polarization, Figure 0.13a) or parallel to the plane of incidence (parallel polarization, Figure 0.13b). The transmission and reflection coefficients [8] are different for the two types of polarization and also become functions of the angle of incidence α_1:

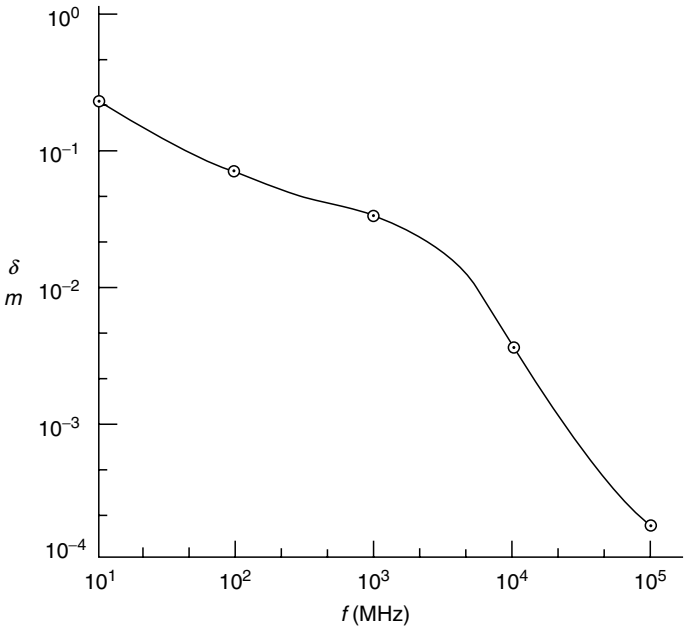

FIGURE 0.12
Electromagnetic skin depth in muscle tissue from plane wave expression (Equation 0.19, Table 0.1).

$$\text{Perpendicular polarization}\begin{cases} T_{\perp} = \dfrac{2\eta_2 \cos\alpha_1}{\eta_2 \cos\alpha_1 + \eta_1 \cos\alpha_2} \\ \Gamma_{\perp} = \dfrac{\eta_2 \cos\alpha_1 - \eta_1 \cos\alpha_2}{\eta_2 \cos\alpha_1 + \eta_1 \cos\alpha_2} \end{cases} \quad (0.32),(0.33)$$

$$\text{Parallel polarization}\begin{cases} T_{\mathrm{p}} = \dfrac{2\eta_2 \cos\alpha_1}{\eta_2 \cos\alpha_2 + \eta_1 \cos\alpha_1} \\ \Gamma_{\mathrm{p}} = \dfrac{\eta_1 \cos\alpha_1 - \eta_2 \cos\alpha_2}{\eta_2 \cos\alpha_2 + \eta_1 \cos\alpha_1} \end{cases} \quad (0.34),(0.35)$$

where α_2 is given by the generalized Snell's law (when both the media have the magnetic permeability of free space) by

TABLE 0.2
Reflection Coefficient ''Capital Gamma'' for Low–Water-Content Materials

	Fat or Bone		
f (MHz)	σ (S/m)	ε_r	Muscle[a]–Fat (Γ)
10^2	0.048	7.5	0.65

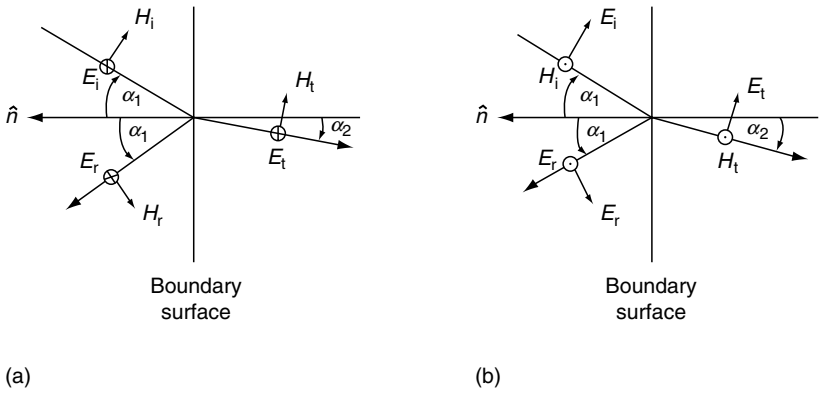

FIGURE 0.13
Oblique incidence of an electromagnetic wave at the boundary between two different media. (a) Perpendicular polarization (E vector perpendicular to plane of incidence); (b) parallel polarization (E vector parallel to plane of incidence). The plane of incidence is the plane formed by the surface normal (unit vector **n** and the direction of the incident wave); $\otimes$ indicates a vector into the plane of the paper; $\odot$ indicates a vector out of the plane of the paper. The orientation of the field vectors in the transmitted field is shown for loss-free dielectrics. For illustration of the transmitted wave into a medium with finite conductivity, where the wave impedance η_2 becomes a complex number, see Stratton, J.A., *Electromagnetic Theory*, McGraw-Hill, New York, 1941, p. 435.

$$\sin\alpha_2 = \frac{\sqrt{\varepsilon}_1}{\sqrt{\varepsilon_2 - \mathrm{j}\frac{\sigma_2}{\omega}}} \tag{0.36}$$

so that $\cos\alpha_2 = \sqrt{1-\sin^2\alpha_2}$ is a complex number unless $\rho_2 = (\sigma_2/\omega\varepsilon_2) = 1$.

As illustration, the variation with angle of incidence of the transmission coefficient for parallel polarization at the air–muscle interface at 10 MHz, is shown in Figure 0.14. It is apparent that the transmitted field is not necessarily maximized by perpendicular incidence in the case of parallel polarization. Furthermore, whenever $p \approx 1$ or $p > 1$ (see Table 0.1, above), α_2 is complex, which causes the waves entering the tissue to be inhomogeneous—they are not simple plane waves, but waves where surfaces of constant phase and constant amplitude do not coincide [3,23]; only the planes of constant amplitude are parallel to the boundary surface.

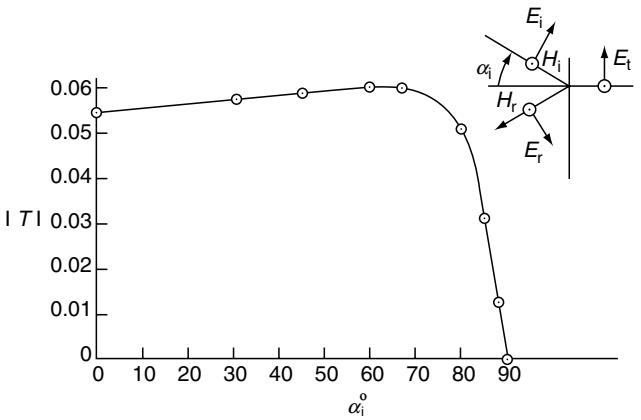

FIGURE 0.14
Magnitude of complex transmission coefficient for parallel polarization versus angle of incidence α_1 at 10 MHz (E field in plane of incidence, H field parallel to boundary plane; $\sigma_2 = 0.7\,\mathrm{S/m}$, $\varepsilon_{r2} = 150$, $T = E_t/E_r$).

Analytical solutions for nonplanar structures taking into account size and shape of entire animals have been given [24] and are also described in the RF modeling Chapter 10 of *BBA*.

0.5 Biophysical Interactions of Fields: Ionization, Ionizing Radiation, Chemical Bonds, and Excitation

RF fields can be characterized as nonionizing radiation. By this we mean that there is not enough energy in a single quantum of energy, hf, to ionize an atom or a molecule at RFs, where h is Planck's constant and f is the frequency. By comparison radiation in the UV or x-rays often lead to ionization. It is desirable to begin by reviewing the differences between ionizing and nonionizing radiations, to explain ionization phenomena and also to discuss related excitation phenomena, which require less energy than ionization. Then a number of the proposed models concerning atomic or molecular-level interactions of fields will be introduced. A number of these theories will be discussed and their predictions compared with experimental results in later chapters, including Chapter 5 through Chapter 7 and Chapter 9 in *BBA*; Chapter 9 and Chapter 11 in *BMA*. Heating, cell excitation, electroporation, and other results of high-intensity fields have been accepted as explanations for many bioelectromagnetic phenomena. For low-intensity exposure, however, no theory is widely accepted as a general explanation for bioelectromagnetic phenomena, and few specific phenomena have accepted explanations. It is quite possible that no general explanation exists and that more than one mechanism of interaction between fields will be found to be operating, depending on the situation. Binhi's book [25] contains a good summary of most recent theoretical proposals, including comparisons with data and critiques of their strong and weak points, as well as his own theory.

We note first that the energy of electromagnetic waves is quantized with the quantum of energy (in joules) being equal to Planck's constant ($h = 6.63 \times 10^{-34}$ J s) times the frequency. This energy can also be expressed in electron volts, i.e., in multiples of the kinetic energy acquired by an electron accelerated through a potential difference of 1 eV (1 eV $\approx 1.6 \times 10^{-19}$ J). Energy quanta for a few frequencies are listed in Table 0.3.

Quantized energy can ''excite'' molecules; appropriate frequencies can couple to vibrational and rotational oscillation; and if the incident energy quantum has sufficient magnitude it can excite other changes in the electron configuration, such as changing an electron to another (unoccupied) energy level or tearing an electron away from one of the constituent atoms, the latter process called as ionization. The energy required to remove one electron from the highest energy orbit of a particular chemical element is called its ''ionization potential.'' Typical ionization potentials are of the order 10 eV; for example, for the hydrogen atom it is 13.6 eV and for gaseous sodium it is 5.1 eV. As chemical binding forces are essentially electrostatic, ionization implies profound chemical changes. Therefore ionization by any outside agent of the complex compounds that make up a living system leads to profound and often irreversible changes in the operation of that system.

Table 0.3 shows that even the highest RF (millimeter waves) has quantum energies well below the ionization potential of any known substance; thus one speaks of nonionizing radiation when referring to electromagnetic waves below UV light frequencies. Ionizing radiation includes UV and higher frequency electromagnetic waves (x-rays, γ-rays).

TABLE 0.3

Wave and Quantum Characteristics of Various Types of Radiation

Name of Radiation or Application	Frequency (Hz)	Wavelength (m)	Energy of 1 Quantum of Radiation (eV)
UHF TV	7×10^8	0.43	2.88×10^{-6}
Microwave radar	10^{10}	3×10^{-2}	4.12×10^{-5}
Millimeter wave	3×10^{11}	1×10^{-3}	1.24×10^{-3}
Visible light	6×10^{14}	5×10^{-7}	2.47
Ionizing UV	10^{16}	3×10^{-4}	41.2
Soft x-ray	10^{18}	3×10^{-10}	4120
Penetrating x-ray	10^{20}	3×10^{-12}	4.12×10^5

This explanation of the difference between ionizing and nonionizing radiation should not imply that nonionizing electromagnetic radiation cannot have profound effects upon inorganic and organic substances. As excitation of coherent vibrational and rotational modes requires considerably less energy than ionization, it could occur at RF; this will be discussed in later chapters. In addition, many other possible biological effects require energies well below the level of ionizing potentials. Examples are tissue heating, dielectrophoresis, depolarization of cell membranes, mechanical stress due to piezoelectric transduction, or dielectric saturation, resulting in the orientation of the polar side chains of macromolecules and leading to the breaking of hydrogen bonds. These and other mechanisms will be discussed by the authors of several chapters (see especially Chapter 5 through Chapter 7 of *BBA* and Chapter 9 of *BMA*), who will also give estimates of rates at which energy must be delivered to produce particular effects.

Returning to the discussion of ionization, it is important to note that ionization of a chemical element can be brought about not only by absorption of electromagnetic energy, but also by collision either with foreign (injected) atoms, molecules, or subatomic particles of the requisite energy, or by sufficiently violent collision among its own atoms. The latter process constitutes ionization by heating, or thermal breakdown of a substance, which will occur when the kinetic energy of the colliding particles exceeds the ionization potential. As the average thermal kinetic energy of particles is related to temperature [26] by $W = kT$ where k is Boltzmann's constant ($= 1.38 \times 10^{-23}$ J/K), we find that the required temperature is

$$1.38(10^{-23})T \approx 5 \text{ eV} \approx (5)1.6(10^{-19}) \text{ J}$$

$$T \approx 5(10^4) \text{ K}$$

which is about twice the temperature inside a lightning stroke [27] and orders of magnitude higher than any temperature obtainable from electromagnetic waves traveling through air.

Actually, initiation of lightning strokes is an example of ionization by collision with injected energetic particles. The few free electrons and ions always present in the air due to ionization by cosmic rays are accelerated by the E fields generated within clouds to velocities corresponding to the required ionization energy. Only when the field is large enough to impart this energy over distances shorter than the mean free path of the free electrons or ions at atmospheric pressure can an avalanche process take place: an accelerated electron separates a low-energy electron from the molecule with which it collides and in the process loses most of its own energy; thus, one high-energy free electron is exchanged for two free low-energy electrons and one positive ion. Both the

electrons are in turn accelerated again by the field, giving them high kinetic energy before they collide with neutral molecules; their collision produces four free electrons and the multiplication process continues. The breakdown field strength for air at atmospheric pressure is approximately 3×10^6 V/m, implying a mean free path of electrons

$$\Delta\ell \approx [5\,\text{eV}/3 \times 10^6\,\text{V/m}] \approx 10^{-6}\,\text{m}$$

However, this model is not entirely accurate because the actual mean free path corresponds to energies of the order of 0.1 eV, which is only sufficient to excite vibrational modes in the target molecule. Apparently such excitation is sufficient to cause ionization if the collision process lasts long enough [28].

Except for some laboratory conditions where a sufficiently high potential difference can be applied directly across a biological membrane to bring about its destruction, collisional ionization is generally not a factor in the interaction of electromagnetic waves with tissue: The potential difference required for membrane destruction [29] is between 100 nV and 300 mV, corresponding to a field strength of the order of 2×10^7 V/m, assuming a membrane thickness ($d = 100$ Å; $E = V/d$). However, there is a third mechanism of ionization that is particularly important in biological systems. When a chemical compound of the type wherein positive and negative ions are held together by their electrostatic attraction, such as the ionic crystal NaCl, is placed in a suitable solvent, such as H_2O, it is separated into its ionic components. The resulting solution becomes an electrolyte, i.e., an electrically conducting medium in which the only charge carriers are ions.

In this process of chemical ionization, the Na^+ cations and Cl^- anions are separated from the original NaCl crystal lattice and individually surrounded by a sheet of solvent molecules, the ''hydration sheath.'' If the solvent is H_2O, this process is called ''hydration,'' or more generally, for any solvent, ''solvation.''

A dilute solution of NaCl crystals in H_2O is slightly cooler than the original constituents before the solvation process, indicating that some internal energy of the system was consumed. Actually energy is consumed in breaking up the original NaCl bonds and some, but less, is liberated in the interaction between the dipole moment of the solvent molecule (H_2O in our example) and the electric charges on the ions. Thus, solvents with higher relative dielectric constant ε_r, indicating higher inherent electric dipole moment per unit volume (P), solvate ions more strongly ($\varepsilon_r = 1 + P/[\varepsilon_o E]$, where E is the electric field applied during the measurement of ε_r). For example, H_2O with $\varepsilon_r \approx 80$ solvates more strongly than methanol with $\varepsilon_r \approx 33$. For biological applications it is worth noting that solvation may affect not only ionic substances, but also polar groups, i.e., molecular components which have an inherent dipole moment, such as—C=O, —NH, or —NO_2. Details of the process are discussed in texts on electrochemistry [30,31].

In biological processes not only chemical ionization and solvation of ionic compounds, but also all kinds of chemical reaction take place. One of the central questions in the study of biological effects of E and H fields is therefore not only whether they can cause or influence ionization, but also whether they can affect—speed up, slow down, or modify—any naturally occurring biologically important chemical reaction.

In Table 0.4 typical energies for various types of chemical bonds are listed. For comparison the thermal energy per elementary particle at 310 K is also shown. Complementing the numbers in Table 0.4 one should also point out that:

1. The large spread in the statistical distribution of energies of thermal motion guarantees that at physiological temperatures some molecules always have sufficient energy to break the strongest weak bonds [32].

TABLE 0.4

Bond and Thermal Energies

Type of Bond	Change in Free Energy (Binding Energy) kcal/mol	eV/Molecule
Covalent	50–100	2.2–4.8
Van der Waals	1–2	0.04–0.08
Hydrogen	3–7	0.13–0.30
Ionic[a]	5	0.2
Avg. thermal energy at 310 K	0.62	0.027

[a]For ionic groups of organic molecules such as COO^-, $NH3_3^-$ in aqueous solution.

2. The average lifetime of a weak bond is only a fraction of a second.
3. The weak binding forces are effective only between the surfaces in close proximity and usually require complementary structures such as a (microscopic) plug and hole, such as are thought to exist, for instance, between antigen and antibody [33].
4. Most molecules in aqueous solution form secondary bonds.
5. The metabolism of biological systems continuously transforms molecules and therefore also changes the secondary bonds that are formed.

Comparison of the last columns in Table 0.3 and Table 0.4 shows that millimeter waves have quantum energies, which are only about one order of magnitude below typical Van der Waals energies (waves at a frequency of 10^{12} Hz with a quantum energy of 0.004 eV have a wavelength of 0.3 mm and can still be classified as millimeter waves). One might expect therefore that such waves could initiate chemically important events, such as configurational changes, by e.g., multiple transitions between closely spaced vibrational states at successively high-energy levels [46].

Energies associated with transition from one to another mode of rotation of a diatomic molecule are given by $W = \ell\,(\ell + 1)\,A$ [26,33], where $\ell = 0, 1, 2, 3 \ldots$ and $A = 6 \times 10^{-5}$ eV; thus an electromagnetic wave with a frequency as low as 29 GHz—still in the microwave region—can excite a rotational mode. Vibrational modes of diatomic molecules [26,33] correspond to energies of the order of 0.04 eV, requiring excitation in the IR region. Vibrational frequencies in a typical H-bonded system [34] are of the order of 3000 GHz; however, attenuation at this frequency by omnipresent free H_2O may prevent any substantial effect [34].

Kohli et al. [34] predict that longitudinal and torsional modes of double helical DNA should not be critically damped at frequencies >1 GHz, although relaxation times are of the order of picoseconds, and Kondepudi [36] suggests the possibility of an influence of millimeter waves at approximately 5×10^{11} Hz upon oxygen affinity of hemoglobin due to resonant excitation of heme plane oscillations. Although Furia et al. [37] did not find resonance absorption at millimeter waves in yeast, such was reported by Grundler et al. [38,47]. The latter experiment has been interpreted [39,40] as supporting Fröhlich's theory of cooperative phenomena in biological systems. That theory postulates ''electric polarization waves'' in biological membranes which are polarized by strong biologically generated [18] fields (10^7 V/m). Fröhlich [41,42] suggests that metabolically supplied energy initiates mechanical vibrations of cell membranes. The frequency of such vibrations is determined by the dimensions and the elastic constants of the membranes;

based on an estimate of the sound velocity in the membrane of 10^3 m/s and a membrane thickness of 100 Å (equal to one half wavelength) one obtains a frequency of $5(10^{10})$ Hz. Individual molecules within and outside the membrane may also oscillate, and frequency estimates vary between 10^9 Hz for helical RNA [43] and 5×10^{13} Hz for hydrogen-bonded amide structures [44]. As the membranes and molecules involved are strongly polarized, the mechanically oscillating dipole electromagnetic fields that are able to transmit energy, at least in some situations, over distances much larger than the distance to the next adjacent molecule.

Electromagnetic coupling of this type may produce long-range cooperative phenomena. In particular, Fröhlich [45] has shown that two molecular systems may exert strong forces upon each other when their respective oscillation frequencies are nearly equal, provided the dielectric permittivity of the medium between them is strongly dispersive or excitation is supplied by pumping, i.e., by excitation at the correct frequency from an external source. The mechanism is nonlinear in the sense that it displays a steplike dependence on excitation intensity. Possible long-range effects may be, for example, attraction between enzyme and substrate [42]. These and related topics have been discussed in detail by Illinger [34] and are reviewed in the present volume in Chapter 11 and Chapter 5 of *BBA*.

Environmental and Occupationally Encountered Electromagnetic Fields

Kjell Hansson Mild and Ben Greenebaum

CONTENTS

1.1 Introduction

We encounter electromagnetic (EM) fields every day, both naturally occurring and man-made fields. This leads to exposure both in our homes as well as in our various

workplaces, and the intensity of the fields varies substantially with the situation. Quite high exposure can occur in some of our occupations as well as our personal activities, for instance, in trains, where the extremely low-frequency (ELF) magnetic field can reach rather high levels. The frequency of the fields we are exposed to covers a wide range, from slowly changing static fields to the gigahertz range.

In this chapter, we give an overview of the fields we encounter in various situations.

1.2 Direct Current and ELF (0–3000 Hz) EM Fields

1.2.1 Naturally Occurring Fields

The most obvious naturally occurring field is the Earth's magnetic field, known since ancient times. The total field intensity diminishes from the poles, with a high of 67 μT at the south magnetic pole and a low of about 30 μT near the equator. In South Brazil, an area with flux densities as low as about 24 μT can be found. Indeed, the angle of the Earth's field to the horizontal (inclination) varies, primarily with latitude, ranging from very small near the equator to almost vertical at high latitudes. More information is available in textbooks (see, e.g., Dubrov [1]) and in databases available on the Web (see, e.g., the U.S. National Geophysical Data Center [2]).

However, the geomagnetic field is not constant, but is continuously subject to more or less strong fluctuations. There are diurnal variations, which may be more pronounced during the day and in summer than at night and in winter (see, e.g., König et al. [3]). There are also short-term variations associated with ionospheric processes. When the solar wind brings protons and electrons toward the Earth, phenomena like the Northern Lights and rapid fluctuations in the geomagnetic field intensity occur. The variation can be rather large; the magnitude of the changes can sometimes be up to 1 μT on a timescale of several minutes. The variation can also be very different in two fairly widely separated places because of the atmospheric conditions. There is also a naturally occurring direct current (DC) electric field at the surface of the Earth in the order of 100–300 V/m (Earth's surface negative) in calm weather and can be 100 kV/m in thunderstorms, caused by atmospheric ions [4].

EM processes associated with lightning discharges are termed as atmospherics or ''sferics'' in short. They consist mostly of waves in the ELF (strictly speaking 30–300 Hz but usually taken in the bioelectromagnetics literature to extend from 0 to 3000 Hz) and very low-frequency (VLF) ranges (3–30 kHz) (see König et al. [3]). Each second about 100 lightning discharges occur globally, and in the United States one cloud-to-ground flash occurs about every second, averaged over the year [3]. The ELF and VLF signals travel efficiently in the waveguide formed by the Earth and the ionosphere and can be detected many thousands of kilometers from the initiating stroke. Since 1994, several experiments studying the effects of short-term exposure to simulated 10-kHz sferics have been performed at the Department of Clinical and Physiological Psychology at the University of Giessen, Germany [5,6]. In the ELF range, very low-intensity signals, called Schumann resonances, also occur. These are caused by the ionosphere and the Earth's surface acting as a resonant cavity, excited by lightning [3,7] (see also http://www.oulu.fi/~spaceweb/textbook/schumann.html). These cover the low-frequency spectrum, with broad peaks of diminishing amplitude at 7.8, 14, 20, and 26 Hz and higher frequencies. Higher-frequency fields, extending into the microwave region, are also present in atmospheric or intergalactic sources. These fields are much weaker, usually by many

orders of magnitude, than those caused by human activity (compare Figure 1.1 and subsequent tables and figures in this chapter).

1.2.2 Artificial DC and Power Frequency EM Fields in the Environment

1.2.2.1 DC Fields

Although alternate current (AC) power transmission is facilitated by the availability of transformers to change voltages, DC is also useful, especially since high-power, high-efficiency solid-state electronic devices have become available. Overland high-voltage DC lines running at up to ± 1100 kV are found in Europe, North America, and Asia [8] (see also, e.g., http://www.answers.com/topic/high-voltage-direct-current, accessed on August 17, 2005). Electric and magnetic fields near these lines are essentially the same as those for AC lines running at the same voltages and currents, which are discussed below. Because potentials on the cables do not vary in time and there are only two DC conductors ($+$ and $-$) instead of the three AC phases, the DC electric fields and space charge clouds of air ions that partially screen them are somewhat different from those near AC transmission lines, though the general features are the same, especially for positions away from the lines. Electric fields, corona, and air ions are discussed further in the AC transmission line section below; see also Refs. [9,10].

For transfer of electric power between countries separated by sea, undersea power cables are especially useful, since their higher capacity causes increased losses in AC.

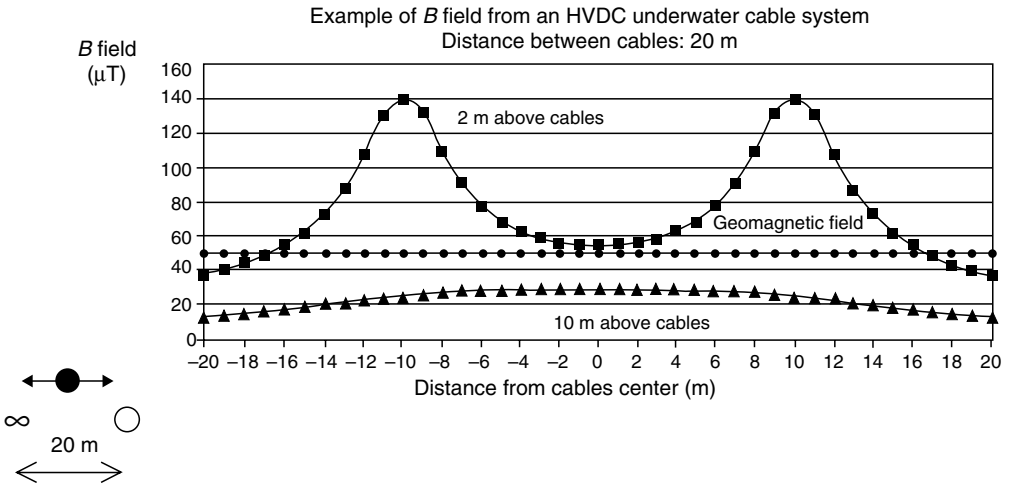

FIGURE 1.2
Predicted DC magnetic field from a high-voltage DC cable with the return cable placed at a distance of 20 m. The current in the cable was assumed to be 1333 A, which is the maximum design current. (From Hansson Mild, K. In Matthes, R., Bernhardt, J.H., and Repacholi, M.H., Eds. Proceedings from a joint seminar, *International Seminar on Effects of Electromagnetic Fields on the Living Environment*, of ICNIRP, WHO, and BfS, Ismaning, Germany, October 4–5, 1999, pp. 21–37. With permission.)

Examples are cables between Sweden and Finland, Denmark, Germany, and Gotland, a Swedish island in the Baltic Sea. Under construction at present is a cable from Sweden to Poland (SwePol). In these cables DC is used, and the ELF component of the current is less than a few tenths of a percent. The maximum current in these cables is slightly above 1000 A, and the estimated normal load is about 30% or 400 A. Depending on the location of the return path, the DC magnetic field will range from a maximum disturbance of the geomagnetic field (with a return through water) to a minimal disturbance (with a return through a second cable as close as possible to the feed cable). With a closest distance of 20 m between the cables, the predicted field distribution can be seen in Figure 1.2, immediately above the cables (2 m), practically the same value as that obtained for a single wire. When the distance between cables is increased beyond 20 m, the distortion at a given distance rises above that of Figure 1.2. Since the cables are shielded, no electric field will be generated outside the cable. For a more detailed discussion of the fields associated with this technique, the reader is referred to the paper by Koops [11].

Few other DC fields from human activity are broadly present in the environment, though very short-range DC fields are found near permanent magnets, usually ranging from a few tenths of a millitesla to a few millitesla at the surface of the magnet and decreasing very rapidly as one moves away. Occupationally encountered DC fields are discussed below.

1.2.2.2 High-Voltage AC Power Lines

The electric and magnetic fields from high-voltage power lines have been figuring for a long time in the debate on the biological effects of EM fields. Although the AC power systems in the Americas, Japan, the island of Taiwan, Korea, and a few other places are 60 Hz, while most of the rest of the world is 50 Hz, the frequency difference has no effect on high-voltage transmission line fields. In the early days of bioelectromagnetics research, the electric field was considered the most important part, and measurements of field strengths were performed in many places. Figure 1.3 shows an example of such

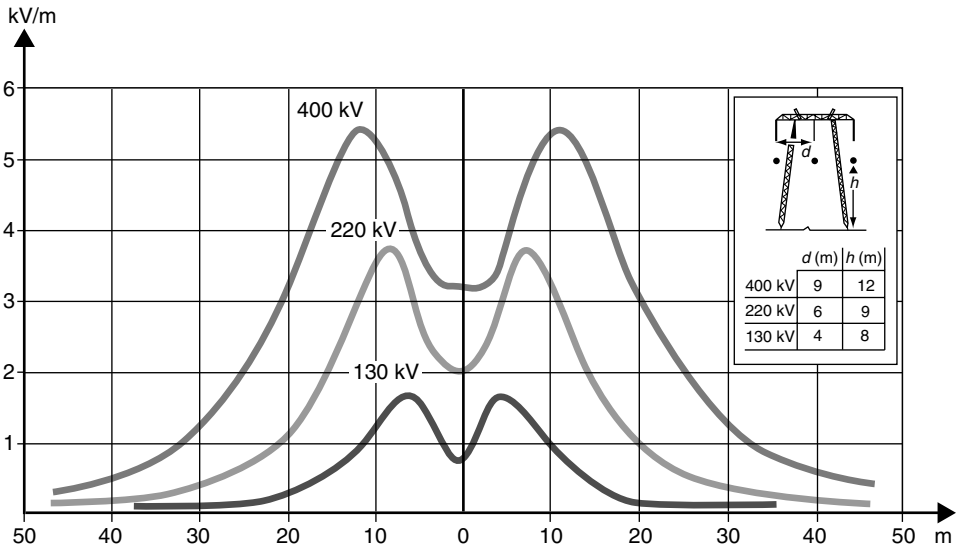

FIGURE 1.3
Electric field from three different high-voltage power lines as a function of the distance from the center of the line. In the inset the distance between the phases as well as the height above ground of the lines are given. (From Hansson Mild, K. In Matthes, R., Bernhardt, J.H., and Repacholi, M.H., Eds. Proceedings from a joint seminar, *International Seminar on Effects of Electromagnetic Fields on the Living Environment*, of ICNIRP, WHO, and BfS, Ismaning, Germany, October 4–5, 1999, pp. 21–37. With permission.)

measurements from three different types of lines: 400, 220, and 130 kV lines, respectively. The field strength depends not only on the voltage of the line but also on the distance between the phases and the height of the tower. The strongest field can be found where the lines are closest to the ground, and this usually occurs midway between two towers. Here, field strengths up to a few kilovolts per meter can be found. Since the guidelines of the International Commission on Non-Ionizing Radiation Protection (ICNIRP) [12] limit public exposure to 5 kV/m and there is no time averaging for low-frequency fields, people walking under high-voltage power lines may on some occasions be exposed in excess of existing international guidelines.

Because electric fields are well shielded by trees, buildings, or other objects, research in the 1970s and 1980s did not turn up any major health effects (see, e.g., Portier and Wolf [13]), and because of the epidemiological study by Wertheimer and Leeper [14] (see also Chapter 6 on ELF epidemiology in this volume), attention turned from electric to magnetic fields in the environment. The magnetic field from a transmission line or any other wire depends on the current load carried by the line, as well as the distance from the conductors; in Figure 1.4 calculations of the magnetic flux density from several different types of transmission lines are shown. There is a very good agreement between the theoretical calculation and the measured flux density in most situations. The flux density from two-wire power lines is directly proportional to the electric current, generally inversely proportional to the square of the distance to the power line for distances greater than several times the distance between the phase lines, and directly proportional to the distance between the phase wires. For three and six-wire systems the fields decrease more rapidly with distance at a rate that is dependent on the phase sequences and the spacing between the wires. For most lower-voltage lines, around 10–20 kv, the distance at which the B field falls below 0.2 μT is generally less than 10 m; this distance still depends on current and the spacing of the wires.

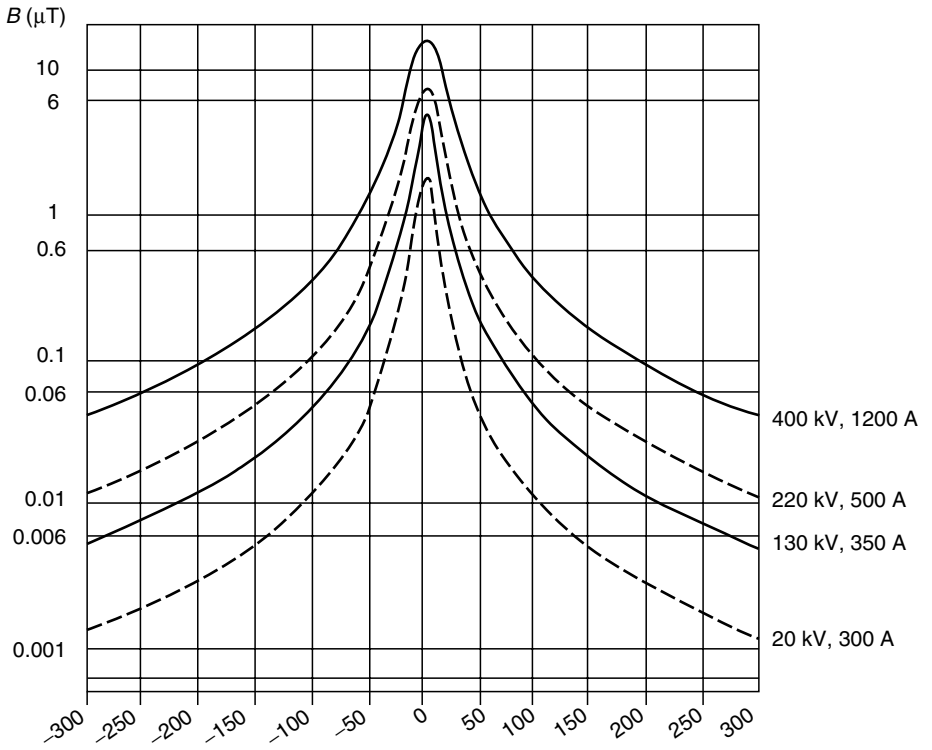

FIGURE 1.4
Magnetic flux density from different high-voltage power lines at a distance (in meters) from the center of the line. The currents in the lines are the maximum values allowed and are given to the right in the figure. (Figure courtesy of Swedish National Institute for Working Life.)

The electric or magnetic field vector from a single AC conductor displays a sinusoidal waveform, oscillating back and forth through zero intensity in a single direction determined by the observation position with respect to the wire, ignoring any small distortions due to harmonics, etc. However, near a three-phase high-voltage transmission line, the electric and magnetic field vectors from the group of conductors, which are at some distance from each other and whose individual sinusoidal variations are out of phase, rotate in space as well as change in magnitude, but their magnitude never decreases exactly to zero [15]. This so-called elliptical polarization may or may not have a different biological significance than the single conductor's ''plane polarization.''

Several approaches have been used for reducing the magnetic field from a line, and in Figure 1.5 some examples are given. Instead of hanging the three phases at the same height and in parallel, the lines can be arranged in a triangular form, thereby reducing the distance between the phases and thus also the flux density. The reduction is of the order of about 1.6. An even greater reduction is obtained if the so-called split phase arrangement is used. Here, five lines are used. One phase is placed in the center, and the other two phases are split into two lines each, which are placed diagonally (see Figure 1.4). The reduction is almost tenfold.

When high voltage is present, there is a possibility of the insulation breaking down, causing a catastrophic discharge—a spark; lightning is an obvious example. There is also the more common possibility of very minor discharges occurring, in which one or a relatively small number of molecules near the high-voltage element become

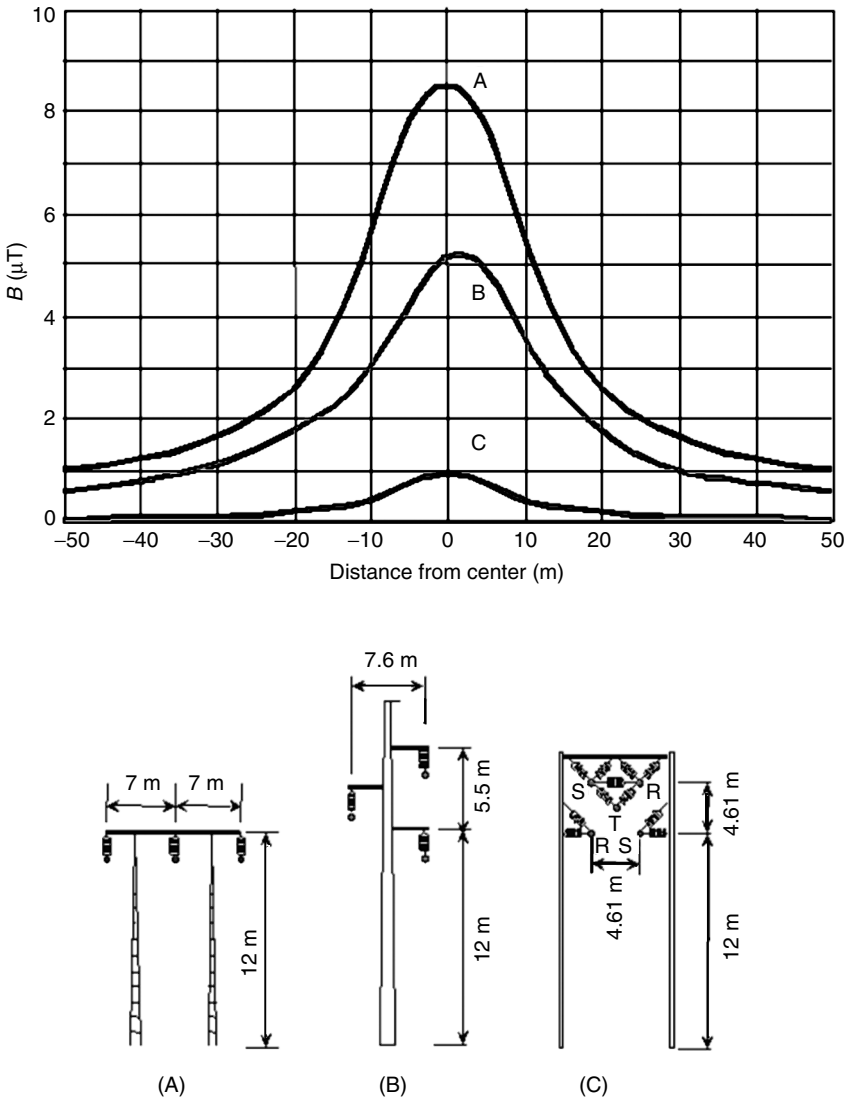

FIGURE 1.5
Examples of reduction of the magnetic flux density from a 220-kV line with a maximum phase current of 500 A. In (A) the normal configuration is used and the maximum flux density is about 8 μT, and in (B) a delta arrangement is used which gives a reduction to about 5 μT maximum under the line. In (C) the split-phase arrangement is used leading to a maximum value of only 1 μT. (Figure courtesy of Swedish National Institute for Working Life.)

ionized; this is often called a *corona*, since in extreme cases a small glow can be seen near parts of the high-voltage system. Corona discharge can also occur at grounded objects near a high voltage and is more likely to occur at more pointed objects; this is the principle of the lightning rod. Minor corona damage has been observed on pine tree needles very close to a 1200 V transmission line [16]. (No other environmental damage to plants or animals from either fields or corona has been found [17].) The resulting ions screen the electric field of the transmission line cables to varying extents, because their number depends on a variety of factors, including humidity, dust, rain, and wind [9,10]. While a hypothesis has been put forward that ions from power lines make small airborne

particles, particularly those carrying naturally occurring radioactive atoms, more likely to enter and remain in the lungs and cause cancer or various other diseases [18], it has not found much acceptance.

1.2.2.3 Exposure in Homes

Although Wertheimer and Leeper [14] initially used transmission and distribution line sizes and configurations as surrogates for estimating magnetic field exposure from transmission lines, it quickly became apparent that the correlation was not very good and that sources of exposure inside the home were at least as important, unless the home was very close to a transmission line [13]. Several studies have explored the exposure to ELF electric and magnetic fields in homes in different countries. Deadman et al. [19] investigated the exposure of children in Canada. A logging device was used, which recorded the fields during two consecutive 24-h periods. For 382 children up to the age of 15 they found an arithmetic mean (AM) of the magnetic field of 0.121 μT with a range of 0.01–0.8 μT. The corresponding values for the electric field were AM 14.4 V/m, range 0.82–64.7 V/m. Hansson Mild et al. [20] compared the ELF fields in Swedish and Norwegian residential buildings. The overall mean values were as follows: E fields 54 V/m (SD = 37) and 77 V/m (SD = 58) in Sweden and Norway, respectively; the corresponding values for B fields were 40 nT (SD = 37) and 15 nT (SD = 17). Table 1.1 shows additional comparisons.

Mccurdy et al. [21] measured women's exposure in the United States by using personal magnetic field exposure meters that were worn during a working day or a day at home. The geometric mean of the time-weighted average for the working day was 0.138 μT with a range of 0.022–3.6 μT, and for the homemakers the corresponding values were 0.113 μT, range 0.022–0.403 μT.

In the meta-analysis by Ahlbom et al. [22] on childhood cancer and residential magnetic fields, it was stated that 99.2% of the population resided in homes with $B \leq 0.4$ μT.

Exposure varies widely in time, according to the time of day and the season. One may be outdoors, far from any field sources at one time, indoors near an operating appliance at another, riding in an electric transit vehicle at some other time, and so forth. Sample exposure values for an individual, recorded as a function of time over a 24-h period in spring and summer, are shown in Figure 1.6.

TABLE 1.1

Comparison of Personal Exposure and Background Fields

Country		Geometric Mean of Personal Exposure (nT)	Geometric Mean of Long-Term Background Field (nT)	Ratio, Personal Mean to Background Mean
United States	Adults at home	134	58	2:3
	Adults at home, not in bed	111	74	1:5
	Children, residential	96	99	1:0
	Children, at home	96	67	1:4
Canada	Children at home	117	107	1:1
	Adults at home	133		1:2
U.K.	Adults at home	54	37	1:5
	Adults	42	29	1:5

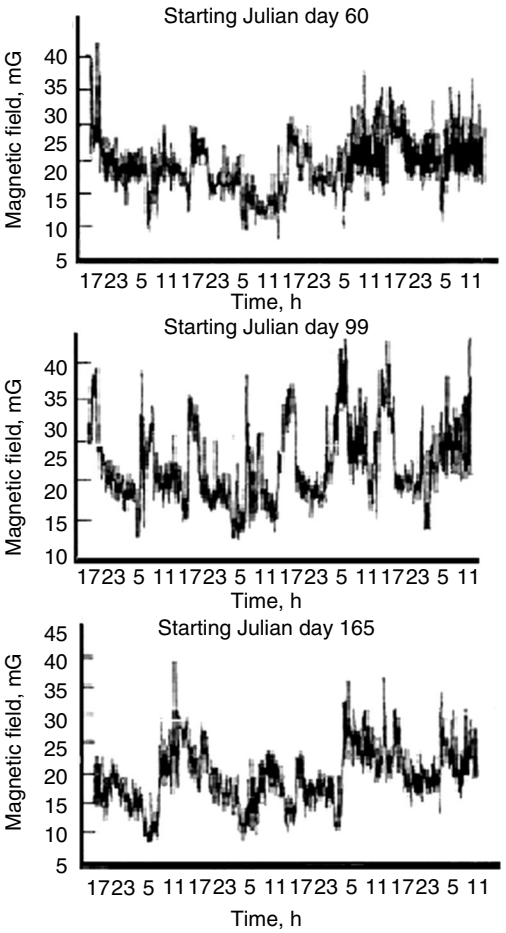

FIGURE 1.6
An individual's measured magnetic field exposure over the course of a day. Note that 1 mG = 0.1 μT. (From Koontz, M.D., Mehegan, L.L., Dietrich, F.M., and Nagda, N.L. Assessment of Children's Long Term Exposure to Magnetic Fields [The Geomet Study]. Final Report TR-101406, Research Project 2966-04, Electric Power Research Institute, Palo Alto, CA, 1992. With permission.)

Since the three-phase systems used for electrical distribution are dimensioned for sinusoidal fields, the harmonic content can create problems. Today we may find large stray currents, usually resulting from unbalanced currents between phases, in water pipes, ventilation systems, concrete reinforcement mesh, etc., and the current flowing also contains these harmonics. Figure 1.7 gives an example of a measurement of a current flowing in a cable in a large apartment building, and Figure 1.8 shows the corresponding Fourier frequency analysis. The magnetic field in the building thus also has these harmonic components. Often, the largest stray currents, which generate large domestic fields, are due to errors in wiring that violate the building code [23] or to a poorly planned wiring layout that has currents flowing in open loops instead of both wires of a circuit being laid next to each other in the same conduit [24].

From Figure 1.6 through Figure 1.8, as well as the data in the rest of this chapter, it is easy to see that average field strength is far from being the only parameter that is needed to characterize electric or magnetic field exposure. Other parameters include frequency or frequencies present (or the related parameters, the rise and fall times of up-and-down excursions or ''transients''), numbers and height of transients, number of

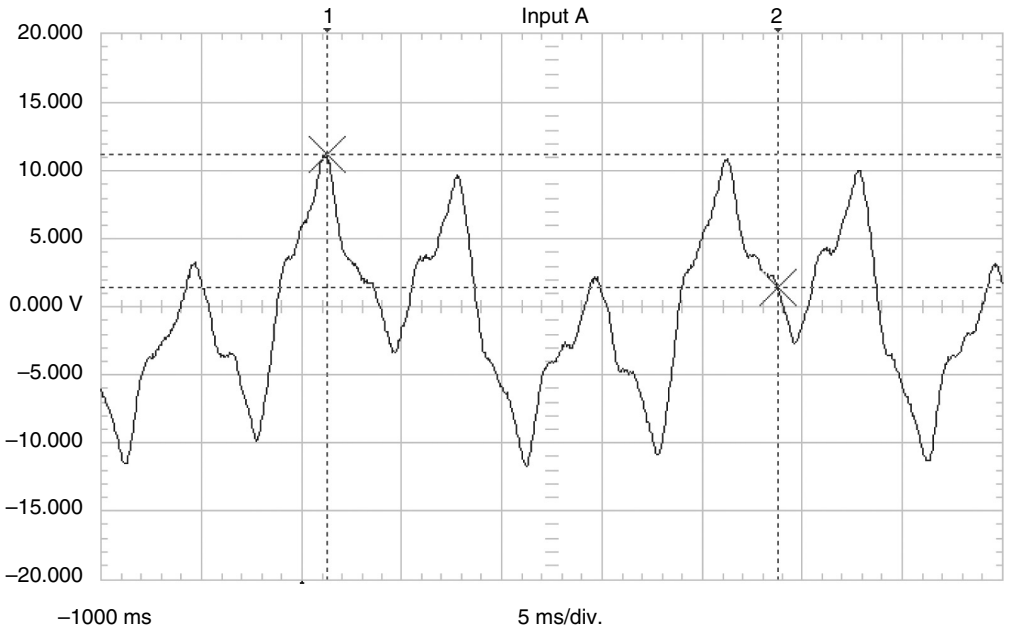

FIGURE 1.7
Stray current wave shape in the 50 Hz power delivery cable in an office building. The peak to peak current is of the order 20 A. (Figure courtesy of Swedish National Institute for Working Life.)

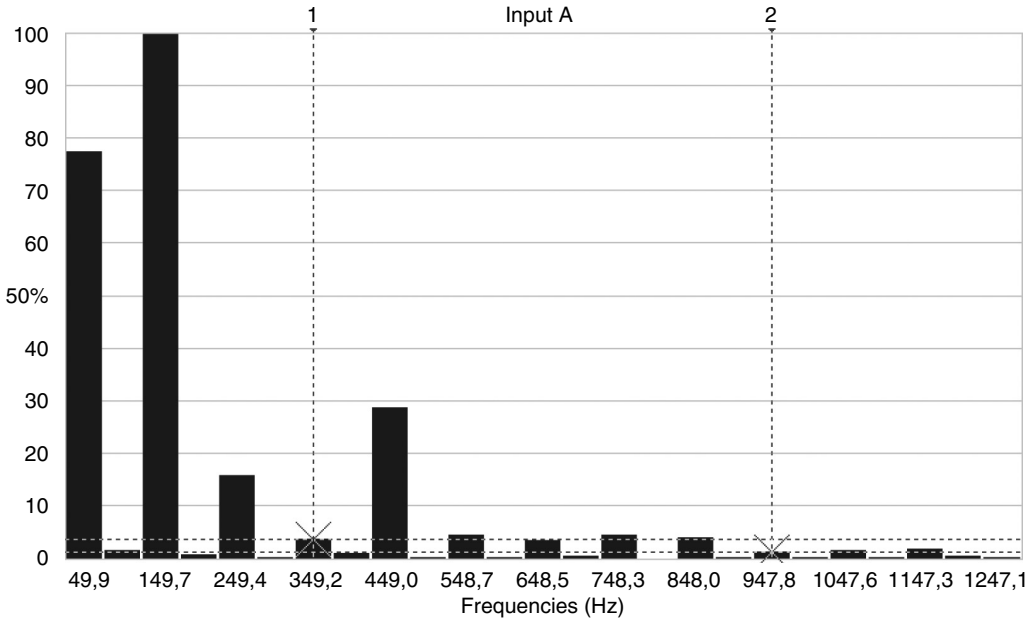

FIGURE 1.8

times the field exceeds or falls below a certain fraction of its average value, whether both DC and time-varying fields are present, relative direction of multiple fields, etc. As discussed elsewhere (e.g., the Introduction and chapters such as Chapter 5, Chapter 6, and Chapter 9 in this volume and Chapter 5 through Chapter 8 and Chapter 11 in *BMA*), it is not clear, in most cases, which one or group of these parameters is related to a particular biological effect. To date, average field strength is the most commonly used parameter, partly because it is the most easily obtainable summary of exposure over an extended period. For a given frequency range, average field strength is related to some other parameters, such as fraction of time over a certain threshold, but not to others, such as number of transients per hour. For further discussion of various parameters and their interrelationships, see, for example, Refs. [25,26].

Most measurements have been done in detached houses, even though many city dwellers live in apartment buildings. In apartment buildings, the current in the wiring in the ceiling of one unit, for instance, for ceiling lamps, may most strongly affect the magnetic field level of the unit above. Also, some apartment buildings have an electric substation in the basement, where a transformer reduces the medium-voltage distribution line power to 110 or 220 V for domestic use. The low-voltage conductors of the substation may carry substantial currents and create magnetic fields up to several tens of microtesla directly above the substation; reduction through placing conductors away from the substation ceiling and shielding with aluminum plates is possible [27].

In the United States and Canada, though not in other countries, the neutral wire of the AC power distribution system is required to be physically connected to the earth (grounded) at regular intervals to avoid injury from electric shocks; building wiring systems' neutral wires must also be grounded, often by connection to the buried water pipe as it enters the building. Unbalanced loading of the system can produce currents in the ground system, sometimes including currents that leave one residence through the grounding system and return to the power grid through another, which further contributes to the residential magnetic fields [28,29].

Kavet and colleagues [30–32] have proposed that effects observed in children, which epidemiology has associated with domestic magnetic fields, are in fact due to small shocks that arise due to potential differences that build up between the water tap and the grounded drain of a tub. Shocks received in the bath can still induce in a small child's body current densities of a magnitude known to induce a biological effect. This alternative hypothesis is still under investigation.

1.2.2.4 Electrical Appliances

The United States, Japan, Canada, and some other countries use 110 V_{rms} AC for basic electrical power, while most of the rest of the world uses 230 V. Since transmission and distribution voltages in the two types of system are about the same, only differences due to appliances or building wiring would be expected. For a given power consumption and similar design, 110 V appliances draw twice as much current and create twice as strong a local magnetic field, although their local electric fields are half as strong. However, because both types of field fall off rapidly with increasing distance from the appliance and metal appliance cabinets shield electric fields, measurements of exposure to magnetic fields have not yielded great differences between the two systems (see Table 1.1). Measurements of magnetic fields from a sample of various appliances show that the fields have a rapid falloff with distance from the device [33]. Very close, the values may exceed international guidelines, but at a distance of 0.5–1 m the fields are seldom higher than few tenths of a microtesla. In general, it can be said that the more power the equipment uses, the higher the magnetic field. Table 1.2 presents some representative values from 110 V appliances.

TABLE 1.2

Ratios (B_{on}/B_{off}) of Magnetic Fields Measured with Appliances Turned On and Off

Appliance	Measurement Location	B_{on}/B_{off} 6–54 Hz	54–606	606–3066 Hz	8–200 kHz

	25 cm from clock	<1.0	1.8	1.0	—
	50 cm from clock	<1.0	1.1	<1.0	—
	100 cm from clock	1.1	1.0	1.0	—
	At subject's head	1.1	1.1	1.0	—

Note: B_{off} was estimated using linear interpolation at those measurement locations where it was not directly measured.

Source: From Kaune, W.T., Miller, M.C., Linet, M.S., Hatch, E.E., Kleinerman, R.A., Wacholder, S., Mohr, A.H., Tarone, R.E., and Haines, C. *Bioelectromagnetics* 23, 14–25, 2002.

Vistnes [34] recently gave some examples of flux densities near 220 V appliances. Of special interest may be a clock radio, which because of bad electrical design may give rise to exposure of the order of 100 μT close to the equipment. Since people are likely to place a clock radio very close to the pillow, the head may be exposed to quite a large magnetic field, exceeding the normal levels in the house.

The general range of magnetic and electric field magnitudes at various distances from transmission lines, local distribution lines, and appliances is shown in Figure 1.9.

Most modern electrical appliances are equipped with an electronically switched power supply in which an electronic circuit replaces the old-style transformer. This means that the current is no longer a pure sinusoidal 50- or 60-Hz signal but contains harmonics. The current used by a low-energy 50-Hz fluorescent lamp is illustrated in Figure 1.10, and the Fourier analysis is shown in Figure 1.11 indicating all the harmonics. Higher harmonics and transients (fast spikelike excursions) are also generated by motor-driven appliances and those run by vibrating mechanisms using make-and-break switching contacts, such as older electric shavers or doorbells (Table 1.2).

The magnetic field in different infant incubators used in hospital nurseries varied between 0.23 and 4.4 μT, with an arithmetic average of 1.0 μT [35]. Most of these values are considerably higher than the exposure that can be measured in residential areas close to transmission lines. The technology to reduce the exposure is at hand and can be easily applied.

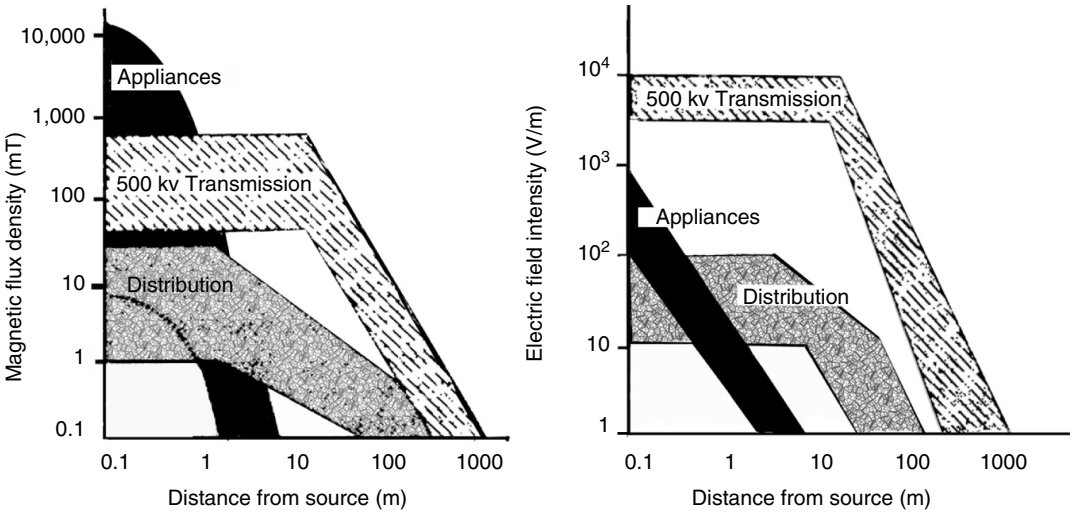

FIGURE 1.9
Magnetic flux density (left) and electric field strength (right) as a function of distance from transmission lines, local distribution lines, and appliances. (From U.S. Office of Technology Assessment. Biological Effects of Power Frequency Electric and Magnetic Fields. U.S. Government Printing Office, Washington, DC, Background Paper OTA-BP-E-53, 1989.)

Occupational exposure from handheld electrical appliances can be quite high. This is mainly equipment that is held close to the body and that uses high power, such as drills and circle saws. These devices usually have adjustable speed, which is done through the switched power supply. Values for the magnetic field of the order 100–200 μT are not uncommon, and in order to show compliance with standards the measurements have to take into account the harmonic contents of the waveform.

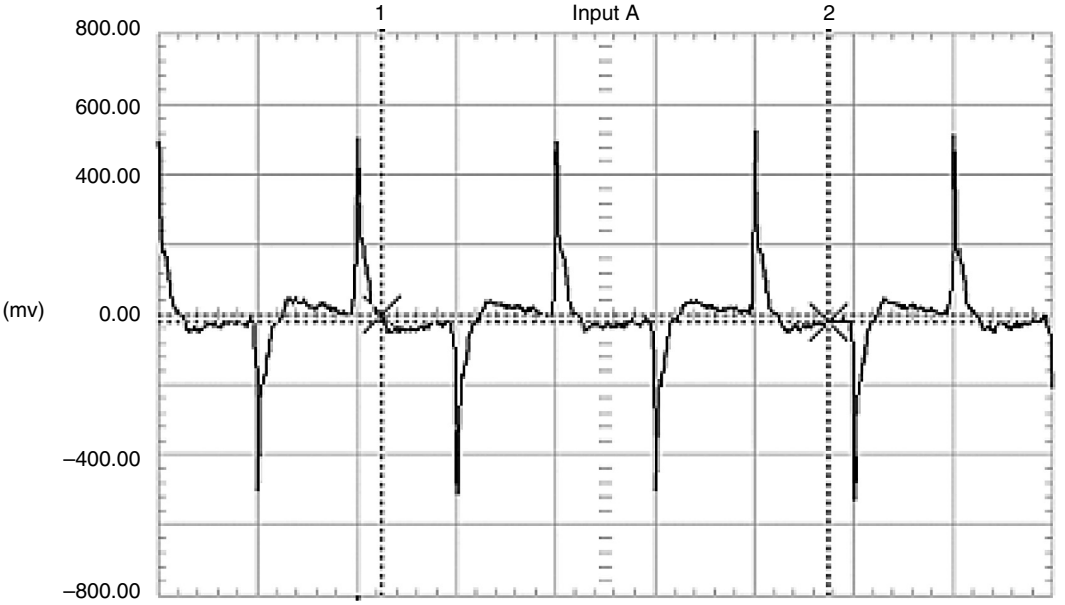

FIGURE 1.10
Wave shape of the current to a low-energy fluorescent lamp. The timescale is 10 ms/div. (Figure courtesy of Swedish National Institute for Working Life.)

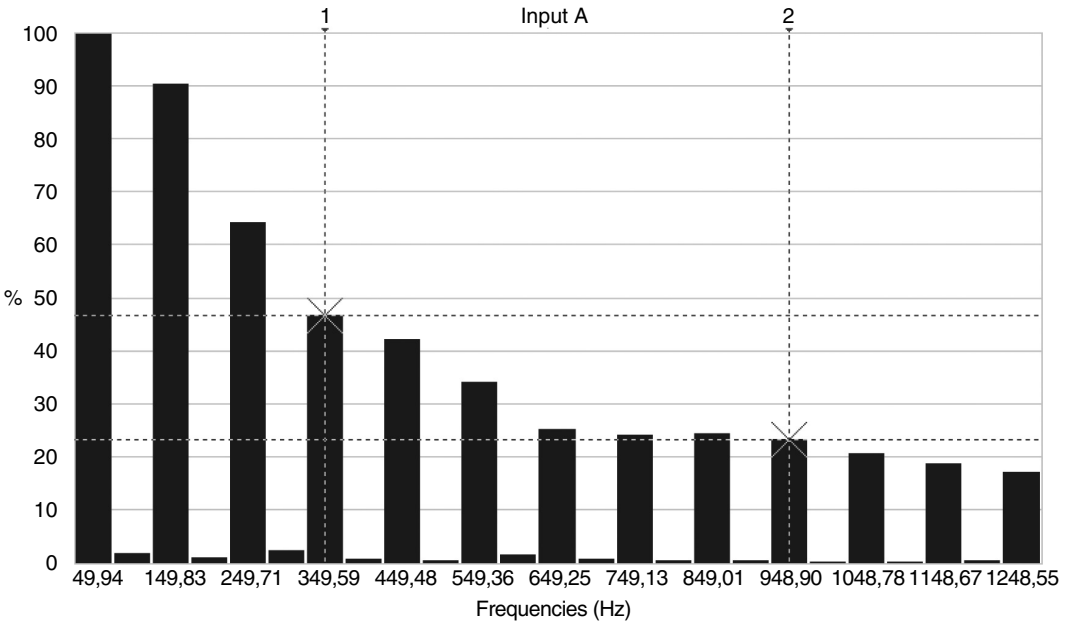

FIGURE 1.11
The Fourier spectrum of the wave shape in Figure 1.7. Note the high 150-Hz component. (Figure courtesy of Swedish National Institute for Working Life.)

1.2.2.5 ELF Fields in Occupational Settings

Wertheimer and Leeper [14] were not only the first to publish evidence in support of increased childhood cancer risk with magnetic field exposure, but they also pointed to increased cancer risk in occupations with high magnetic field exposure. Since then, hundreds of studies have looked into this problem, and the assessment of workers' exposure has been debated. There are studies where individual estimates of the exposure have been made for male [36] and females [37]. For workday means, the 25th, 50th, and 75th percentiles were 0.13, 0.17, and 0.27 μT, respectively, for males, and the corresponding values for females were almost similar: 0.14, 0.17, and 0.23 μT. The study on exposure of males investigated the 1000 most common occupations in Sweden, and the study on female exposure included 61 job categories. Table 1.3 shows additional estimates for various professions.

Sewing machines—Near sewing machines increased magnetic fields can be found, and depending on the type of machines used the values differ. The mean average value logged during some working hours is of the order of several tenths of a microtesla [38].

Welders—Among the occupations where quite high exposure exists, electric arc welders are a prominent example. They handle cables carrying hundreds of amperes very close to their bodies. The welder normally grasps the cable, and it sometimes also is in contact with other parts of the body, for instance, it might be draped over the shoulder. Depending of the technique used—DC or AC, type of rectification, etc.—the ELF magnetic field varies, but several studies report values in the range of tens to hundreds of microtesla [39]. Skotte and Hjøllund [40] found a mean of 21 μT for a full-shift average workday of manual metal arc welders. During the actual welding, the *B* field can be up to several millitesla.

The frequency content of the signal can be rather complex. In one of the most common situations the welding equipment is connected to a three-phase outlet, and the current for the weld is thus three-phase full-wave rectified. This means that we have first a DC

TABLE 1.3

EMF Exposures in Common Environments

Environment	Median[a] Exposure	Top 5th Percentile	Environment	Median[a] Exposure	Top 5th Percentile
Office Building			*Machine Shop*		
Support staff	0.6	3.7	Machinist	0.4	6.0

Assessment of Health Effects from Exposure to Power-Line Frequency Electric and Magnetic Fields. NIH Publication 98-3981, National Institute of Health Sciences, Research Triangle Park, NC, 1998 (accessed April. 7, 2005, at http://www.niehs.nih.gov/emfrapid/html/WGReport/WorkingGroup.html).

component and on that a large AC ripple with main frequency 300 Hz (50 Hz power system), but it also has harmonics at 600, 900, 1200 Hz, etc. A newer type of equipment has a pulsed DC (50–200 Hz pulse frequency) as a base with a 53 kHz current applied between the pulses. This leads to frequencies in the current equal to the pulse frequency and its harmonics and also 53 kHz and harmonics. It is a very complex situation to evaluate with respect to compliance with guidelines, because of the complexity of the signal.

Since in many cases, high exposure results from the cables being very close to the body, much can be done to reduce the exposure of the welder by carefully arranging the workstation to keep the cables away from the body. By placing the welding machine on the right-hand side of the worker (if right-handed) and seeing that the return cable is as close as possible to the current cable, the exposure can be reduced by one order of magnitude.

Induction heaters—Induction heating is used for heating metals for purposes that include surface or deep hardening, welding, melting, soft soldering, brazing, annealing, tempering, and relieving stress. The frequency can be from 50 Hz to the low megahertz range, depending on the desired skin depth and purpose. Since high currents are used, the leakage magnetic field can be substantial. At the operator's position, values of the order of 0.5–8 μT are common, and the maximum field near the coil, where, for instance, the hands can be exposed, can reach several hundreds of microtesla. The field strength is in many cases high compared with recommended limits [12].

Railway workers—Engine drivers of AC electric engines experience rather high magnetic field exposure. The intensity depends of several factors, one of them being the age of the engine. Nordensson et al. [41] (see also Refs. [42,43]) found that drivers of Swedish model RC engines were exposed to flux densities of the order of 10–100 μT. The older

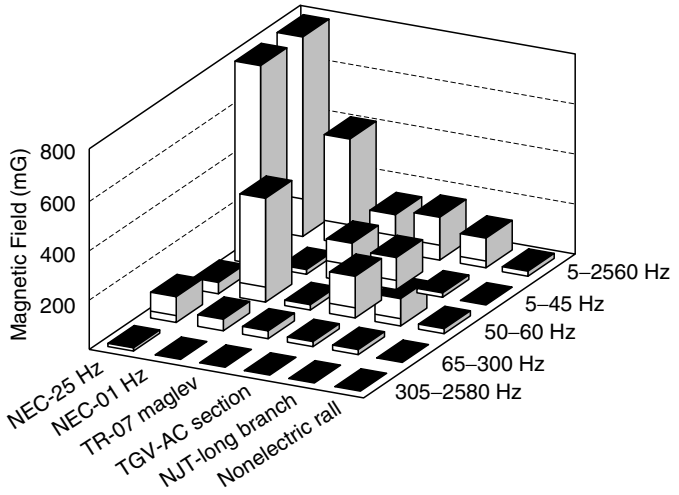

FIGURE 1.12
Maximum (top of bar) and average (horizontal bar) magnetic fields in various frequency bands in the passenger compartment of several intercity rail systems. NEC = U.S. Amtrak Northeast Corridor (Washington, DC, to Boston, MA), which has both 25- and 60-Hz segments; TR-07 = German Transrapid maglev system; TGV = French ''Train a Grande Vitesse,'' AC-powered segment of Paris-Tours line; NJT = New Jersey Transit, NJ Coast Line Long Branch section. (From Bernardi, A., Fraser-Smith, A.C., and Villard, O.G., Jr. *IEEE Trans. Electromagn. Compat*. 31, 413–417, 1989.)

models of engines had the higher values. The mean average values for a full workday ranged from 2 to 15 μT. The main input power frequency is $16\frac{2}{3}$ Hz, and this frequency was dominant at idle, but at full power, harmonics up to 150 Hz existed. Wenzl [44] measured the exposure of rail maintenance workers in the United States and found peak values ranging from 3.4 to 19 μT, and the time-weighted average was in the range 0.3–1.8 μT. Chadwick and Lowes [45] have examined the exposure of passengers on trains in the U.K., and they found static magnetic flux densities up to several microtesla. The alternating field was also substantial in some locations and reached up to 15 mT at floor level. However, none of the whole-body alternating magnetic flux densities approached the National Radiological Protection Board (NRPB) investigation levels.

Trains operating on DC, such as in the Washington, DC, and San Francisco, CA, transit systems, also produce time-varying fields in the passenger compartments, particularly below 5 Hz [46,47]. Figure 1.12 shows field intensity in various frequency bands in the passenger compartment of several representative electric rail systems and a nonelectric one. Interestingly, the figure shows that an experimental magnetic levitation (maglev) system does not exhibit substantially different field levels [48].

Electrochemical plants—In factories producing, for instance, aluminum, copper, or chloride through electrochemical processes, very high DC currents are used, often of the order of tens of kiloamperes. The DC current is obtained through rectification of the incoming three-phase AC power. Often there is still a substantial AC component of the current and hence an AC magnetic field. Measurements have shown broadband ELF measurements of the order of 10–50 μT, with many different frequencies present that need to be taken into account in the evaluation of the exposure situation. Typically, a 50 Hz component can be present, because of unbalance between the three phases, and the full-wave rectification gives 300, 600, and 900 Hz components. The exposure guidelines can often be exceeded in some locations in the plants, and special requirements may be needed to reduce the exposure. DC fields in these smelters are often on the order of several millitesla, with peaks of at least 20–30 mT; up to 70 mT has been reported [49,50].

1.2.2.6 *Internal ELF Fields Induced by External and Endogenous Fields*

Because the bodies of humans, other animals, and even plants contain ionic solutions and because cell cultures, as well as many one-celled and other organisms such as fish or the roots of plants, live in conductive media, external exposure to electric or time-varying magnetic fields can produce internal fields, which can be quite different than the unperturbed external fields.

In an electric field, as discussed in Chapter 3 and Chapter 4 in this volume on properties of materials, the conductivity and dielectric constants of tissue are quite different from those of air or vacuum, creating a layer of charge due to polarization at the surface of the body, which decreases the internal field, often by many orders of magnitude. For a human standing in the ELF electric field below a high-voltage transmission line, the field inside the body may be only 10^{-6} of the external field. The shape of the body also affects the amount of polarization. Since a standing humans body has more of a ''lightning rod'' shape than a crouching rat, a rat must be exposed to a much lower external field to achieve an equivalent internal electric field. A squatting human will experience lower and the rearing rat, higher fields. The body shape and foot area also affect the average current densities in various body locations because of the external electric field. Figure 1.13 illustrates these differences [51]. As shown in the figure, current densities increase in areas of smaller cross section, for example, the human neck or leg, and closer to the ground, for example, the upper and lower human torso. When calculated without averaging across a cross section, current densities are higher near a junction point; for instance, they are higher and more horizontal at the armpit than in the middle of the chest area [52].

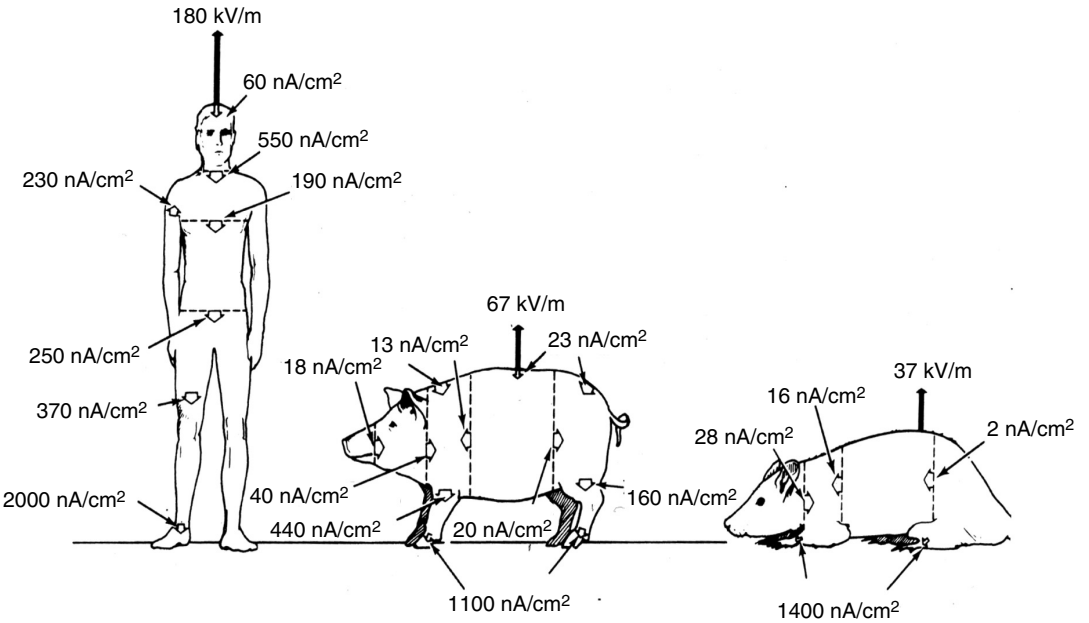

FIGURE 1.13
Estimated external electric field and current densities of a grounded man, pig, and rat exposed to a vertical 0-Hz, 6-kV/m electric field. Calculated internal current densities are averaged over sections through bodies as shown; calculated current densities perpendicular to the body surface are shown for man and pig. (From Figure 4 in Kaune, W.T. and Phillips, R.D. *Bioelectromagnetics* 1, 117–129, 1980; Copyright John Wiley & Sons, reproduced With permission.)

It is important to recognize that electric fields and current densities such as those in Figure 1.13 are averages, whether across the whole cross section of the body or a limb or across a localized region. Fields vary greatly across very small distances when one examines them at dimensions on the order of a cell or a molecule; this is called *micro-dosimetry*. Forming a good picture at this level of fields from either endogenous or external sources is an unsolved but very important problem. Chapter 5 in this volume on basic mechanisms discusses this issue further.

An external magnetic field's value is little changed as it enters a biological system, whether the human body or cells in culture, since the average biological magnetic susceptibilities are very close to those of air or vacuum (see Chapter 3 and Chapter 4 in this volume on magnetic properties of materials). However, the internal electric fields and currents induced in the body according to Faraday's Law are strongly determined by bodys (or specimen) shape, electric conductivity, and orientation with respect to the field. Table 1.4 gives some comparisons between the current induced in a human by the ELF magnetic fields generated in various situations and the external vertical 60 Hz electric field needed to produce the same current densities.

As discussed further in several chapters in this volume, especially Chapter 2 on endogenous fields, Chapter 5 on the basic interactions of fields and biological systems, and Chapter 7 on noise, as well as in the various discussions of models of field–biological system interaction, an externally applied field is unlikely to cause a biological effect unless the part of the biological system with which the field interacts is able to distinguish the external field from the internal electric fields and currents that are an integral part of the system. Exactly how to formulate the aspects of the endogenous field or current

TABLE 1.4

Magnetically Induced Total Body Current and Current Densities and Vertical 60-Hz Electric Field Inducing Equivalent Currents

Source	Current (μA)	Current Density (A/m^2)	Electric Field (kV/m)
Sinusoidal waveforms

Wachtel, University of Colorado, private communication, copyright 1992; reprinted with permission.)

density that should be compared with the local field or currents in a particular situation is still an open research question; for example, over what region (how many molecules or cells) and over what range of frequencies (very narrow or broad) does the biological system average?

These endogenous fields range from the normal ~50–100 mV DC transmembrane potentials of most cells (negative in animals, sometimes positive in plants) to the relatively rapid pulses of nerve cell depolarization or repolarization spikes and the less rapid pulses of, for instance, muscle cells (see Figure 1.14 for examples). They also include the very large and often highly local and hence very nonuniform fields because of local charge densities on some macromolecules or changes in the double ion layer next to a membrane because of the inclusion of a protruding structure, such as a channel, at a particular location (see, e.g., diagrams in Chapter 5 in this volume on basic interactions of fields and biological systems).

1.3 EM Fields at Intermediate and Radio Frequencies (3 kHz to 300 MHz)

1.3.1 Electronic Article Surveillance

Many libraries and stores are currently equipped with electronic article surveillance systems, which generate EM fields ranging from ELF to radio frequencies (RFs). Sometimes, employees spend long periods of time close to parts of these systems, and they might therefore be exposed to strong EM fields, well in excess of the reference levels (RLs). RLs are the levels of easily measured fields in air that exposure-limiting regulations or guidelines state may, but do not necessarily, create health questions in those exposed to them. Above RLs, more precise measurements or calculations are needed for each specific situation to determine whether limits for the actual fields inside the body, the basic restrictions (BRs), are exceeded (for a discussion of RLs and BRs, see Chapter 8 in *BMA*) on standards in [82]).

Kjellsson et al. [53] made measurements on two different systems, one used in a shop and one in a library. The coils in the library at the exit were working at 920 Hz, and the

flux density at the center of the coils was of the order of 10 μT, compared with the RL for the general public of 6.25 μT. When the books are returned to the library, the electronic tag in the book has to be activated before the book is put back into the library. The system used for deactivating operates at 50 Hz, and at close range the flux densities were of the order of some millitesla, thus again above the RL for occupational exposure at 500 μT. In the store the signal was a mixture of 17 Hz and 6.25 kHz. The flux densities at the lower frequency were of the order of 200–300 μT, and at the higher frequency the values were well in excess of 100 μT. The RLs at 6.25 kHz for the general public is 6.25 μT, so the RLs are clearly exceeded, and more in-depth analysis is needed to see if the BRs are still not violated. See also Harris et al. [54] for a technical description of these devices.

Both at the shop and in the library there are situations and places where the general public as well as the employees are exposed to magnetic fields that exceed the RL. Logging the exposure during a work shift at the shop also showed that the cashiers are exposed to magnetic fields generated by the transmitter signal of the detection gates, which were often activated by customers during the work shift studied. The cashiers are therefore a highly exposed category of personnel and hence are of interest to include in epidemiological studies. Eskelinen et al. [55] have published similar results and conclusions in a previous study.

In the library not only the detection gates but also the activators and deactivators contribute to the high magnetic fields. One problem is the handheld activator used by the employees. Because of its small size, it is possible to hold the activator against almost every part of the body. If for example, a user is wearing a pacemaker and is not aware of the magnetic fields, the worst case could lead to disturbances in the pacemaker.

1.3.2 EM Fields from Video Display Terminals

A very commonly used appliance emitting EM fields is the computer video display terminal (VDT). Flat panel displays are increasingly replacing the cathode ray tube (CRT)-based VDTs at present, but a great many CRTs are still in use. There are five different types of fields present in the vicinity of the CRT: an electrostatic field, VLF electric and magnetic fields at the horizontal sweep frequencies, and various ELF electric and magnetic fields at the screen refreshing rate, related to the power frequency. These are considered separately in the next few sections. Measurements show that the equivalent electrostatic surface potential on the screen can reach up to 20 kV for some VDTs, and the ELF electric fields in front of the VDT at a distance of 0.5 m range from a few to tens of volts per meter, although most of the time it is not distinguishable from the office background 50 or 60 Hz electric field. The ELF magnetic field can reach a few tenths of a microtesla, and close to the tube the values are up to a few microtesla. The VLF electric fields range from a few to tens of volts per meter, and the corresponding magnetic field is of the order of a few tenths of a microtesla at 0.5 m in front of the VDT. The VLF B field time derivative ranges from a few to a few hundreds of millitesla per second (see Ref. [56]).

In Figure 1.15 a schematic drawing of a CRT-based VDT is shown with the deflection coils. Since these coils are to move the electron beam horizontally, from left to right, the magnetic field affecting the electrons has to be vertically directed; therefore, the coils are in horizontal planes above and below the neck of the tube as shown in Figure 1.15. The stray field from these coils at the operator's position is mainly vertical. The sawtooth wave shape of the magnetic field is also schematically shown in Figure 1.10. The times, 3 and 30 μs, given in the figure are typical examples of values found on some VDTs. Also shown in the figure is the time derivative of the signal. Since the vertical deflection requires a horizontal magnetic field, the coils for the vertical deflection (omitted in the drawing in

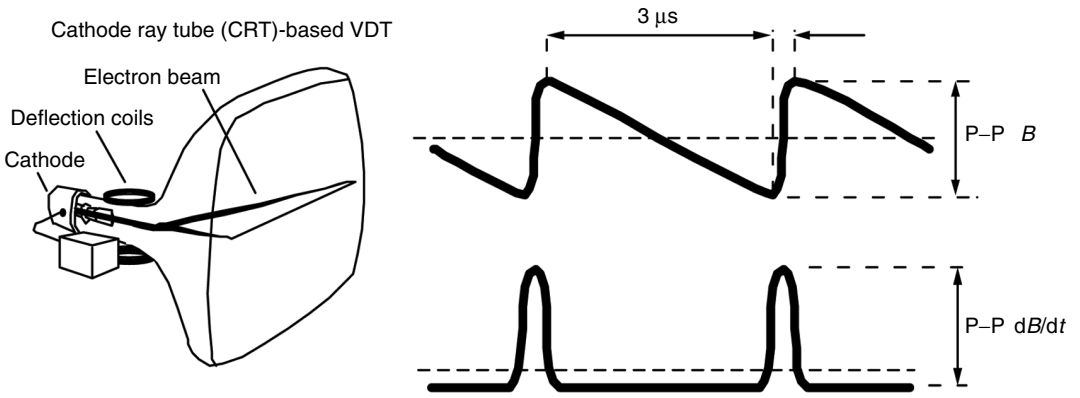

FIGURE 1.15
Schematic drawing of CRT-based VDT. To the right, examples of an idealized waveform of the VLF magnetic field and its time derivative are given. (Figure courtesy of Swedish National Institute for Working Life.)

Figure 1.15) lie in vertical planes on each side of the neck of the tube, giving a horizontal field and, thus, a corresponding stray field. The field from these coils has a frequency equal to the refresh rate, usually equal to or a small harmonic of the line frequency, and has a sawtooth wave shape. The electric field experienced by the operator is usually due to charge accumulating on the screen and is directed between the screen and the operator's body.

The time derivative, dB/dt, is usually measured only for the maximum field component in front of the VDTs. The median values found are 0.63 and 15 mT/s for the ELF and VLF frequency ranges, respectively. The corresponding maximum values are 1.9 and 101 mT/s for the ELF and VLF fields. For the ELF magnetic field in front of the VDT the median value was 0.21 μT. This is then a combination of the general magnetic field level in the office (median value 0.07 μT) and the emission from the VDT [56].

Flat panel displays for computers are presently based primarily on liquid crystal technology, particularly in portable computers. Compared with VDTs they use much lower internal voltages and currents and do not use magnetic field deflection, leading to the presumption that users' exposures are quite low. Even with a flat panel display, it or various sources inside the computer may expose portions of an operator's body to some fields that can approach few tenths of a microtesla in the ELF and VLF regions, especially for a portable computer that is held on the knees. At the time of writing, any values of the fields from laptop computers or other flat panel displays do not seem to have been published in the peer-reviewed literature. Swedish and Australian trade union tests on several laptop computers have shown magnetic field emissions below their internal certification limits for exposure (see Swedish levels in Table 1.5), initially established for VDTs. The Australians found two exceptions: a peak of up to 10 mG for up to 5 s during the program loading and a 0.01–0.16-μT fluctuating field at 30 cm, emanating from the computer transformer (frequencies not given) [57]. Computers with flat panel displays that have ungrounded power supplies, including laptops running either on batteries or on an ungrounded charger, can generate considerable static charges on their screens, producing DC potentials that exceed the Swedish unions' specifications. Older displays using cold-cathode backlighting sometimes also exceed the specifications for ELF or intermediate RF electric fields (Y. Hamnerius, Chalmers University, private communication, 2005).

Computers equipped for local area RF networking, such as ''Wi-Fi'' systems, and hubs for such networks emit and receive fields in the same general ranges of frequency and

TABLE 1.5

Swedish Tjänstemännens Central Organisation (TCO) Certification Limits for Computer Display Terminal Fields

Frequency Band	Quantity	Field Strength	Measurement Distance From Screen
DC	Electric potential	±0.5 kV	0
Band I	Electric field	≤10 V/m	30 and 50 cm
5 Hz–2 kHz	Magnetic field	≤200 nT	30 and 50 cm
Band II	Electric field	≤1 V/m	30 and 50 cm
20–400 kHz	Magnetic field	≤25 nT	30 and 50 cm

intensity and are subject to the same sorts of limits as other portable RF devices, such as portable or cell phones. These are discussed later.

CRT-based VDTs use magnetic deflection of the electron beam, and therefore an external magnetic field can cause jitter and flicker on the screen. Sandström et al. [58] applied both 50 and 60 Hz magnetic fields to monitors with different refresh rates. The distortion was detectable from 0.6 up to 1.1 μT for seven monitors investigated. Background magnetic fields higher than 0.5 μT are not uncommon in offices; Sandström et al. [56] found that 5% of the workplaces measured exceeded this value. The ability to detect jitter depends, among other things, on the frequency of the disturbance. Since the frequency of the jitter oscillation is equal to the difference between the frequency of applied magnetic field and the refresh rate, the sensitivity to the external magnetic field will be different with different frequencies of the applied magnetic field.

1.3.3 RF Transmissions

1.3.3.1 Shortwave Transmission

High-power shortwave transmitters (approximately 2–25 MHz) are used for international broadcasts. Often the power supplied to the antenna system can be several hundreds of kilowatts. The antenna systems used are most often movable log-periodic or steerable curtain-type antennas.

Measurements of field strengths from such transmitters have been recently presented by Altpeter et al. [59] in connection with their study on health effects on people living near a station. The magnetic field values ranged from tens of milliamperes per meter for those at a distance of 500 m from the antenna to some tenths of a milliampere per meter for those at a distance of a few kilometers. In a study of leukemia and residence near a high-power shortwave transmitter in Italy, Michelozzi et al. [60] reported spot measurements of the electric field in some of the closest houses to be between 3 and 20 V/m. (Under far-field conditions 3 V/m corresponds to a magnetic field of 8 mA/m and 20 V/m to 53 mA/m.) For a review of measured field strengths see also Mantiply et al. [61].

1.3.3.2 FM Radio and TV Transmission

Exposures to RF fields have been occurring for as long as we have had radio broadcasting. Since the antenna towers are usually quite high and the emissions are directed for reaching a long distance, exposure levels near the towers are minimal. The Environmental Protection Agency has done field strength measurements in the United States, and an

TABLE 1.6

Electric Field Strengths

Source	Distance		
	1 km	**10 km**	**50 km**
(a) Combined electric field strengths from large radio and TV transmitters and one type of base station for mobile phones[a]

	10 m	**100 m**	**1000 m**
Base station	7	0.7	0.07

Note: E field in V/m.

[a]Radio: 60 kW ERP; TV1: 60 kW ERP; TV2: 1000 kW ERP. $S = PG/(4\pi R^2) = E^2/120\pi$. (ERP is the effective radiated power, also expressed as PG, where P is the total power to the antenna and G is the gain; R is the distance to the antenna.)

overview is given by Mantiply et al. [61]. At a distance, the fields can be estimated from calculations using the far-field formula, and some examples are given in Table 1.6. The input power is often highest for UHF TV broadcasting. The TV signal consists of an amplitude-modulated video signal and a frequency-modulated audio signal. In Sweden, for instance, 30 kW of power is used for the video signal and about 5 kW for the audio. With the antenna gain this gives an effective radiated power (ERP) of 1000 kW.

There have not been many radio and TV towers built during the last 10 y or so, although a number have been moved or upgraded, e.g., moved to taller buildings for greater range, but we have seen an increase in the number of terrestrial channels available. New ways of transmitting information have also come into play with digital radio and TV. However, with these the output RF power may be lower; instead, this technique uses a much larger frequency bandwidth.

The total power density of RF exposure of the public has undeniably increased during the last 10 y. Tell and Mantiply [62] reported in 1980 that the average level in the United States from FM radio and TV transmitters was about 50 $\mu W/m^2$. Today, exposure due to such sources is about the same [50], but with mobile phone base stations added, the total power density is now often found to be on the order of 100 $\mu W/m^2$ or so (see Figure 1.16). Despite the proliferation of mobile telephone systems, most of the power is still due to broadcasting (Figure 1.11). Although the total level of RF exposure of the general public has increased during the last few years, it should be clearly stated that at all distances the RF field levels on the ground from base stations are well within the international guidelines for RF exposure of the general public.

1.3.3.3 Wireless Communication Systems (Base Stations, Personal Wireless Devices Such as Cellular Telephones and Pagers)

1.3.3.3.1 Mobile Phone Base Stations

Current mobile telephone systems operate at frequencies between 800 and 2100 MHz, but some older systems operating near 450 MHz are still in use (see Table 1.7). With the rapid increase in the use of mobile phones, the number of base stations has also increased. The phones operate by communicating with a nearby base station, which is a low-powered

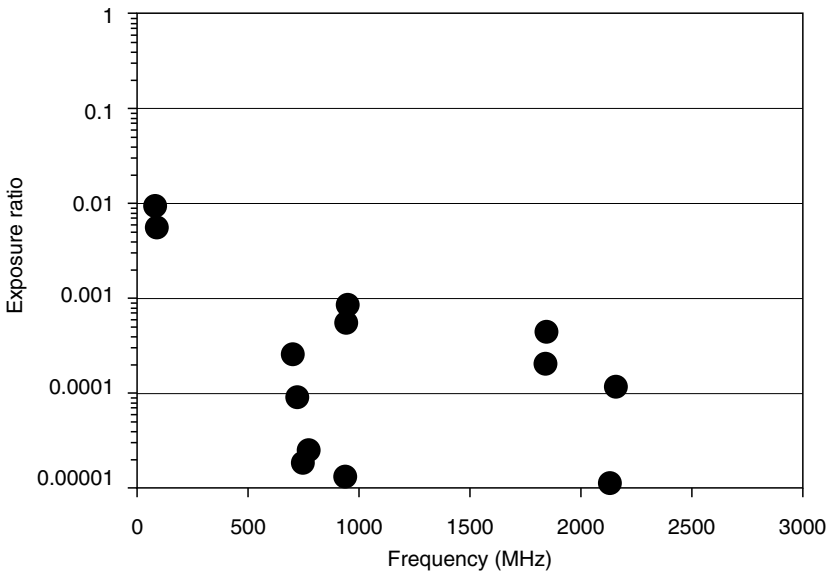

FIGURE 1.16
Power and frequency of environmental RF fields at a sample urban location in Sweden, plotted at each frequency as a comparison to the ICNIRP guideline power limit for personal exposure at the same frequencies, which is set equal to 1 (for plot of limits as a function of frequency, see Chapter 8 in *BMA* on standards in Ref. [82]). (From Hamnerius, Y. COST 281 Workshop 2004/09, Workshop on RF Exposure Assessment, Paris, September 20–21, 2004. With permission.)

radio transmitter, typically mounted on a tower or the roof of a building, that relays calls between the user and the telephone system. In Nordic countries the market penetration is over 100%; that is, there are more mobile phone subscribtions than people; many have more than one phone, and practically everone in the working population has access to a mobile phone. The number of base stations in Sweden is estimated at over 20,000. In 2000,

TABLE 1.7

Frequencies and Modulation Characteristics of Various Mobile Telephone Systems

System	Carrier Frequency	Modulation	Multiplexing Type
TETRA	380–470 MHz	17 Hz	TDMA
MIRS	806–821 MHz	11.1 Hz	TDMA
NADC	824–849 MHz	50 Hz	TDMA
CDMA	824–849 MHz	800 Hz	Multichannel
Analog	824–849 MHz	FM	None
GSM	890–915 MHz	217 Hz	TDMA
PDC	929.2 MHz/1.5 GHz	50 Hz	TDMA

the United States had more than 82,000 cellular base station sites, some with more than one base station in operation, while there were some 20,000 base stations sites in the U.K. [63].

The antenna system used for base stations comprises often either omnidirectional (whip) antennas, which radiate in all directions in the horizontal plane, or directional (panel) antennas, which radiate energy primarily from their front surfaces. Most commonly employed is a sectorized panel arrangement with three sets of directional transmitting and receiving antennas, oriented 120° apart.

The antennas have a high gain, giving a narrow beam in the vertical direction but a quite wide one in the horizontal direction. In the main beam of the antenna, that is, several meters or more directly in front of and at the same height as the antenna, the intensity of the beam (i.e., the power density) decreases as the inverse square of the distance from it. The RF exposure a person receives from a base station thus depends both on the distance from the antenna and on the angle with respect to the direction of the main beam. At ground level, the signal is relatively weak near the base of the antenna tower since the main beam is passing directly overhead. The ground level signal characteristically increases with distance from the tower to a maximum at between 10 and 100 m from the base of the tower and then decreases at still greater distances. Panel antennas only radiate significant amounts of energy in the forward direction. Thus, for panel antennas mounted facing outward on building parapets, the exposure is low for people on the rooftop or in rooms below the antenna. (See further the 1999 report on cellular telephones and health by the U.K. House of Commons Committee on Science and Technology [64].)

In rural areas, where there is a lower user density, base stations are typically a couple of kilometers apart. In towns and cities where there are more users the cells are smaller and transmitter base stations can be as little as a few hundred meters apart. The actual levels of transmitted power vary widely between urban and rural areas. Since a longer reaching distance is wanted in rural areas, the output power tends to be greater, whereas the large increase in the number and density of base stations within the cities will make the cells smaller and thereby also permit a reduction of output power from the surrounding base stations. Therefore, the levels of public exposure to RF energy from any system will not increase in proportion to the number of its base stations in an area.

In Table 1.6b an example is given of the calculation of electric field strength under far-field conditions. The values given are for the main beam, and since the beam would not be aimed at the ground in the near zone, the theoretical values are presumably overestimating the field strength for close distances. Measurements of field strength from base stations have recently been reported by Thuroczy et al. [65] and Hamnerius and Uddmar [66]. They found levels encountered within about 20 m from the antenna in the range of a few to some tens of volts per meter. However, at distances where most people would be exposed, the field strength is down to tens of millivolts per meter within cities, and in rural area values as low as a few millivolts per meter can be measured. For an estimation of maximum encountered levels, the formula used in Table 1.6b above may be used, and as can be seen from this table values in the range of tens of millivolts per meter are estimated for a distance of 1000 m from the station.

1.3.3.3.2 Handheld Mobile Phones

The technical details of analog and digital systems used for mobile phones have been described in detail [67,68], and only a short background is given here. The Nordic Mobile Telephone (NMT) system operates at 900 MHz with a continuous carrier wave. The maximum output from the handheld NMT900 phones is 1 W. The NMT phones have their output power regulated through the base station in two levels, 0.1 or 1 W; the closer to the station, the lower is the output power likely to be.

To make more efficient use of the available frequencies, various schemes that take advantage of the relatively slow way speech transmits information have allowed more than one conversation to occur in the same frequency channel. Some of these systems include pulsing the RF signal at various frequencies, often in the ELF frequency region, or otherwise modulating it. The result is a departure from a pure, continuous sinusoidal field. In the digital Global System for Mobile Communications (GSM), which is in very common use worldwide, the information is sent in pulses with a repetition rate of 217 Hz. The pulse length and repetition frequency give a duty cycle of 1/8. The maximum output power is 2 W, which gives a time-averaged value of 0.25 W maximum. The GSM system also provides a battery-saving function, which in practice reduces the output power to about half of the maximum. The output power is also regulated from the base station, from a maximum of 2 W down to a minimum of 20 mW, depending on the strength of the signal received at the phone; with the newest phones sold today an even lower value of 5 mW is used. The mean output power is thus normally well below 0.1 W. Frequencies and coding patterns of some other current or proposed mobile telephone signal systems are indicated in Table 1.7.

Different models of phones have different specifications for the antenna design position and physical dimensions, for instance, a dipole antenna or a helical antenna. Kuster [69] measured 16 different European digital phones and found a very wide variation in the SAR values. The phone giving the lowest value, when averaged over time and 10 g of tissue, had a specific absorption rate (SAR) of 0.28 W/kg in the user's head, and the one with the highest value had an SAR of 1.33 W/kg, all normalized to an antenna input power of 0.25 W, which is the maximal value for a GSM phone. If the averaging was done over 1 g of tissue, the span was from a low of 0.42 W/kg to a high of 2.0 W/kg. Anger [70] reported the measurement of SAR on 21 different phones, and his result is similar. The SAR ranged from 0.3 to 1.7 W/kg over 10-g tissues. He also reported the telephone communication power value, that is, how much of the output power can be used for communication, and he found values ranging from only about 5% in the lowest phone to just less than 50% in the ''best'' phone. Thus, more than half of the output power from the phone is lost because of mismatch between the phone and the antenna, and some is deposited as SAR in the user.

These SAR measurements were done under normal user conditions. However, when the phone is slightly tilted toward the head, Kuster [69] shows that the value can go up from 0.2 to 3.5 W/kg. Thus, for different phones under maximal output, we have a factor of about 5 between the extremes, and to this the personal handling of the phone gives a factor of tenfold or more. It should be noted that all given values are the maximum SAR values found, regardless of the anatomical location. An equal weight is given to the values, independent of whether they are obtained on the external ear, in the middle or inner ear, or behind the ear. In the future, it will be necessary to make the comparison at the same anatomical location. Presumably then, the values as given by Kuster [69] might differ even more.

Taken together there is a rather large uncertainty in estimating the actual SAR that depends on the specific situation, including a factor of 100 from the distance to the base station and at least a factor 10–50 depending on the make and model of the telephone and the personal style of use.

The currents from the battery also give rise to magnetic fields near the phone. For GSM phones magnetic flux densities of a few microtesla near the phone have been measured [66,71]. The fields are pulsed DC fields with a frequency of 217 Hz. For the NMT phones the magnetic field from the battery current can be regarded as pure DC. Jokela et al. [72] recently measured seven different GSM phones and examined the frequency content of the magnetic pulse, and he found that a considerable amount is found in the low kilohertz range. It was even found that some phones exceeded the ICNIRP guideline reference values when the multiple frequency formula was applied, but calculations show that the BRs were not exceeded.

1.3.4 RF EM Fields in Industrial Settings (RF Dielectric Heaters, Worker Exposure to Broadcast Systems)

1.3.4.1 RF Sealers

Operators of RF plastic sealers (RF operators) are an occupational category highly exposed to RF with frequencies around 27 MHz. RFs are used to produce heat to seal, for instance, plastics for tarpaulins, tents, rain clothes, and covers. Around an RF plastic sealer (RF sealer), both a magnetic and an electric field will be present, and close to the machine the coupling between the two is complex since far-field conditions are not at hand.

During RF exposure, a current is induced in the body, the magnitude of which is dependent on many factors such as the electric and magnetic field strength, the polarization of the field, and the grounding conditions. See further Wilén et al. [73], who tested different techniques to measure the induced current in grounded as well as ungrounded conditions.

Within the category of RF sealer operators, many different exposure situations exist, which can roughly be divided into two main types: tarpaulin workers and readymade clothing workers. Tarpaulin workers often stand in front of the RF sealer and will experience whole-body exposure, which often causes a high current to pass through the ankles. Readymade clothing workers often sit down in front of the RF sealer, often without perfect contact with the ground, but with their hands close to the electrode.

To get a good weld, both the welding time and the total power can be adjusted. The combination of the two will produce enough energy to seal the plastic. Typical welding times range from 1 to 10 s, depending on the material being sealed. The total exposure time will also vary between different RF-sealing processes; in the same amount of time, more welds are made in the readymade clothing industry than in the tarpaulin industry. For more information about the welding process see Refs. [74–76].

In a recent study, Wilén et al. [77] studied the exposure among RF sealer operators. The mean values of the calculated 6-min spatially averaged field strengths, in line with ICNIRP recommendations, are 107 V/m and 0.24 A/m, respectively. The maximum measured field strengths were 2 kV/m and 1.5 A/m, respectively. The induced current in ankles varied depending on the work situation, with a mean value of 101 mA and a maximum measured value of 1 A. In total, 16 out of the 46 RF plastic sealers measured exceeded the ICNIRP guidelines.

1.3.4.2 Occupational Exposure from Broadcasting and Radars

Workers in the fields of communication and radar are only exposed to low-level field strength in most situations. However, when climbing FM or TV towers, for instance, accidental exposure can be intense if proper safety precautions are not taken to keep exposure below the regulated limits. The same is true when someone is working near transmitter cabinets with the interlocks defeated and doors open. In these instances, the exposure, usually inadvertent, can be substantial.

Radar is used to detect the presence and directions of aircraft, ships, or other usually movable objects. The systems usually operate in the frequency range from 300 MHz to 15 GHz depending on the purpose of their use. The output power can range from a few milliwatts from police radar to several kilowatts for large air surveillance systems. A short description of various systems can be found, for example, on the WHO Fact Sheet No. 226 [78]. Here, as an example, a short description is given of one usual system where environmental exposure may occur. For civilian air traffic control, radars operating at 1305 MHz are used. The systems use a pulsed field with pulse duration of 2 μs and

repetition rate of 625 pps. The peak power is 1.8 MW, and with the antenna gain this gives 3590 MW peak ERP in the maximum direction. Calculations using the far-field formula then give a peak electric field at 5 km of 65 V/m (equivalent power density of 11 W/m^2). However, with the pulsing this comes down to a time-averaged power density of 1.4 μW/cm^2, and since the antenna is rotating at 9 rpm and the lobe width is 1.2° this is then further reduced to 3×10^{-5} μW/cm^2. For a review of measurements on different systems see Mantiply et al. [61]

In all known exposure situations of exposure of the general public to EMF from radar systems, the level is below the limiting values given in international guidelines. However, occupational exposure in the near field can occur, and strict adherence to safety instructions is needed, in form of both engineering controls, for example, interlocks, and administrative controls, for instance, strong training and enforcement of safety policies.

1.3.4.3 Exposure in Medical Applications

When medical uses of EM devices are considered, a distinction is made between exposure of patients and medical workers operating the equipment. The balance between any possible risks and the anticipated benefit of exposure of the patient has to be considered by consultation between the patient and the prescribing physician; as a result, exposures are often in excess of limits for workers or the general public. However, operator exposure is governed by the usual rules for occupational exposures; hence, only operator exposure is considered here.

One of the earliest applications of RF energy was shortwave diathermy, which usually operates at 27 MHz. Usually, unshielded electrodes are used, and this may lead to high stray fields. The person operating the equipment, therefore, may be exposed to high field strengths, and the time-averaged guideline for exposure may be exceeded for both RF electric (E) and magnetic (H) fields, depending on the working conditions at hand. Microwave diathermy at 2.45 GHz is also being used in therapy. In this case, the antenna is such that the beam can be directed toward the area to be treated, but the microwave beam may easily be directed toward the patients. Although the beam may not be exposed to the therapist, it may be exposed to the people in the immediate vicinity, including people waiting in the next room. It is therefore necessary to take this into account when planning the space where the microwave diathermy treatment is to be performed.

Electrosurgical units are commonly used in operating suites. They employ RF energy for cutting and coagulation and typically operate at frequencies from about 0.5 MHz to a few megahertz. The energy is supplied to the cutting tool via unshielded cable, which may pass close to the arm and hand of the surgeon, resulting in exposure of operating room personnel to RF energy. The electric and magnetic field near the active lead may be quite high, from a few hundred volts per meter to several kilovolts per meter [79,80]. The induced current in the tissue is of the same order of magnitude as the basic guideline limit for these frequencies, about 5 A/m^2. Since the exposure is rather high, precautionary action would be wise, and shielded wires should be used for the active lead.

Operator and general public exposure to static and RF fields may occur in connection with the use of magnetic resonance imaging (MRI) and nuclear magnetic resonance spectrometers. MRI systems use strong DC magnets, typically from 0.05 to about 3 T, as well as rapidly changing gradient magnetic fields with time derivatives (dB/dt) typically from 1 to 3 mT/ms (1–3 T/s). The RF fields (10–100 MHz) are low and almost fully contained within the patient enclosure, and the RF exposure of the operators is negligible. Inside treatment rooms, near MRI equipment, the maximum exposure level is about 1 T in front of the magnet, and nurses and technicians staying with patients can be exposed to magnetic flux densities up to 200 mT, approaching the protection guideline. When professional activities

take place very close to or inside the magnet's tube, workers can be exposed to higher fields (up to 1–2 T), for example, when assisting the patient, plugging in RF cables of treatment coils, or device cleaning. Reduction of the workers' exposure level is possible if MRI device design is required to include operation with workers no less than 0.5 m from the magnet. Workers' training should also include methods for exposure reduction.

Transcranial magnetic stimulation (TMS) has been introduced recently as a noninvasive and focal stimulation tool for the study of connectivity of brain regions, localization of functions, and pathophysiology of neuropsychiatric disorders and a therapeutic intervention method in the treatment of chronic depression. A high-intensity, fast magnetic field pulse produces a cortical stimulus through the induction of locally confined eddy currents; therefore, tailored coil arrangements can be used to achieve controlled local levels of stimulus. The TMS makes use of magnetic fields that can have intensities of up to 1 T with pulse durations in the range of ~0.05 to 0.2 ms. The resulting time derivative of the field can be several tens of kilotesla per second. This impulsive field transient is able to induce a rapid depolarization of the nerve cells within a volume of about 5 mm^3 at the cortical level.

In some instances, the operator holds the TMS transducer coil in place during exposure. Measurements of the leakage magnetic field at different distances from the coils of the transducer show that the intensity of the field decays proportionally to $1/r^3$ (r = distance). The regulations set limits aimed at avoiding excitation of the central nervous system, while TMS or repetitive TMS aims at just reaching the level of local exposure high enough to produce cortical excitations in patients. For the pulse trains in use, one group found a pulse spacing of ~0.3 ms and about 72-μs active pulse width, which gives an equivalent frequency of about 3.5 kHz. For this the limit value is about 1 T/s, and this is transgressed at distances of about 0.7 m from the surface of the transducer's coils under normal treatment conditions [81].

1.4 Conclusion

EM fields, both natural and of human origin, are ubiquitous. Fields of human origin are primarily a result of technological developments that did not begin until late in the 19th century. In general, the natural fields in the environment are much smaller than those inside organisms; natural environmental fields are also usually smaller than fields of human origin at the same frequency. Inside an organism, naturally occurring charges, currents, and fields in cells, tissues, and organs are very important physiologically, and electric charges and magnetic moments are crucial factors in determining molecular structure and chemical reaction rates. Since organisms, including humans, evolved in the natural fields alone, it is not clear how their adaptation to artificial ones might affect them. The other chapters of this handbook explore this question.

Endogenous Electric Fields in Animals

Richard Nuccitelli

CONTENTS

2.1 Introduction

In a volume presenting the biological effects of electromagnetic fields it is appropriate to review the information we have regarding endogenous electric fields in the body. After all, imposed electromagnetic fields may augment the naturally occurring ones, so a complete understanding of the possible effects of imposed fields requires consideration of those electric fields already present. Here, I will provide a brief overview of the direct current (DC) endogenous fields that have been best characterized in animals and will touch on the evidence that these electric fields are required for the function of various cellular and organ systems. Other well-known variable fields that are generated by various electrically excitable organs such as the heart (electrocardiogram), brain (electroencephalogram), and

eye (electrooculogram) will not be covered here. Another very comprehensive review of endogenous fields that will be of interest has appeared quite recently in *Physiological Reviews* by McCaig et al. (2005), and another review of the roles of such fields in development was presented by Levin (2003).

In order to put these endogenous fields in perspective for the reader, I would like to summarize here their main characteristics. Unlike much of the material considered in this volume, these endogenous fields are small and very slowly changing. Endogenous fields typically fall into the 10- to 100-V/m range and are generally very steady, DC fields generated by the flow of ionic currents through cells and embryos. This can be compared with the much higher fields required to electroporate cells (3 V/cell diameter or 3×10^5 V/m for a 10-μm-diameter cell), which are usually only applied for a short time on the order of a millisecond.

2.1.1 Sources of Endogenous Electric Fields

In order to generate an electric field in the body, a voltage generator or power source is required. There are two main sources of such a power source in living systems: (1) the plasma membrane surrounding every cell in the body and (2) the epithelium that surrounds every organ in the body as well as the entire body itself in the form of the skin. The plasma membrane forms the defining boundary for every cell and is a lipid bilayer with many embedded transporter proteins whose main function is to control the movement of molecules inside or outside of the cell. One of these transporter proteins is the Na^+/K^+-ATPase, which is responsible for maintaining two ion concentration gradients across the plasma membrane (high internal [K^+] and low internal [Na^+]). The K^+ concentration gradient, in combination with a large number of K^+ channels in the plasma membrane, results in the outward diffusion of K^+. This outward movement of K^+ leaves behind the anion that was associated with maintaining electroneutrality and thereby separates charge across the membrane. This separation of charge generates a voltage difference or membrane potential (inside negative). This membrane potential is used for a wide variety of cellular functions, from capturing nutrients to signaling the occurrence of important events, such as sperm–egg fusion in many egg types or light absorption in retinal rods. Indeed, we expend more than half of our energy in maintaining this voltage across all of the cells in our brain and kidney, where excitatory events and Na^+-dependent transport constitute major functions (Clausen et al., 1991).

Voltage differences are also found across all epithelial layers, and this is called the transepithelial potential (TEP). Both organs and embryos are surrounded by one or more monolayers of cells called an epithelium. The outer epithelium belongs to the organ while the plasma membrane to the cell, and epithelia pump ions across themselves to generate the TEP. One clear difference between these two voltage sources (plasma membrane and epithelial layer) is their opposite polarity. Whereas the plasma membrane potential is usually negative on the inside with respect to the outside, the TEP is usually positive on the inside or basal side of the epithelial monolayer with respect to the outside or apical side of the monolayer.

This polarity difference results from the opposite flow of charge across these layers. The plasma membrane of most animal cells generates a potential difference across itself that is negative on the interior. This results from the outward diffusion of K^+ that separates charge across the membrane. In contrast, most animal epithelia are composed of highly polarized cells in which Na^+ channels are localized to the apical end of the cell and both the K^+ channels and the Na^+/K^+ ATPases are localized at the basal end. This polarized distribution of these transport proteins leads to Na^+ influx at the apical end and both Na^+ and K^+ efflux at the basal end to drive positive charge to the interior of the epithelial

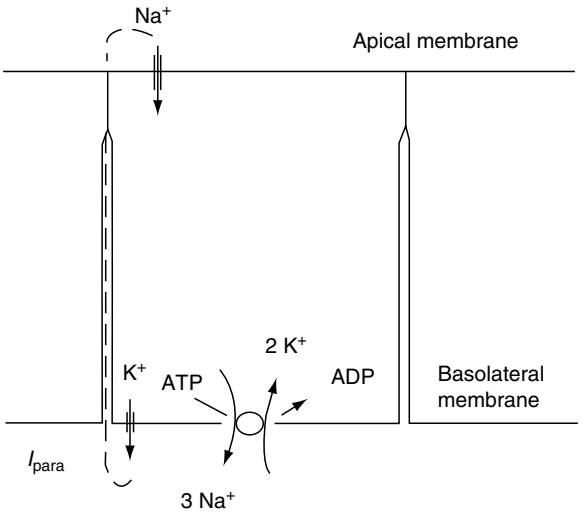

FIGURE 2.1
Diagram of a typical epithelial cell in a monolayer with Na^+ channels localized on the apical plasma membrane and K^+ channels localized on the basolateral membranes along with the Na^+/K^+-ATPase. This asymmetric distribution of ion channels generates a transcellular flow of positive current that must flow back between the cells through the paracellular pathway (I_{para}). This current flow generates a TEP that is positive on the basolateral side of the monolayer.

layer. However, this current cannot flow freely in the extracellular medium because these polarized epithelial cells are attached to each other with both tight and adherent junctions. As the apical–basal transcellular current flows back extracellularly, it must follow a pathway between the cells called the paracellular pathway (Figure 2.1). Current flow through this pathway encounters a high-resistance region at the tight junctions near the apical end, and the current flow through this resistance leads to a TEP that is positive on the basal side of the monolayer with respect to the apical side. The TEP will be proportional to the resistance of this paracellular pathway, and typical values for this TEP range from 15 to 60 mV, basal side positive.

It is this TEP that is the driving force for most endogenous ionic currents in embryos and adults. This voltage across epithelia will drive current out of regions of low resistance where there has been a break in the epithelium (wounds) or where tight junction resistance is low, such as along the primitive streak (Jaffe and Stern, 1979; Winkel and Nuccitelli, 1989), the posterior intestinal portal (Hotary and Robinson, 1990) in chick or mouse embryos, or at the forming limb bud in amphibian, chick, and mouse embryos (Borgens et al., 1983; Robinson, 1983; Altizer et al., 2001). This ''leakage current'' will in-turn generate a lateral electric field along its path that will be proportional to the resistivity in that region. This electric field results from Ohm's law in a conductive medium,

$$E = \rho J$$

where J is the current density and ρ is the local resistivity.

The earliest measurements of the leakage current associated with wounds were made more than a century ago. DuBois-Reymond (1843) used a unique galvanometer that he built himself with more than two miles of wire and measured about 1 μA flowing out of a cut in one of his fingers. This was confirmed in 1849 and 1910 by other investigators, and the history of these measurements is presented in a scholarly review by Vanable (1991). More modern techniques have also been used to study this wound current as discussed. Direct measurements of electric fields *in situ* have been made, and I will discuss them next.

2.1.2 Methods for Measuring Endogenous Electric Fields

2.1.2.1 Self-Referencing Probe

Lionel Jaffe and I developed a technique for exploring transcellular ionic currents, called the vibrating or self-referencing probe (Jaffe and Nuccitelli, 1974). This instrument vibrates a small platinum sphere between two points about 10 μm apart at about 300 Hz and measures the voltage between those points using signal averaging to improve the signal-to-noise ratio. In a conducting medium where most cells find themselves, a voltage difference can exist only where there is a current flowing through the medium. Ionic currents entering or leaving cells can be readily detected by measuring the voltage they generate as they flow through the extracellular medium, and the past 30 years of research on more than 30 cell types has revealed that most cells have an asymmetrical distribution of ion channels that naturally leads to a transcellular current density on the order of 1–10 $\mu A/cm^2$ (Nuccitelli, 1988, 1990). Most epithelia that have been studied exhibit extracellular current densities on the order of 10–100 $\mu A/cm^2$ flowing through the organ or embryo with which they are associated. This technique detects the current that is flowing outside the cell or tissue, and the exact electric field that is generated by this current when it flows inside the cell or tissue can only be estimated based on tissue resistivity. It is more accurate to directly measure the electric fields in the tissue or cells as described here.

2.1.2.2 Microelectrode Techniques for Measuring Endogenous Electric Fields

The classic approach to these measurements is to use KCl-filled glass microelectrodes to penetrate the outer epithelium and measure the voltage just beneath it in several positions. Such electrodes are typically connected via a Ag–AgCl junction to a very high-input impedance preamplifier, so that they do not drain current from the system under study, and their tips are small (on the order of 0.1–1 μm) to minimize tissue damage (Wallis, 1993). If ionic currents are flowing within a tissue, these currents will generate an electric field that can be detected as the difference in potential at various sites along the current path. We will see below that this is the most commonly used approach to measure intraembryonic electric fields.

2.1.2.3 Voltage-Sensitive Fluorescent Dyes for Measuring Endogenous Electric Fields

Another popular technique for measuring the voltage across lipid membranes uses lipophilic fluorescent dyes whose fluorescence is voltage sensitive (Loew, 1992; Loew et al., 2002). For some of these dyes, their fluorescence intensity is dependent on their position within the lipid bilayer, which is in turn influenced by the membrane potential drop across this region. Membrane potential changes can be monitored by measuring the fluorescence intensity of these dyes, and differences in the membrane potential of cells making up an organ or embryo can also be detected. One example of the use of this approach, which will be discussed below, is to provide information about electric fields within sheets of cells that are electrically coupled via gap junctions in the chick embryo.

2.2 Measurements of Endogenous Extracellular Electric Fields

2.2.1 Amputated Limbs

Among the earliest direct measurements of endogenous extracellular electric fields were those made in the regenerating amphibian limb (McGinnis and Vanable, 1986). Upon

amputation, the skin battery of the amphibian limb drives 10–100 $\mu A/cm^2$ out of the cut end of the limb stump. This current flow generates an electric field within the limb tissue that is 60 mV/mm near the lesion during the first hours after amputation, and this field drops to about 25 mV/mm within 6 h as the healing process leads to an increase in the resistance of the wound.

Electric fields of this magnitude have been found to stimulate the growth of neurons into the limb via galvanotropism, and the presence of enhanced nerve in limbs has been correlated with enhanced regeneration (Borgens et al., 1979). The study of nerve galvanotropism has a long and fascinating history that is thoroughly reviewed by McCaig et al. (2005). Briefly, most neurons exhibit sensitivity to imposed electric fields by either bending their outgrowth direction toward the negative pole of the field or in the case of a neural ganglion, exhibiting a higher density of outgrowths on the side of the ganglion facing the negative pole. This galvanotropism may play a role in the guidance of neurons to their targets during development and has also been found to play an important role in regeneration.

2.2.2 Embryonic Electric Fields Beneath the Skin

Direct measurements of electric fields have been made in both avian and amphibian embryos during normal development. Hotary and Robinson (1990) used both the self-referencing probe and microelectrodes to first detect the transembryonic current in the 2- to 4-day-old chick embryo and then measure the electric field that the transembryonic current generates beneath the epidermis. They measured current entering much of the epidermis during stage 14 of development with the outward current focused mainly at the posterior intestinal portal, where up to 105 $\mu A/cm^2$ was measured (Figure 2.2). One would expect that this large anterior–posterior current would generate an internal electric field, so they then used microelectrodes to measure the TEP along this axis. Here, they measured electric fields of 5–20 mV/mm.

They then proceeded to test the hypothesis that these fields are important for normal development by perturbing them (Figure 2.3). They implanted a glass capillary that was filled with either conductive saline agar or nonconducting glass, used as a control, through the ectoderm at the dorsal trunk of the embryo (Hotary and Robinson, 1992). The conductive capillary allowed large currents of about 5 $\mu A/cm^2$ to leak out of the embryo. While the control embryos developed quite normally, most embryos with the implanted conducting capillary exhibited abnormalities in posterior structures where the endogenous electric field is normally the largest but was reduced by the capillary shunt. Perturbing the normal voltage pattern within the embryo resulted in striking tail abnormalities; and an investigation of a genetic mutant, rumpless, that exhibits similar tail abnormalities led to a very interesting correlation. They found that most rumpless mutants exhibited a much lower transembryonic current density and lower electric field within the embryo and those mutants that exhibited a normal electric field pattern also exhibited normal development. Therefore, they found a good correlation between the internal electric field and the normal posterior development. These observations certainly support the hypothesis that the endogenous field is important for the development of posterior structures.

Studies of endogenous fields have also been carried out on the stage 14–21 developing axolotl embryo (Metcalf et al., 1994; Shi and Borgens, 1995). Current is driven out of the lateral walls of the neural folds and the blastopore and enters most of the rest of the embryo's body surface (Figure 2.4). Measurements of the TEP indicate an internal, caudally negative electrical field beneath the neural plate ectoderm. The magnitude of the endogenous field is on the order of 10–20 mV/mm (Figure 2.5). When these embryos

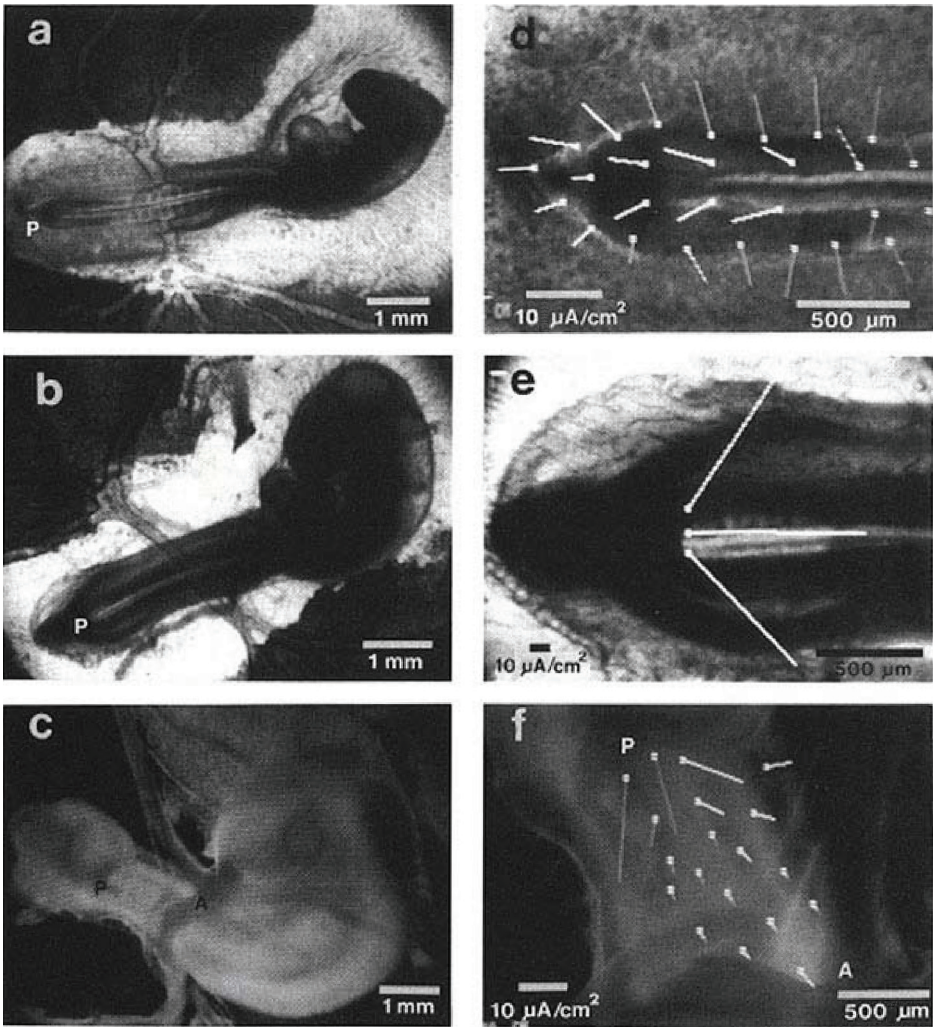

FIGURE 2.2
Ventral surface of three chick embryos at stages 14 (a and d), 17 (b and e), and 20 (c and f). Low-magnification views of the whole embryo are shown in (a)–(c), while (d)–(f) show the current pattern around the posterior intestinal portals of the embryos. Current vectors are represented by lines originating at a dot that indicates the position of the self-referencing probe when the measurement was made. The direction of the vector line away from the dot indicates the direction of current flow at that point, and the length of the line is proportional to the current density. At stage 14 (d), all vectors point toward the posterior intestinal portal or the lateral walls of the midgut. The three vectors shown at stage 17 (e) indicate large currents of about 100 $\mu A/cm^2$ leaving the posterior intestinal portal. At stage 20 (f), outward currents were also found at the posterior intestinal portal. Current densities were much lower by this stage. Note the inward current at the anterior intestinal portal (A). (From Hotary, K.B. and Robinson, K.R. (1990). *Dev. Biol. 140*, 149–160. With permission.)

were placed into an external electric field designed to modify the internal field, abnormalities were observed that depended on the developmental stage (Metcalf and Borgens, 1994). Gastrula-stage embryos exhibited normal development after exogenous field exposure, indicating that the imposed field does not harm the embryo in some nonspecific way. In contrast, neurula-stage embryos exhibited developmental abnormalities when exposed to similar electric fields of 25–75 mV/mm. These data support the hypothesis that the natural electric field within the embryo influences normal morphogenesis.

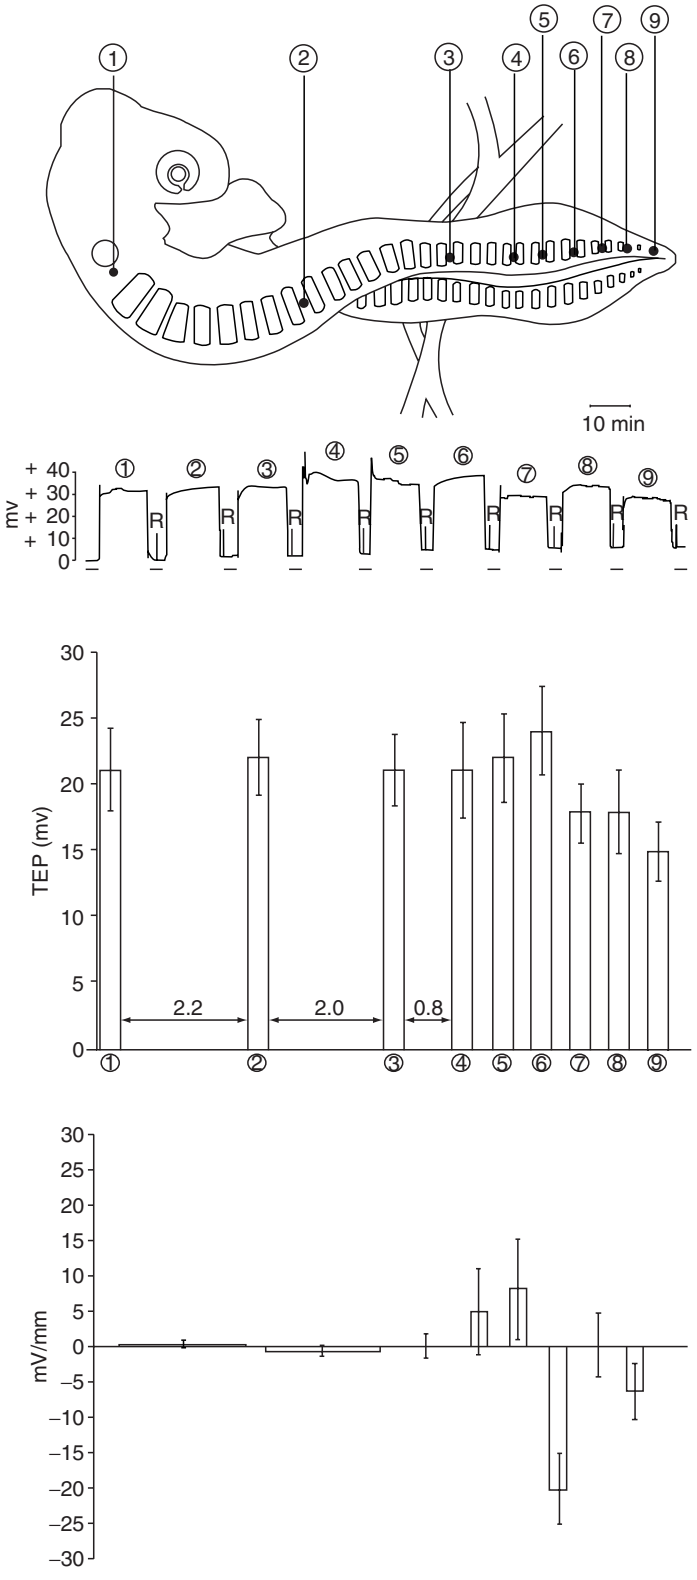

FIGURE 2.3
Stage 17 chick embryo TEP measured in nine rostral–caudal positions. Numbered measurement positions are shown in the drawing in the upper part of the figure. Below the drawing is a chart recording, tracing, and showing the TEP at the different measurement positions. At each numbered peak (corresponding to the positions shown in the drawing) the integument of the embryo was impaled and a stable positive potential was measured. Times at which the embryo was not impaled are indicated by a solid line below the recording. The upper bar chart shows the TEP at each position. The numbers below each bar correspond to the measurement positions indicated. The numbers between bars indicate the average distance (in mm) between each position. Where this is not indicated, the average distance is 0.3 mm. The lower chart shows the average voltage gradient between each consecutive position. Error bars indicate the standard error of the mean, $N = 6$. A steep voltage gradient was found between positions 6 and 7. (From Hotary, K.B. and Robinson, K.R. (1991). *Dev. Biol.* 140, 149. With permission.)

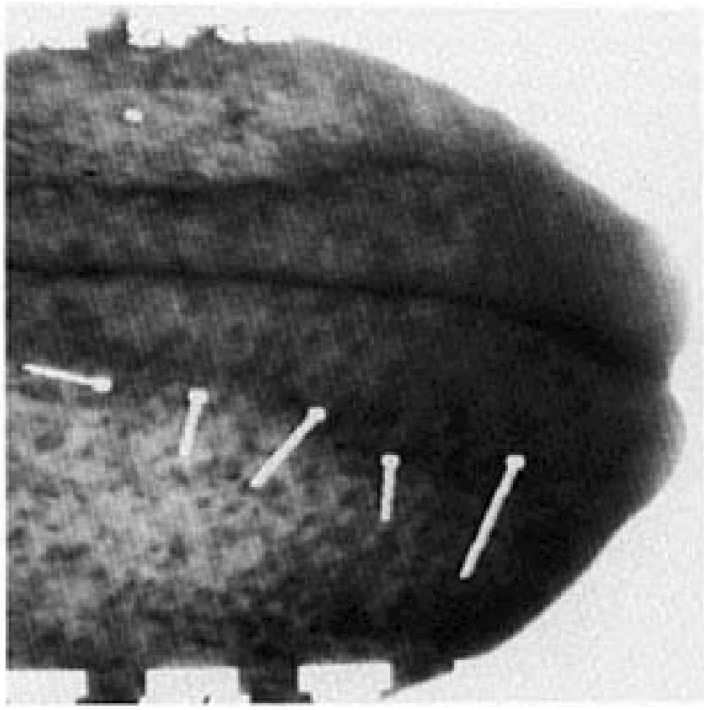

FIGURE 2.4
Neural fold currents in a stage 18 axolotl embryo measured with a two-dimensional self-referencing probe. Current vectors are displayed as a line originating at a dot that marks the measurement position. The direction of current flow from the dot is denoted by the line direction, and its length is proportional to the current density. Note the outwardly directed currents at the edge of the cranial neural folds. (From Metcalf, M.E.M., Shi, R.Y., and Borgens, R.B. (1994). *J. Exp. Zool. 268*, 307–322. With permission.)

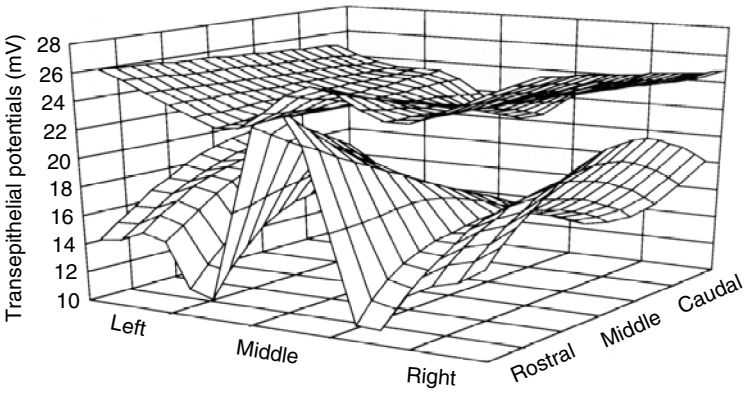

FIGURE 2.5
Summary of three-dimensional plot of TEPs at stage 15/16 (bottom) and stage 18/19 (top) axolotl embryos. The overall increase in the magnitude of TEPs at stage 18/19 is real, permitting these two views to be presented adjacent to each other. Note that only a hint of the characteristic voltage gradients beneath the ectoderm is evident at stage 18/19, and the potentials are not statistically different from one another. The embryo is essentially isopotential within the extracellular domain of the neural plate near the climax of neurulation. (Reproduced from Shi R.L and Borgens R.B. (1995) Dev. Dyn. *202*, 101–114, 1995. With permission.)

2.2.3 Fields Associated with the Neural Tube

The neural tube forms during development as a folding over of neural plate epithelium, inverting the normal polarity of this layer. The apical end of the neural plate becomes the inside of the tube so that transport of Na^+ occurs from the inside to the outside of the tube and the trans-tube potential is inside negative. This potential has been measured in both frog and axolotl to be as large as −90 mV (Hotary and Robinson, 1991; Shi and Borgens, 1994). Neuroblasts within the wall of the tube are therefore exposed to very large electric fields, since the wall is only about 50 μm thick and the 90 mV across this distance generates a field of roughly 1800 mV/mm. There is little doubt that such a large field will influence the migration and sprouting of these neuroblasts.

2.2.4 Fields Associated with Epithelial Wounds

As noted above, the earliest measurements of the electrical phenomena associated with wounds did not measure the electric field itself but rather the current flowing out of the wound. More modern techniques have also been used to study this wound current. The leakage current that is driven out of epithelia in low-resistance regions has been measured using the vibrating probe technique (Jaffe and Nuccitelli, 1974) in several systems. One of the earliest such measurements was a current as large as 100 $\mu A/cm^2$ leaving the stumps of regenerating newt limbs (Borgens et al., 1977). Similar measurements have also been made on fingertip amputation currents in humans (Illingworth and Barker, 1980), where up to 30 $\mu A/cm^2$ was detected leaving the accidentally amputated stump for about 3 wk. These currents will certainly generate electric fields just beneath the epidermis that will be proportional to the resistivity encountered in the tissue. The range of human tissue resistivity spans 200–1000 Ω cm (Faes et al., 1999), so these currents would be expected to generate an electric field within the tissue of about 10–100 mV/mm.

However, since this tissue resistivity can vary substantially as a function of cell density and tissue anatomy, it is always more reliable to measure these fields directly in the tissue rather than estimating them based on the transembryonic current density. This has been accomplished in four different wound types in skin and cornea. The classic approach to these measurements is to use KCl-filled glass microelectrodes to penetrate the outer epithelium and measure the voltage just beneath it in several positions along a line leading away from the wound. However, for skin measurements, another approach is more common. This method is to measure the potential gradient just beneath the stratum corneum on the surface of the epidermis, either with surface electrodes or by other means. The field generated by the current flowing between the upper surface of the epidermis and the stratum corneum is often larger than that generated below the epidermis because of the higher resistivity of that upper region. The range of field strengths measured in the four cases in the literature is surprisingly small, between 40 and 200 mV/mm (Table 2.1). The field direction is a function of position. Beneath and within the epidermis the field polarity has the negative pole at the wound center, and above the epidermis the wound current is flowing in the opposite direction so that the positive pole is at the wound (Figure 2.6).

These wound fields have some useful properties for signaling. First, they appear immediately upon wounding since the TEP is continuously present to drive current out of any low-resistance region as soon as it is formed. Second, the lateral electric field illustrated in Figure 2.6, that is generated by the wound current, will persist until the resistance increases as the wound heals. Thus, we have a signal that is immediate and persistent. These are ideal properties for a physiological signal to stimulate wound healing. If the epithelial cells forming the epidermis were able to detect such electric

TABLE 2.1

Endogenous Electric Fields Measured near Wounds

Species	Tissue	Wound Type	*E* Field (mV/mm)	Reference
Bovine	Cornea	Cut	42	Chiang et al., 1992; Sta Iglesia and Vanable, 1998
Notophthalmus viridescens	Digit	Digit tip amputation	40	McGinnis and Vanable, 1986; Chiang et al., 1989; Iglesia et al., 1996
N. viridescens	Limb stump	Amputation	7–50	McGinnis and Vanable, 1986
Guinea pig	Skin	Small cut	100–200	Barker et al., 1982

fields, they would be able to initiate wound healing immediately upon wounding. This is in fact the case, as discussed in the next section.

Measurements of endogenous electric fields near epithelial wounds have been made in three different systems. The first was a skin wound in the guinea pig (Barker et al., 1982). The transepidermal potential was measured in several locations lateral to a skin wound (Figure 2.7). At the wound itself, there is no epidermis, so the transcutaneous potential is zero, whereas about 1 mm away, the transcutaneous potential exhibited the normal value of 50–70 mV. The steepest voltage gradient was found immediately adjacent to the wound edge where values as high as 150 mV/mm were measured. The second direct measurement of the electric field near a wound was made in two regions of the newt limb. The electric field adjacent to an amputated digit was measured with microelectrodes and found to be about 40 mV/mm (McGinnis and Vanable, 1986; Chiang et al., 1989; Iglesia et al., 1996). This is very similar to the field near an amputated limb of the newt of 7–50 mV/mm (McGinnis and Vanable, 1986). The third direct measurement was made on the bovine cornea, and the magnitude of the electric field was 42 mV/mm (Chiang et al., 1992; Sta Iglesia and Vanable, 1998).

The fields in the cornea and the newt digit have been found to play a role in wound healing. When the field strength associated with the wound is modified, the rate of wound healing changes. The newt's wound healing rate can be optimized under normal

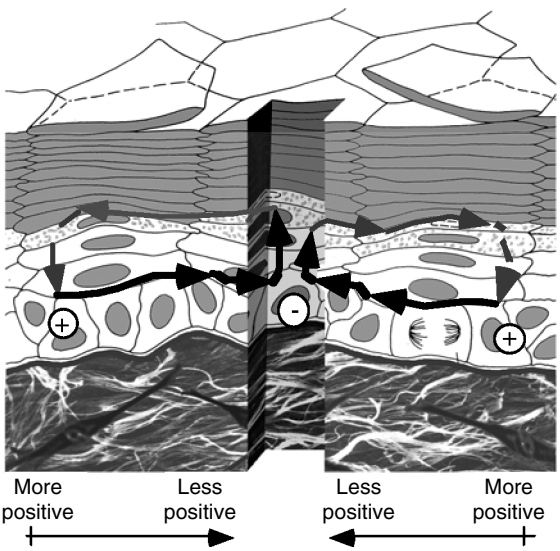

FIGURE 2.6

Generation of skin wound electric fields. Unbroken skin maintains a ''skin battery'' or TEP, generated by the apical influx of Na^+ and basolateral efflux of K^+. When there is a wound, the potential drives current flow through the newly formed low-resistance pathway, generating an electric field whose negative vector points toward the wound center at the lower portion of the epidermis and away from the wound on the upper portion below the stratum corneum.

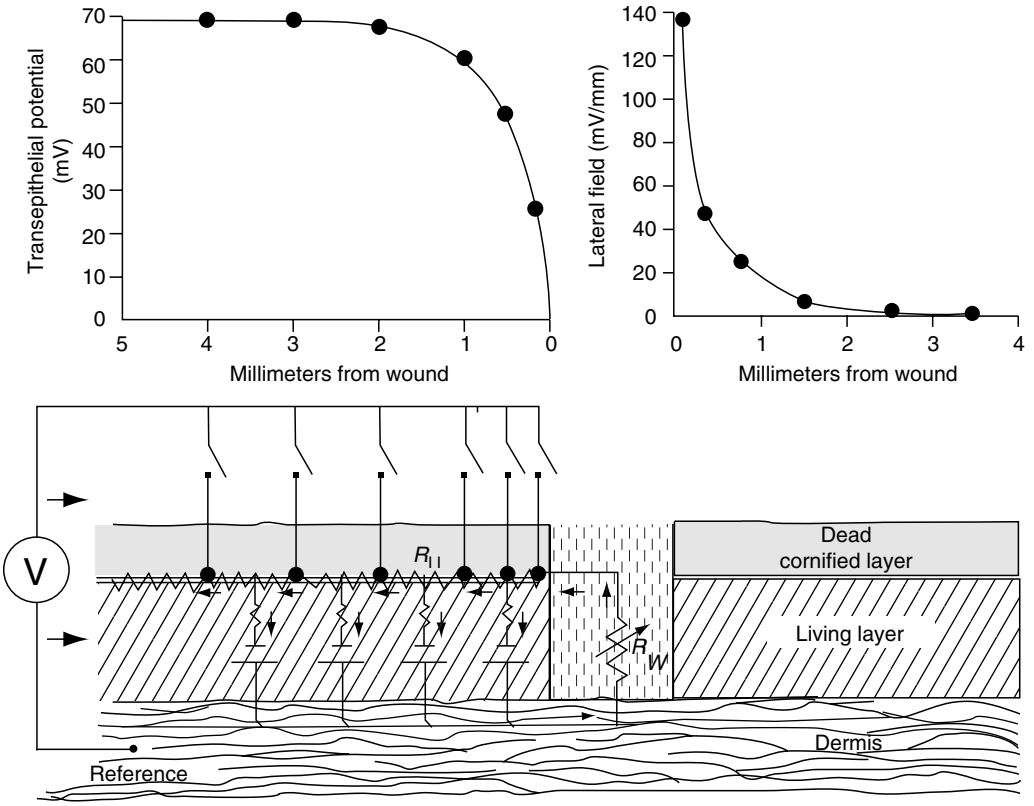

FIGURE 2.7
The electric field near a skin wound in a guinea pig. Bottom: diagram of the method used. A metal probe penetrated the stratum corneum to contact the epidermis at various distances from the wound site, and the surface voltage at each location was recorded with respect to the potential within the dermis. This voltage is the TEP and is plotted in the upper left of the figure. The voltage at the wound must be zero because the epidermal layer has been broken there, and far from that region, the TEP is 70 mV. The electric field at a given location is given by the voltage difference between sampling sites divided by the distance between those sites and is plotted on the upper right of the figure.

conditions but cannot be speeded up, removing the endogenous field does slow down the rate of wound healing by about 25%. However, the rate of bovine corneal wound healing can be enhanced by increasing the electric field strength. Epithelization was fastest in wounds with the field strength raised to 80 mV/mm, more than twice the normal field strength present in wounds maintained in Hanks' solution alone. Epithelization decreased, however, when the field strength was increased to 120 mV/mm. A similar pattern was also observed when the field's polarity was reversed. Decreasing the field strength by submersion of the lesions or by treating the lesions with the Na^+ channel blocker, benzamil, significantly retarded healing. In addition, an increase in the field strength of lesions treated with Na^+-depleted Hanks' solution, by the addition of DC, increased the rate of epithelization. These observations suggest that the endogenous electric field plays a role in the normal wound healing process.

More recent studies of rat cornea have reported a similar correlation between the wound healing rate and the electric field strength. The mammalian cornea exhibits an internally positive TEP of 30–40 mV. Na^+ and K^+ are transported out of the tear fluid and into the epithelium while Cl^- is transported in the opposite direction. A wound in this

epithelium exhibits the same current pattern as skin (Figure 2.6), and a laterally oriented electric field is generated by this wound current with the cathode at the wound site. Recent work from McCaig, Zhao, and colleagues has indicated a strong correlation between the rate of wound healing in the rat cornea and the electric field strength lateral to the wound (Zhao et al., 1996; Song et al., 2004). They have used drugs to either increase the trans-corneal potential or decrease it. Drugs that increased this voltage difference also increased the rate of wound healing, while drugs that reduced this voltage difference also slowed down the rate of wound healing. In addition, when current was injected to restore and amplify the endogenous electric field in bovine cornea, the wound healing rate increased (Sta Iglesia and Vanable, 1998). These data provide very strong support for the hypothesis that these electric fields near corneal wounds play an important role in influencing the healing of these wounds.

2.3 Measurements of Endogenous Intracellular Electric Fields

2.3.1 Nurse Cell Complex in Insects

In the silk moth oocyte-nurse cell complex or the ovarian follicle, the oocyte cytoplasm is about 10 mV more positive than that of the nurse cell cytoplasm despite their connection by a broad cytoplasmic bridge. Woodruff and Telfer have published several studies of this system in which they show that the polarized transport of fluorescently labeled proteins between nurse cells and oocyte depends on the charge of these proteins in a manner consistent with intercellular electrophoresis driven by the voltage gradient across the cytoplasmic bridge of the silk moth and other insects (Jaffe and Woodruff, 1979; Woodruff and Telfer, 1980; Woodruff and Cole, 1997; Cole and Woodruff, 2000). Since these nurse cell complexes arise from incomplete cell division they must be considered electrically as a single cell that is generating a significant voltage gradient across a small region.

2.3.2 Development of Left–Right Polarity in Chick and Frog

The most recent study of the role of electric fields in development utilized both frog and chick embryos. The generation of left–right asymmetry in these systems was found to depend on both functioning gap junctions and voltage difference between blastomeres in very early stages of development (Levin and Mercola, 1998, 1999; Levin et al., 2002). This work started with a pharmacological screen to identify drugs that interfered with the development of left–right patterning. The most effective drugs were the ones that interfered with K^+ and H^+ ion fluxes. Lansoprazole and chromanol 293B were the most effective and these block the H^+ pump and a specific K^+ channel (KvLQT-1), respectively. Next most effective was SCH28080 and omeprazole, which block the H^+/K^+-ATPase, followed by $BaCl_2$, which blocks all K^+ channels.

They further tested the hypothesis that these ion fluxes were important for left–right patterning by injecting mRNA for either the alpha or beta subunits of the H^+/K^+-ATPase or the K^+ channel into the frog egg. They found that heterotaxia was induced when either was injected but by far the largest increase, 37%, occurred when all three mRNAs were injected. This suggests that overexpression of these molecules, which can influence or perturb ion concentration gradients of K^+ or H^+, disrupted the normal left–right patterning of the embryo.

In order to learn more about the mechanism through which H^+/K^+-ATPase influenced patterning, they used *in situ* hybridization to show an asymmetrical distribution of the K^+/H^+-ATPase. It was concentrated in the right ventral blastomere of the 4-cell stage frog embryo. the addition of Both K^+ channels and K^+/H^+-ATPase should hyperpolarize cells making them more negative than their neighbors. This voltage difference between the blastomeres of the 4-cell stage embryo could be used to segregate low molecular weight determinants through gap junctions to achieve asymmetric gene expression. They further tested this hypothesis by measuring the membrane potential of cells near the primitive streak during early chick development. They used an anionic fluorescent dye, $DiBAC_4$, whose distribution depended on membrane potential to show that the early chick embryo exhibited a voltage gradient across the primitive streak. The left side of the primitive streak was 10–20 mV more positive than right side and this difference was inhibited by the K^+ channel blocker, $BaCl_2$, and the H^+/K^+-ATPase inhibitor, omeprazole. Since these drugs also partially inhibited the development of left–right patterning, the membrane potential difference appears to play a role in this aspect of development. This paper is the first to demonstrate a role for membrane potential differences between blastomeres in early vertebrate pattern formation.

2.4 Methods for Modifying Endogenous Electric Fields

Modifying endogenous fields within embryos or cells is really quite challenging. The only way to generate a relatively steady field in a conducting medium is to pass current through it. However, the outer membranes or epithelia surrounding the targets here make this very hard to accomplish. These structures have high resistance to current flow so that slowly varying fields placed outside the cell or embryo will not effectively penetrate to the inside but will mainly generate current flow around the outside of the cells or embryos. Because of this there have been precious few attempts to modify endogenous fields, but I will discuss some of them.

The only exception to this field penetration problem is the application of ultrashort pulses in the nanosecond domain that have risen times faster than the charging time of biological membranes (Schoenbach et al., 2004). These pulses penetrate beyond the plasma membrane into the interior of cells and tissues but are present only for very short times. It is conceivable that by combining millions of these short pulses per second, one could significantly modify the DC electric field within cells and tissues. This remains to be explored.

2.4.1 Passing Current between Electrodes

If two electrodes can be placed within a single cell or in different regions of an embryo, current can be passed between them and a well-defined electric field can be generated. However, this requires penetrating the outer membrane or epithelium and may damage this outer layer. The longer the field is applied, the more likely that some damage will occur due to vibrations or embryo movement. This approach has been used with some success in the regenerating tip of newt limbs (Chiang et al., 1991; Iglesia et al., 1996), where current was passed along the limb by inserting one electrode into a slit made at the knee and the current delivery electrode was placed distal to the wounded digit tip. The electric field at the newt limb could be manipulated in this way, and elimination of this field significantly slowed down the rate of wound healing.

2.4.2 Low-Resistance Shunts

One way to perturb the natural transembryonic current pattern is to place a low-resistance pathway or shunt into a resistive membrane or epithelium. The endogenous fields will drive current out through this shunt, and this new current flow will definitely perturb the endogenous field within the tissue. This technique was used with striking results by Robinson's group in the chick embryo as described above (Hotary and Robinson, 1994).

2.4.3 Placing Tissues in an External Electric Field

While DC electric fields cannot penetrate into the conducting cytoplasm of a cell or tissue, they have been found to perturb normal development at certain stages in amphibians (Metcalf and Borgens, 1994). In addition, there is a very extensive old literature in which the polarity of both development and regeneration could be strongly influenced by imposed DC electric fields (Jaffe and Nuccitelli, 1977; Levin, 2003). One interpretation of these observations is that the imposed field has its effective target along the exterior of the embryo via lateral electrophoresis of membrane glycoproteins.

The only external electric field that can penetrate into the interior of cells is the one that rises faster than the charges within the cell can redistribute (Schoenbach et al., 2004). Such a pulsed field could certainly modify internal electric fields for the extremely short duration of the pulse. Perhaps by using either a large field strength or multiple pulses, such brief pulsed fields might have a significant effect on endogenous fields. This relatively new area deserves future investigation.

2.5 Summary

All plasma membranes and epithelia generate voltage differences across themselves. These batteries are the power sources that drive ionic currents through cells, tissues, and organisms. These currents will generate internal electric fields as they traverse tissue, and such fields can do work through electrophoresis of charged molecules within and between cells as well as in the plane of the plasma membrane. Cases in which such fields have been measured include the following:

1. Two- to 4-day-old chick embryos generate a 20-mV/mm field near the posterior intestinal portal that is important for normal development of posterior structures.
2. Stage 14–21 amphibian embryos generate similar internal electric fields, and modifying these fields during neurulation but not gastrulation results in developmental abnormalities.
3. Neural tubes in amphibians generate an internally negative voltage difference of as much as 90 mV across the wall of the tube, and cells in this region are exposed to fields as large as 1800 mV/mm.
4. Mammalian skin wounds generate 150-mV/mm fields just below the stratum corneum, and corneal epidermal wounds exhibit fields of 40 mV/mm lateral to wounds.
5. The development of left–right asymmetry in frog and chick embryos utilizes an electric field between blastomeres that is generated by an asymmetrical distribution of the K^+/H^+-ATPase among the blastomeres.

In nearly all of these well-documented examples, the electric field plays a critical role in either the development of the organism or the wound healing and regeneration of adult structures. Because of this, imposed electric fields may be utilized to perturb or influence normal development. One intriguing possible perturbation is the use of imposed electric fields to enhance the rate of wound healing, particularly in cases where the normal healing process is slower than normal, as observed in chronic wounds.

Dielectric Properties of Biological Materials

Camelia Gabriel

CONTENTS

3.1 Introduction

At some level of organization, all matter consists of charged entities held together by various atomic, molecular, and intermolecular forces. The effect of an externally applied electric field on the charge distribution is specific to the material; the dielectric properties are a measure of that effect; they are intrinsic properties of matter used to characterize nonmetallic materials. Biological matter has free and bound charges; an applied electric field will cause them to drift and displace, thus inducing conduction and polarization currents. Dielectric spectroscopy is the science that relates the dielectric properties to the underlying microscopic mechanisms of polarization and conduction. These dielectric phenomena are determined by and are informative about the structure and composition of the material. Consequently, knowledge of the dielectric properties is of practical importance in all fields of science where electromagnetic fields impinge or are used to probe or process matter. It is equally important in biomedical fields such as electrophysiology, where endogenous bioelectric sources provide signals that are sensed through various body tissues and are affected by their dielectric properties.

The past decade has seen a dramatic increase in the exposure of people to electromagnetic fields from wireless telecommunication devices and infrastructure. This situation sparked large research programs on the assessment and quantification of exposure of people and on the biological effects resulting from the exposure. Information on the dielectric properties of tissues is vital to these studies, for the computation of exposure metrics and the provision of a mechanistic explanation for biological effects. To satisfy the need of current research activity, this chapter will review the dielectric data for body tissue and the underlying mechanisms of interaction at the cellular, subcellular, and molecular levels. In doing so, we will draw on the authoritative article by Foster and Schwan (1996), published in the second edition of this book, which goes a long way toward establishing dielectric spectroscopy as a powerful tool for mechanistic studies.

Another area of scientific activity in the last decade revolved around the formulation of standard procedures for the experimental assessment of human exposure from electromagnetic sources, mostly telecommunication radio transceivers and their accessories. This created the need to formulate and measure the dielectric properties of tissue equivalent material and made dielectric measurement and the assessment of the associated uncertainty part of the compliance testing procedure. This chapter will deal with the fundamental issues that need to be established if dielectric measurement is to become a routine but accurate laboratory procedure.

It is not possible to review the dielectric properties and the polarization mechanisms in biological material without singling out the contribution to this field of Herman P. Schwan, whose name is associated with all the major findings over the past 50 years (Foster, 2002). Indeed, his 1957 review of the bulk electrical properties of cells and cell suspensions is one of the earliest and most studied texts on the subject. There are other reviews by Pethig (1979), Stuchly (1979), Schwan and Foster (1980), Pethig and Kell (1987), and Foster and Schwan (1989). The fundamental aspects and a more extensive treatment of the theoretical aspects of this subject can be found in books by Cole (1972), Grant et al. (1978), Schanne and Ceretti (1978), Pethig (1979), and more recently, Craig (1995), Roussy and Pearce (1995), and Grimnes and Martinsen (2000).

For most biological materials, the magnetic permeability is close to that of free space (i.e., diamagnetic), which implies that there is no direct interaction with the magnetic component of electromagnetic fields at low field strengths. However, this position is now changing following relatively recent reports of the presence of magnetite in human nervous tissue (see, e.g., Dobson and Grassi, 1996), which suggest that magnetite may provide a mechanism for direct interaction of external magnetic fields with the human central nervous system. The role of these strongly magnetic materials in organisms is only just beginning to be unraveled. This subject is elaborated in the second part of next chapter.

3.2 Dielectric Properties—Molecular Origin

From a historical perspective, the dielectric properties of materials were first observed experimentally by Faraday in the 1830s as a change in the capacity of an empty capacitor when a material is introduced inside it. Faraday introduced the term *specific inductive capacity* to describe the ratio of the capacities of the filled and empty capacitor. This quantity is now known as the permittivity and is denoted by ε. It is a fundamental property of nonmetallic or dielectric materials. Under quasistatic conditions, the capacitance C_0 of a perfect capacitor of area A and plate separation d changes to $C > C_0$:

$$C = \varepsilon\varepsilon_0 = \varepsilon\frac{\varepsilon_0 A}{d} \tag{3.1}$$

where ε is the relative permittivity of the material (dimensionless), ε_0 is the permittivity of free space (8.8542×10^{-12} F/m), and the product $\varepsilon\varepsilon_0$ is the absolute permittivity. The increase in capacity is due to the additional charge density induced by the field in the material. The field is said to have polarized the medium; polarizability or the ability of the material to polarize is the main determinant of its dielectric properties.

This section will start with the fundamental concepts of the interaction of homogenous matter with static fields and proceed, in steps, to heterogenous mixtures and their dynamic response to time-varying fields leading to the dielectric properties of tissues.

3.2.1 Quasi-Static Response

Considering the simple case of a monomolecular material, three main interaction mechanisms are possible: electronic, atomic, and molecular polarization. Electronic polarization is the shift of electrons, in the direction of the field, from their equilibrium position with respect to the positive nuclei. Atomic polarization is the relative displacement of

atoms or atom groups relative to each other. The orientation of permanent or induced molecular dipoles, when present, is known as molecular polarization. The total polarizability α_T is the sum of the contribution of, in this case, all three processes, termed α_e, α_a, and α_d.

In view of the relative importance of molecular orientation processes in defining the total polarization ($\alpha_e + \alpha_a < \alpha_d$) and hence the dielectric properties, it is usual to differentiate between the polar and nonpolar materials when these properties are considered.

For ideal nonpolar materials, the relationship $\varepsilon = n^2$, where n is the optical refractive index, holds true. When a dielectric material becomes polarized by the application of an external electric field E, the dipole moment of the constituent molecules is given by

$$\overline{m} = \alpha_T \overline{E}_l \tag{3.2}$$

where E_l is the local field acting on the molecules. The dipole moment per unit volume of the material P increases the total displacement flux density D, defined from the relationship $D = \varepsilon_0 E$ in vacuum and $D = \varepsilon_0 \varepsilon E$ in a medium of relative permittivity ε. The latter expression may also be written as

$$D = \varepsilon_0 E + P \tag{3.3}$$

The dependence of P on E can take several forms, the simplest and most common being a scalar proportionality:

$$P = \varepsilon_0 \chi E \tag{3.4}$$

where $\chi = \varepsilon - 1$ is the relative dielectric susceptibility. This simple relationship is valid for a perfect isotropic dielectric, at low or moderate field intensities and at static or quasi-static field frequencies.

If the material contains N dipoles per unit volume, then

$$P = N\alpha_T E_l \tag{3.5}$$

and

$$\varepsilon - 1 = \frac{N\alpha_T}{\varepsilon_0} \frac{E_l}{E} \tag{3.6}$$

The molecular description of the permittivity requires that the relationship between the microscopic and the macroscopic field intensities be known. In most cases, there is no exact solution to this problem, only more or less good approximations that hold within the confines of the assumptions and simplifications made, as will be briefly illustrated for typical classes of materials.

3.2.2 Permittivity of Low-Pressure Gases

At low pressures the molecules are far apart from each other, and their interaction with each other may be assumed to be negligible in comparison with the macroscopic field intensity E. Under these conditions $E_l \approx E$ and

$$\varepsilon - 1 = \frac{N\alpha_T}{\varepsilon_0} \tag{3.7}$$

The relative permittivity of a nonpolar gas is very close to 1, typically of the order of 1.0001 at atmospheric pressure.

3.2.3 Permittivity of Liquids and Dense Gases

When the intermolecular interactions are such that $E_l \neq E$, the local field must be estimated. One approach is to consider a spherical region inside the dielectric that is large compared to the size of a molecule; the field inside it is estimated for nonpolar materials to be

$$E_l = \left(\frac{\varepsilon + 2}{3}\right) E \tag{3.8}$$

which yields

$$\frac{3(\varepsilon - 1)}{\varepsilon + 2} = \frac{N}{\varepsilon_0}\alpha_T \tag{3.9}$$

The above expression is known as the Claussius–Mossoti–Lorentz formulation. It is not always valid, such as when the density of the material corresponds to $N = 3\ \varepsilon_0/\alpha_T$. An alternative formulation, valid when the molecules are polarizable point dipoles of permanent moment μ, was provided by Onsager:

$$\frac{(\varepsilon - n^2)(2\varepsilon + n^2)}{\varepsilon(n^2 + 2)^2} = \frac{N\mu^2}{9kT\varepsilon_0} \tag{3.10}$$

where k is the Boltzman constant and T is the absolute temperature.

Debye separated out the contribution to the total polarization of the permanent dipole from those associated with electronic and atomic displacements and arrived at the following relationship

$$\frac{\varepsilon - 1}{\varepsilon + 2} = \frac{N}{3\varepsilon_0}(\alpha + \mu^2/3kT) \tag{3.11}$$

While Onsager and Debye used semistatistical techniques to estimate the local field, others like Kirkwood, and later Fröhlich, used statistical methods to obtain a rigorous expression of the permittivity after taking local interactions into consideration and obtained

$$\frac{(\varepsilon - 1)(2\varepsilon + 1)}{3\varepsilon} = \frac{N}{\varepsilon_0}(\alpha + g\mu^2/3kT) \tag{3.12}$$

This is Kirkwood's equation for permittivity in which g is known as the Kirkwood correlation parameter, introduced to account for the effect of local ordering in the material. Fröhlich's theory gives

$$\frac{(\varepsilon - n^2)(2\varepsilon + n^2)}{\varepsilon(n^2 + 2)^2} = \frac{Ng\mu^2}{9kT\varepsilon_0} \tag{3.13}$$

which, except for the correlation parameter g, is identical to Onsager's equation.

This brief outline of the dielectric theory gives an idea of the nature of the electric field interaction problems and of the various techniques used to partially solve them under static field conditions. The solutions hold for slow time-varying fields as long as there is a quasistatic state. References to the original work by Debye (1929), Kirkwood (1936), Onsager (1936), and Fröhlich (1955) are given in Böttcher and Bordewijk (1978) and other well-known texts (Hill et al., 1969; Jonscher, 1983).

3.3 Time and Frequency Dependence of the Dielectric Response

Much of the interest in the dielectric properties of biological materials is concerned with their response to time-varying electric fields. This can be explained by the same macroscopic variables used for the quasi-static state except for the introduction of a time dependence for the excitation and response. The general discussion will assume sinusoidal fields and linear and isotropic responses, nonsinusoidal fields and material anisotropy, and nonlinearity being special cases.

3.3.1 Time-Dependent Polarization—Impulse Response—Kramers–Krönig Relations

The following relationship holds irrespective of the polarization mechanism:

$$P(t) = D(t) - \varepsilon_0 E(t) \tag{3.14}$$

For an ideal dielectric material with no free charge, the polarization follows the pulse with a delay determined by the time constant of the polarization mechanism. Assuming a rate process, which is that the rate of polarization is proportional to the constantly decreasing number of unpolarized units, the simplest expression for the polarization is obtained from the solution of the first-order differential rate equation with constant coefficients and time constant τ, giving

$$P(t) = P(1 - \mathrm{e}^{-t/\tau}) \tag{3.15}$$

The decay of polarization is also an exponential function

$$P(t) = \mathrm{e}^{-t/\tau} \tag{3.16}$$

For a linear system, the response to a unit-step electric field is the impulse response $f(t)$ of the system. The response of the system to a time-dependent field can be obtained from summation in a convolution integral of the impulses corresponding to a sequence of elements making up the electric field. For a harmonic field and a causal, time-independent system, the Fourier transform exists and yields

$$P(\omega) = \varepsilon_0 \chi(\omega) E(\omega) \tag{3.17}$$

indicating that the dielectric susceptibility $\chi(\omega)$ is the Fourier transform of $f(t)$. In general, the susceptibility is a complex function reflecting the fact that it informs on the magnitude and phase of the polarization with respect to the polarizing field

$$\chi(\omega) = \chi' - \mathrm{j}\chi'' \tag{3.18}$$

The real and imaginary parts of $\chi(\omega)$ can be obtained from the separate parts of the Fourier transform:

$$\begin{aligned}\chi'(\omega) &= \int_{-\infty}^{+\infty} f(t)\cos(\omega t)\,\mathrm{d}t = \int_{0}^{+\infty} f(t)\cos(\omega t)\,\mathrm{d}t \\ \chi''(\omega) &= \int_{-\infty}^{+\infty} f(t)\sin(\omega t)\,\mathrm{d}t = \int_{0}^{+\infty} f(t)\sin(\omega t)\,\mathrm{d}t\end{aligned} \tag{3.19}$$

The limit of integration can be changed from $-\infty$ to 0 since $f(t)$ is causal.

The impulse response $f(t)$ defines the dielectric response, and conversely, knowledge of the complex susceptibility allows the determination of the impulse response by carrying out the reverse transformation, which gives $f(t)$ in terms of either $\chi'(\omega)$ or $\chi''(\omega)$:

$$\begin{aligned}f(t) &= (2/\pi)\int_{0}^{+\infty} \chi'(\omega)\cos(\omega t)\,\mathrm{d}\omega \\ f(t) &= (2/\pi)\int_{0}^{+\infty} \chi''(\omega)\sin(\omega t)\,\mathrm{d}\omega\end{aligned} \tag{3.20}$$

Eliminating $f(t)$ from the above equations gives an expression of $\chi'(\omega)$ in terms of $\chi''(\omega)$ and vice versa. Thus, there is a relationship between the real and imaginary parts of the complex susceptibility of any material, such that knowledge of either enables the other to be calculated. The expressions of real and imaginary parts of the susceptibility or permittivity in terms of each other are known as the Kramers–Krönig relations and have been derived as

$$\begin{aligned}\chi'(\omega) &= \chi'(\infty) + \frac{2}{\pi}\int_{0}^{\infty} \frac{u\chi''(u) - \omega\chi''(\omega)}{u^2 - \omega^2}\,\mathrm{d}u \\ \chi''(\omega) &= \frac{2}{\pi}\int_{0}^{\infty} \frac{\chi'(u) - \chi'(\omega)}{u^2 - \omega^2}\,\mathrm{d}u\end{aligned} \tag{3.21}$$

where u is a variable of integration. Recalling the relationship between relative dielectric susceptibility and relative permittivity $\chi = \varepsilon - 1$, the permittivity is a complex function given by

$$\hat{\varepsilon}(\omega) = \varepsilon'(\omega) - \mathrm{j}\varepsilon''(\omega) = (1 + \chi'(\omega) - \mathrm{j}\chi''(\omega)) \tag{3.22}$$

Thus, the Kramers–Krönig relations relate ε' to the complete spectrum of ε'' and vice versa. A clear account of their derivation can be found in Jonscher (1983).

3.3.2 Permittivity of a Polar Substance—The Debye Equation

When a step field E is applied to a polar dielectric material, the electronic and atomic polarizations are established almost instantaneously compared to the time scale of the

molecular orientation; the total polarization reaches a steady state as a first-order process characterized by the time constant of the dipolar rotation. When the field is removed, the process is reversed; electronic and atomic polarizations subside first, followed by a relatively slow decay in dipolar polarization (Figure 3.1). The time constant τ depends on the physical process, in this case the rotational dynamics of the dipole determined by the size, shape, and intermolecular relations of the molecules. If P_∞ and P_0 are the instantaneous and steady-state polarization, respectively, then the total polarization for a first-order process characterized by a time constant τ is

$$P = P_\infty + (P_0 - P_\infty)(1 - \mathrm{e}^{-t/\tau}) \tag{3.23}$$

In time-varying fields the permittivity is a complex function originating from the magnitude and phase shift of the polarization with respect to the polarizing field:

$$\hat{\varepsilon} = \varepsilon' - \mathrm{j}\varepsilon'' = \varepsilon' - \mathrm{j}\sigma/\omega\varepsilon_0 \tag{3.24}$$

The real part ε' is a measure of the induced polarization per unit field and the imaginary part ε'' is the out-of-phase loss factor associated with it. The loss factor can also be represented by a conductivity term $\sigma = \omega\varepsilon_0\varepsilon''$ where ω is the angular frequency. The SI unit of conductivity is siemens per meter (S/m).

The frequency response of the first-order system is obtained from the Laplace transformation, which provides the relationship known as the Debye equation:

$$\hat{\varepsilon} = \varepsilon_\infty + \frac{(\varepsilon_0 - \varepsilon_\infty)}{1 + \mathrm{j}\omega\tau} = \varepsilon' - \mathrm{j}\varepsilon'' \tag{3.25}$$

The limiting values of the permittivity, ε_s and ε_∞, are known as static and infinite permittivity, respectively. The relaxation time τ corresponds to a relaxation frequency $f_\mathrm{r} = 1/2\pi\tau$. For a highly associated liquid such as water, the static permittivity can be expressed in terms of molecular parameters in accordance with the discussions in the previous section as

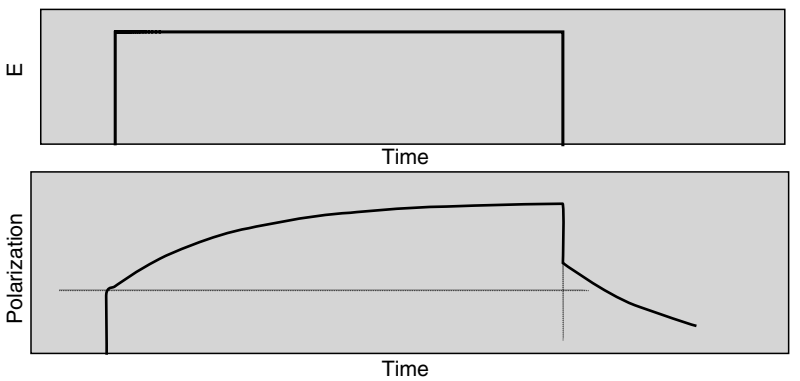

FIGURE 3.1
Schematic graph of dielectric response of a polar material expressed as polarization in the time domain in response to the step onset and removal of a polarizing electric field E. The nearly instantaneous rise in polarization, indicated by the horizontal dotted line, is P_∞; the vertical dotted line marks the instant and equivalent drop in polarization occurs when the field is removed.

$$\varepsilon_s = \varepsilon_\infty + \frac{Ng\mu^2}{2kT\varepsilon_0} \tag{3.26}$$

The relaxation time may be identified with the time constant of the molecular polarization and expressed in terms of molecular parameters. If η is the viscosity, then for a spherical molecule of radius a

$$\tau = 4\pi a^3 \eta / kT \tag{3.27}$$

For most polar materials, though not for water, ε_∞ corresponds to the optical permittivity and is equal to the square of optical refractive index n of the medium:

$$\varepsilon_\infty = n^2 \tag{3.28}$$

The dielectric properties of polar molecules vary with temperature; in general, both ε_s and τ decrease with increasing temperature.

As with the charge density and polarization, the time dependence of the current density J and σ, the current density per unit field, also follows a first-order law such that

$$J/E = \sigma_\infty + (\sigma_s - \sigma_\infty)(1 - e^{-t/\tau}) \tag{3.29}$$

This transforms into the conductivity equivalent of the Debye equation:

$$\hat{\sigma} = \sigma_\infty + \frac{(\sigma_s - \sigma_\infty)}{1 + j\omega\tau} \tag{3.30}$$

Figure 3.2 shows the variation in the permittivity, loss factor, and conductivity with frequency for a single time constant relaxation; such behavior pertains to an idealized monomolecular polar substance with no residual frequency-independent conductivity, that is $\sigma_s = 0$. The best, if not the only, example of such material is pure water as will be discussed later.

At the relaxation frequency, the permittivity is halfway between its limiting values and the loss factor at its highest. In the case of a single time constant as described in Figure 3.2, the conductivity is halfway between its limiting values at the relaxation frequency.

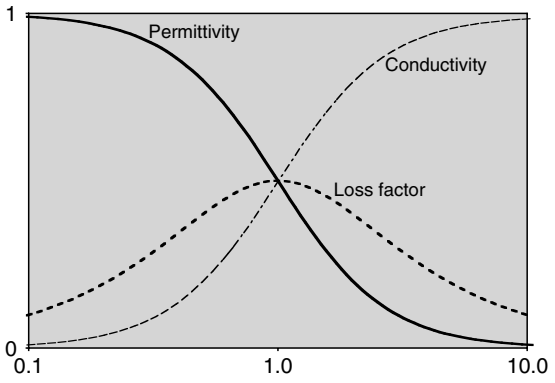

FIGURE 3.2
Normalized permittivity $(\varepsilon' - \varepsilon_\infty)/(\varepsilon_s - \varepsilon_\infty)$, loss factor $\varepsilon''/(\varepsilon_s - \varepsilon_\infty)$, and conductivity $\omega\varepsilon_0\,\varepsilon''/(\varepsilon_s - \varepsilon_\infty)$ for a single time constant relaxation plotted against f/f_r.

3.3.3 Nonpolar Molecules

The permittivity of nonpolar materials is virtually constant throughout the frequency range. In general, the temperature dependence is not significant. The static and optical values of the permittivity are almost identical, hence the Maxwell relation $\varepsilon = n^2$ holds true throughout the frequency and temperature range.

3.4 Observed Responses of Real Systems—Conduction—Multiple Relaxations—The Universal Law

In the previous section we described the expected behavior of idealized materials; we now need to deal with the observed responses of real systems. Few materials exhibit single relaxation time dispersions as in the Debye model; real materials depart from this ideal behavior to a greater or lesser extent depending on the complexity of the underlying mechanisms. To describe these responses we need to introduce the concepts of multiple dispersions and distribution of relaxation time. Moreover, biological materials exhibit conduction as well as polarization mechanisms; this needs to be taken into consideration in describing their dielectric response.

3.4.1 Conduction

The Debye expression does not include the effect of conduction currents as would arise from, for example, the drift of free ions in static fields. If σ_s is the static conductivity, the Debye expression becomes

$$\hat{\varepsilon} = \varepsilon_\infty + \frac{(\varepsilon_s - \varepsilon_\infty)}{1 - j\omega\tau} - \frac{j\sigma_s}{\omega\varepsilon_0} \tag{3.31}$$

In terms of real and imaginary parts we have

$$\begin{aligned} \varepsilon' &= \varepsilon_\infty + \frac{(\varepsilon_s - \varepsilon_\infty)}{1 + (\omega\tau)^2} \\ \varepsilon'' &= \frac{\sigma_s}{\omega\varepsilon_0} + \frac{(\varepsilon_s - \varepsilon_\infty)\omega\tau}{1 + (\omega\tau)^2} \end{aligned} \tag{3.32}$$

The total conductivity σ is given by

$$\sigma = \omega\varepsilon_0\varepsilon'' = \sigma_s + \frac{(\varepsilon_s - \varepsilon_\infty)\varepsilon_0\omega^2\tau}{1 + (\omega\tau)^2} \tag{3.33}$$

The total conductivity is thus made of two terms corresponding to the residual static conductivity and polarization losses. In practice, it is only possible to measure the total conductivity of a material; σ_s is obtained from data analysis or by measurement at frequencies corresponding to $\omega\tau \ll 1$ where the dipolar contribution to the total conductivity is negligible.

3.4.2 Multiple Relaxation Models—Distribution of Relaxation Times—Fractional Power Law Behavior

The occurrence of multiple interaction processes or the presence of more than one molecular conformational state or type of polar molecule may cause the dielectric behavior of a substance to exhibit multiple relaxation time dispersions. Deviation from Debye behavior may also indicate a polarization process whose kinetics are not first order or the presence of a complex intermolecular interaction. Models are needed to analyze the dielectric spectra of complex systems to unravel the underlying interaction mechanisms.

The simplest case is that of a dielectric response arising from multiple first-order processes; in this case the dielectric response will consist of multiple Debye terms to correspond to the polarization processes such that

$$\hat{\varepsilon} = \varepsilon_\infty + \frac{\Delta\varepsilon_1}{1 - j\omega\tau_1} + \frac{\Delta\varepsilon_2}{1 - j\omega\tau_2} + \cdots \tag{3.34}$$

where $\Delta\varepsilon_n$ corresponds to the limits of the dispersion characterized by time constant τ_n. If the relaxation times are well separated such that $\tau_1 \ll \tau_2 \ll \tau_3 \ll \cdots$, a plot of the dielectric properties as a function of frequency will exhibit clearly resolved dispersion regions.

If, as is quite often the case, the relaxation times are not well separated, the material will exhibit a broad dispersion encompassing all the relaxation times. In the limit of a continuous distribution of relaxation times, the multiple Debye expression would be

$$\hat{\varepsilon} = \varepsilon_\infty + (\varepsilon_s - \varepsilon_\infty) \int_0^\infty \frac{\rho(\tau)\, d\tau}{1 - j\omega\tau} \tag{3.35}$$

where

$$\int_0^\infty \rho(\tau)\, d\tau = 1 \tag{3.36}$$

The above equations can be used to represent all dielectric dispersion data, provided an appropriate distribution function $\rho(\tau)$ is available. Conversely, it should also be possible, at least in principle, to invert dielectric relaxation spectra to determine $\rho(\tau)$ directly; however, this is not easily achievable in practice. More commonly, one has to assume a distribution to describe the frequency dependence of the dielectric properties observed experimentally. The choice of distribution function should depend on the cause of the multiple dispersions in the material. For example, one can assume a Gaussian distribution as is known to occur for other physical characteristics (Figure 3.3) would be

$$\rho(t/\tau) = \frac{b}{\sqrt{\pi}} e^{-b^2[\ln(t/\tau)]^2} \tag{3.37}$$

where τ is the mean relaxation time. The shape of the Gaussian function depends on the parameter b; it reduces to the delta function when b tends to infinity and becomes very broad when b decreases; the area under the curve remains the same as required by the normalization condition. Incorporated into the expression for complex permittivity, it produces an expression that cannot be solved analytically, which makes it impractical for experimental data analysis.

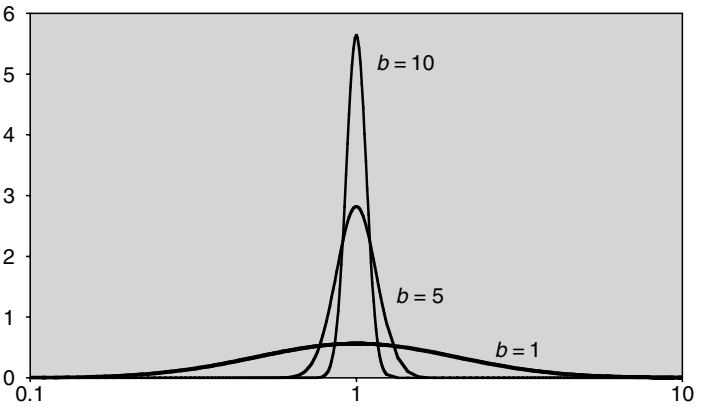

FIGURE 3.3
Gaussian distribution function as a function of t/τ.

Numerous empirical distribution functions or models have been proposed to model the experimental data without elaboration of the underlying mechanisms. One of the most commonly used models, a modified version of the Debye expression, was proposed in 1941 by Cole and Cole and is widely known as the Cole–Cole model:

$$\hat{\varepsilon} = \varepsilon_\infty + \frac{(\varepsilon_s - \varepsilon_\infty)}{1 - (j\omega\tau)^{1-\alpha}} = \varepsilon' - j\varepsilon'' \tag{3.38}$$

In it, α is a distribution parameter in the range $1 > \alpha \geq 0$; for $\alpha = 0$, the model reverts to the Debye equation. The real and imaginary parts are

$$\begin{aligned} \varepsilon' &= \varepsilon_\infty + \frac{(\varepsilon_s - \varepsilon_\infty)[1 - (\omega\tau)^{1-\alpha} \sin(\alpha\pi/2)]}{1 + (\omega\tau)^{2(1-\alpha)} + 2(\omega\tau)^{1-\alpha} \sin(\alpha\pi/2)} \\ \varepsilon'' &= \frac{(\varepsilon_s - \varepsilon_\infty)(\omega\tau)^{1-\alpha} \cos(\alpha\pi/2)}{1 + (\omega\tau)^{2(1-\alpha)} + 2(\omega\tau)^{1-\alpha} \sin(\alpha\pi/2)} \end{aligned} \tag{3.39}$$

Eliminating $\omega\,\tau$ from the above equations gives

$$\left(\varepsilon' - \frac{(\varepsilon_s + \varepsilon_\infty)}{2}\right)^2 + \left(\varepsilon'' + \frac{(\varepsilon_s + \varepsilon_\infty)}{2} \cot\frac{(1-\alpha)\pi}{2}\right)^2 = \left(\frac{\varepsilon_s - \varepsilon_\infty}{2} \operatorname{cosec}\frac{(1-\alpha)\pi}{2}\right)^2 \tag{3.40}$$

indicating that a plot of ε' against ε'' is a semicircle with its center below the real axis. For $\alpha = 0$, the Debye equivalent of the above equation is

$$\left(\varepsilon' - \frac{(\varepsilon_s + \varepsilon_\infty)}{2}\right)^2 + \varepsilon''^2 = \left(\frac{\varepsilon_s - \varepsilon_\infty}{2}\right)^2 \tag{3.41}$$

which indicates that ε' against ε'' is a semicircle with its center on the real axis (Figure 3.4); these semicircle plots are known as Cole–Coles.

The distribution function that corresponds to the Cole–Cole model is

$$\rho(t/\tau) = \frac{1}{2\pi} \frac{\sin(\alpha\pi)}{\cos h[(1-\alpha)\ln(t/\tau)] - \cos(\alpha\pi)} \tag{3.42}$$

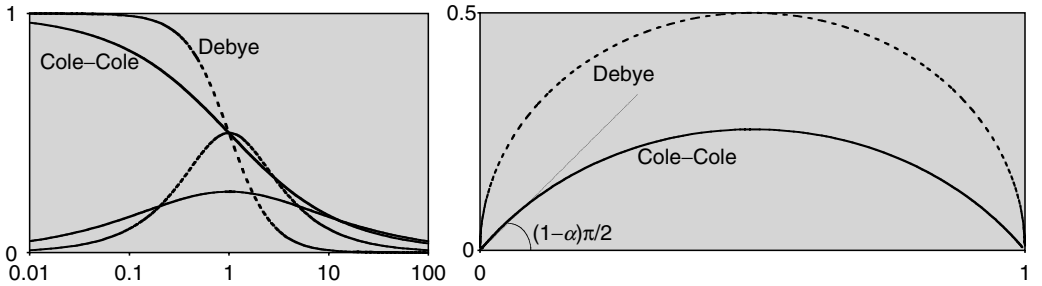

FIGURE 3.4
Left: Frequency dependence of normalized permittivity $(\varepsilon' - \varepsilon_\infty)/(\varepsilon_s - \varepsilon_\infty)$ and loss factor $\varepsilon''/(\varepsilon_s - \varepsilon_\infty)$ against frequency, normalized to the relaxation frequency, for a Debye and Cole–Cole with $\alpha = 0.4$. Right: Plot of normalized permittivity against loss factor showing a semicircle with its center on the real axis in the case of the Debye and an arc of a semicircle with its center below the real axis in the case of the Cole–Cole; the apex of the arc corresponds to the mean relaxation frequency.

Here again, τ is the mean relaxation time. As with the Gaussian, this distribution is logarithmically symmetrical about t/τ (Figure 3.5).

In 1951, Davidson and Cole proposed another variant of the Debye equation in which an exponent β is applied to the whole denominator:

$$\hat{\varepsilon} = \varepsilon_\infty + \frac{(\varepsilon_s - \varepsilon_\infty)}{(1 - j\omega\tau)^\beta} \tag{3.43}$$

which gives

$$\begin{aligned} \varepsilon' &= \varepsilon_\infty + (\varepsilon_s - \varepsilon_\infty)\cos(\beta\phi)(\cos\phi)^\beta \\ \varepsilon'' &= (\varepsilon_s - \varepsilon_\infty)\sin(\beta\phi)(\cos\phi)^\beta \end{aligned} \tag{3.44}$$

where $\phi = \arctan(\omega\tau)$. The corresponding distribution of relaxation times is

$$\rho(t/\tau) = \frac{1}{\pi}\left(\frac{t}{\tau - t}\right)^\beta \sin(\pi\beta) \tag{3.45}$$

When $\beta = 1$, the model reverts to the Debye equation. A plot of the real and imaginary parts of the model presents a skewed arc, similar to the Debye plot at low-frequencies, where it intercepts the abscissa at $\pi/2$, but at high frequencies the tangent to the arc is $\beta\pi/2$ (Figure 3.6).

The distribution function is shown graphically in Figure 3.7. It has a singularity at $t/\tau = 1$ and returns zero at $t > \tau$.

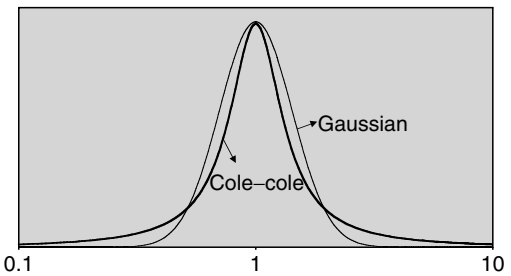

FIGURE 3.5
Gaussian distribution with $b = 2$ and Cole–Cole distribution with $\alpha = 0.09$ as a function of t/τ.

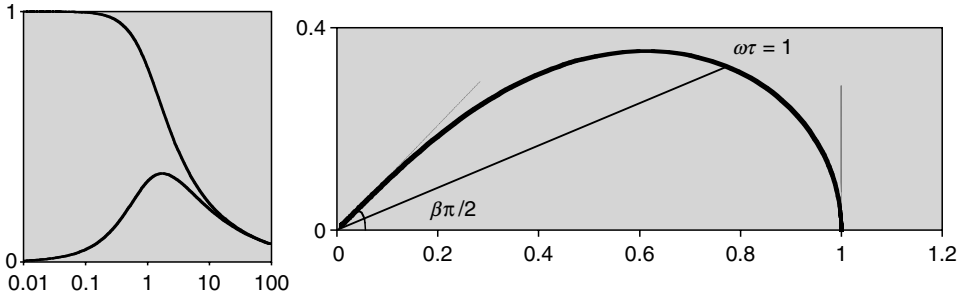

FIGURE 3.6
Left: Frequency dependence of normalized permittivity $(\varepsilon' - \varepsilon_\infty)/(\varepsilon_s - \varepsilon_\infty)$ and loss factor $\varepsilon''/(\varepsilon_s - \varepsilon_\infty)$ for a Cole–Davidson model with $\beta = 0.5$. Right: Plot of normalized loss factor against permittivity showing the characteristic Cole–Davidson skewed arc where the maximum in ε'' does not correspond with $\omega\tau = 1$; this point is found at the interception of the bisector of the high-frequency limiting angle with the data plot.

Another expression, sometimes used to model dielectric data, is the Havriliak–Negami relation (Havriliak and Negami, 1966). It combines the variations introduced in both the Cole–Cole and the Cole–Davidson models, giving

$$\hat{\varepsilon} = \varepsilon_\infty + \frac{(\varepsilon_s - \varepsilon_\infty)}{(1 - (j\omega\tau)^{(1-\alpha)})^\beta} \tag{3.46}$$

with real and imaginary parts:

$$\begin{aligned} \varepsilon' &= \varepsilon_\infty + \frac{(\varepsilon_s - \varepsilon_\infty)\cos(\beta\phi)}{1 + 2(\omega\tau)^{(1-\alpha)}\sin(\alpha\pi/2) + (\omega\tau)^{2(1-\alpha))^{\beta/2}}} \\ \varepsilon'' &= \frac{(\varepsilon_s - \varepsilon_\infty)\sin(\beta\phi)}{1 + 2(\omega\tau)^{(1-\alpha)}\sin(\alpha\pi/2) + (\omega\tau)^{2(1-\alpha))^{\beta/2}}} \end{aligned} \tag{3.47}$$

in which $\phi = \arctan\{[(\omega\tau)^{(1-\alpha)}\cos(\alpha\pi/2)]/[1 + (\omega\tau)^{(1-\alpha)}\sin(\alpha\pi/2)]\}$ and the corresponding distribution of relaxation times is

$$\rho(t/\tau) = \frac{1}{\pi}\frac{(t/\tau)^{\beta(1-\alpha)}\sin(\beta\theta)}{(t/\tau)^{2(1-\alpha)} + 2(t/\tau)^{(1-\alpha)}\cos(\pi(1-\alpha)) + 1)^{(\beta/2)}} \tag{3.48}$$

where $\theta = \arctan\{[(\sin(1-\alpha)\pi)/((t/\tau) + \cos(1-\alpha)\pi)]\}$.

The Cole–Cole plot of the Havriliak–Negami model is an asymmetric curve intercepting the real axis at different angles at high and low-frequencies (Figure 3.8). The distribution of relaxation times is also asymmetric (Figure 3.9).

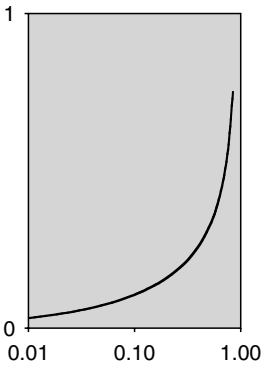

FIGURE 3.7
Cole–Davidson distribution with $\beta = 0.5$ as a function of t/τ.

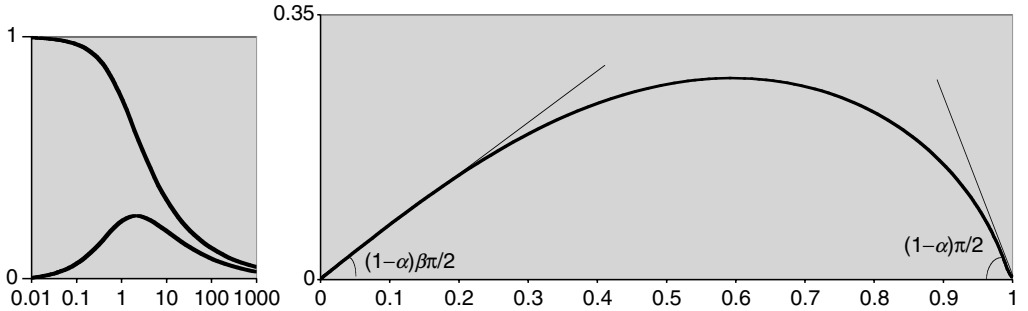

FIGURE 3.8
Left: frequency dependence of normalized permittivity $(\varepsilon' - \varepsilon_\infty)/(\varepsilon_s - \varepsilon_\infty)$ and loss factor $\varepsilon''/(\varepsilon_s - \varepsilon_\infty)$ for a Havriliak–Negami model with $\alpha = 0.2$ and $\beta = 0.5$. Right: Cole–Cole plot of the same data. As with the Cole-Davidson plot, the $\omega\tau = 1$ point is found at the interception of the bisector of the high-frequency limiting angle with the data plot.

Havriliak–Negami expressions revert to their Cole–Cole, Cole–Davidson, and Debye equivalents at the limiting values of β, α, and α and β, respectively. In principle, this should be the model of choice for dielectric data analysis. In practice, it is not widely used to describe the dielectric properties of biological material, as will be discussed later. It is important to recall that these empirical distribution functions lack mechanistic justification; however, they do serve a useful purpose in enabling the parametrization of the experimental data, albeit with very limited clarification of the underlying mechanisms.

Another limitation of this type of analysis is the possibility of obscuring multirelaxation processes, particularly the presence of a small amplitude dispersion following in the high-frequency tail end of a much larger principal one. This point is well illustrated by Wei and Sridhar (1993); they point out that a graphical representation of the parameter $\sigma'' = \omega\varepsilon_0(\varepsilon' - \varepsilon_\infty)$ versus $\sigma' = \omega\varepsilon_0\varepsilon''$ provides a more sensitive visualization of multirelaxation processes.

The Debye model and its many variations, including those described in this section, have been widely used over more than half a century primarily because they lend themselves to simple curve-fitting procedures. In particular, the Cole–Cole model is

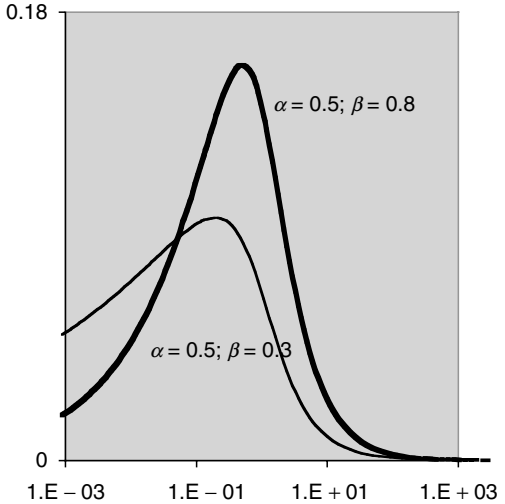

FIGURE 3.9
Havriliak–Negami distribution as a function of t/τ showing the effect of β for a given value of α.

used almost as a matter of course in the analysis of the dielectric properties of biological materials. Mathematically, at the limit of high frequencies, the Cole–Cole function simplifies to a fractional power law, that is, both ε' and ε'' are proportional to $(\omega\tau)^{(\alpha\ -1)}$. This fractional power law behavior is at the basis of what is known as the universal law of dielectric phenomena developed by Jonscher, Hill, and Dissado (Jonscher, 1983) for the analysis of the frequency dependence of dielectric data.

3.4.3 Universal Law of Dielectric Relaxation

Jonscher and his collaborators (Hill and Jonscher, 1983; Dissado and Hill, 1989) collated and analyzed extensive dielectric data obtained from numerous sources, pertaining to a wide range of materials, measured over a broad range of temperatures and frequencies. Their aim was to observe how dielectrics behave rather than presume a model for their frequency dependence; they studied the data on a log–log scale to better recognize the presence of a power law dependence, if present. Figure 3.10 shows plots for Debye and non-Debye responses where ω_p is the loss peak radial frequency.

Very few materials exhibit a pure Debye behavior where, at frequencies in excess of ω_p, the logarithmic slopes for $\varepsilon'(\omega)$ and $\varepsilon''(\omega)$ are -2 and -1, respectively, which is a Kramers–Krönig compatible result. However, for most materials a power law dependence of the type ω^{n-1}, with $n \neq 0$, applies for both $\varepsilon'(\omega)$ and $\varepsilon''(\omega)$. This is in compliance with the Kramers–Krönig relations, which require that at frequencies exceeding ω_p, both parameters follow the same frequency dependence, making the ratio $\varepsilon''(\omega)/\varepsilon'(\omega)$ frequency independent. Under such conditions, the ratio of energy dissipated to energy stored per radian of sinusoidal excitation is constant. The universal law can be summarized by the following frequency dependencies for the normalized complex permittivity:

$$\text{for } \omega < \omega_p, \quad \varepsilon''(\omega) \approx \omega^m \quad \text{and} \quad \varepsilon'(\omega) \approx 1 - \varepsilon''(\omega) \tag{3.49}$$

$$\text{for } \omega > \omega_p, \quad \varepsilon''(\omega) \approx \omega^{n-1} \quad \text{and} \quad \varepsilon'(\omega) \approx \varepsilon''(\omega) \approx \omega^{n-1} \tag{3.50}$$

Observation of the experimental data showed that ω_p is temperature dependent and follows an Arrhenius function:

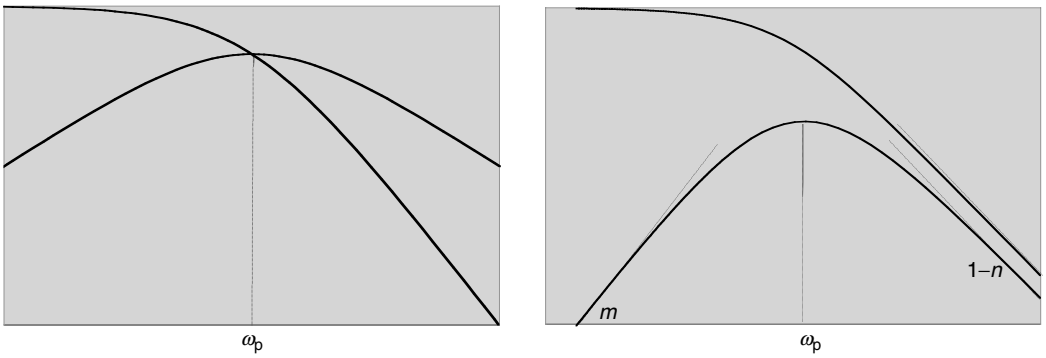

FIGURE 3.10
Log–log plot of the normalized permittivity and loss factor against frequency for a Debye-type behavior (left) and a non-Debye response (right).

$$\omega_{\mathrm{p}} = A\mathrm{e}^{-W/kT} \tag{3.51}$$

and the functional form for $\varepsilon''(\omega)$ is

$$\varepsilon''(\omega) = \frac{A}{(\omega/\omega_{\mathrm{p}})^{1-n} + (\omega_{\mathrm{p}}/\omega)^{\mathrm{m}}} \tag{3.52}$$

The values for $\varepsilon'(\omega)$ can then be determined numerically from the Kramer–Krönig relations.

Although the features of the dielectric spectra of most materials can be described using this approach, there is no theoretical justification for it. This makes it yet another empirical model, albeit a very general and mathematically elegant one.

3.4.4 Combined Response Model

A model that combines features from Debye-type and universal dielectric response behavior was proposed by Raicu (1999). In the course of modeling broad dielectric dispersions, as is often observed in the dielectric spectrum of biological materials, Raicu found that neither approach was good enough over a wide frequency range. He proposed the following very general function

$$\hat{\boldsymbol{\varepsilon}} = \boldsymbol{\varepsilon}_{\infty} + \frac{\Delta}{[(\mathrm{j}\omega\tau)^{\alpha} + (\mathrm{j}\omega\tau)^{1-\beta}]^{\gamma}} \tag{3.53}$$

where α, β, and γ are real constants in the range [0,1], τ is the characteristic relaxation time, and Δ is a dimensional constant, which becomes the dielectric increment $(\varepsilon_{\mathrm{s}} - \varepsilon_{\infty})$ when $\alpha = 0$, and the above expression reverts to the Havriliak–Negami model, which further reduces to the Debye, Cole–Cole, or Cole–Davison models with an appropriate choice of the α, β, and γ parameters. For $\gamma = 1$, it reverts to Jonsher's universal response model; in the special case where $\gamma = 1$ and $\alpha = 1 - \beta$, it becomes

$$\hat{\boldsymbol{\varepsilon}} = \boldsymbol{\varepsilon}_{\infty} + \left(\mathrm{j}\frac{\omega}{s}\right)^{\beta-1} \tag{3.54}$$

which is known as the constant phase angle model (Dissado, 1990). In this expression S is a scaling factor given by $S = (\Delta/2)^{1/(1-\beta)}\tau^{-1}$. The above expression was successfully used to model the dielectric spectrum of a biological material over five frequency decades from 10^3 Hz to 10^8 Hz.

3.5 Dielectric Properties of Biological Materials—Main Components

Tissue is a heterogenous material containing water, dissolved organic molecules, macromolecules, ions, and insoluble matter. The constituents are highly organized in cellular and subcellular structures forming macroscopic elements and soft and hard tissues. The presence of ions plays an important role in the interaction with an electric field, providing means for ionic conduction and polarization effects. Ionic charge drift creates conduction currents and also initiates polarization mechanisms through charge accumulation at

structural interfaces, which occur at various organizational levels. Their dielectric properties will thus reflect contributions to the polarization from both structure and composition. In this section, the contribution of each of the components will be determined individually and then collectively, leading to the formulation of models for the dielectric response of biological tissue.

3.5.1 Water

Water is a constituent of all living things; it is the environment in which body electrolytes and biomolecules reside and interact. Knowledge of its properties must precede the study of the more complex system. Many of the physical properties peculiar to water are due to its molecular asymmetry, polar nature, and ability to hydrogen bond, which are all interrelated. Water is described as an associated liquid because of its intermolecular hydrogen bonding. One practical reason for emphasizing the study of water in this chapter is its increasing use as a reference liquid, that is, a material of well-known dielectric properties. Consequently, it is often used as a standard for the calibration and testing of dielectric measuring procedures.

The dielectric properties of water are among the most studied and reported in the literature. Over the past decades, many experimental studies have been carried out to determine the dielectric properties of water over wide frequency and temperature ranges. These include Haggis et al. (1952), Lane and Saxton (1952), Hastead and El Sabeh (1953), Grant et al. (1957), Grant and Shack (1967), Grant and Sheppard (1974), Schwan et al. (1976), Grant et al. (1981), Hastead et al. (1985), Kaatze (1986, 1988), Buckmaster (1990), and Buchner et al. (1998). A comprehensive list of references and a historical overview of the subject can be found in Ellison et al. (1996). Other notable reviews were carried out by Kaatze (1989) and Liebe et al. (1991).

Data up to 100 GHz exhibit a near-perfect Debye dispersion with fairly well-defined parameters. Table 3.1 gives the Debye parameters for water at 20°C from three relatively recent reviews. Kaatze (1989) used a Debye expression to model his own extensive experimental data covering −4°C to 60°C and 1 to 57 GHz in addition to what he considered to be credible data from other sources.

Liebe et al. (1991) gathered extensive static and high-frequency data. For frequencies up to 100 GHz and temperatures from 0°C to 30°C, the data were a very good fit to the Debye function. However, including data at higher frequency somewhat reduced the goodness of the fit, suggesting the possible presence of a much smaller secondary dispersion in the hundreds of gigahertz range. The next logical step was then to use a two-Debye model. This proved a good fit to all experimental data up to 1 THz, thus confirming the presence of a small, high-frequency dispersion, probably due to some subtle molecular mechanism.

TABLE 3.1

Debye Parameters for Pure Water at 20°C

Review	ε_s	τ (ps)	ε_∞
Kaatze (1989)	80.2	9.47	5.2
Liebe et al. (1991)	80.1	9.35–9.39	5.3–5.4
Buchner et al. (1998)	80.2	9.32–9.52	5.9–6.0

Notes: For Liebe et al. (1991), τ and ε_∞ values are those of the single-Debye model (<100 GHz) and of the principal dispersion in the two-Debye model (up to 1 THz). Buchner et al. (1998) provide upper and lower bounds for τ and ε_∞ of the principal relaxation of a two-Debye model.

This secondary dispersion, centered around 670 GHz, brought down the high-frequency permittivity from 5.4 to 3.3 and made practically no impact on the characteristics of the principal dispersion, which were almost unchanged (Table 3.1). Liebe et al. (1991) extended the model to the far infrared (30 THz) by accounting for two near-infrared resonance absorption terms.

The most recent and comprehensive analysis of the dielectric properties of water is provided by Ellison et al. (1996), who critically reviewed the literature spanning the late 19th and most of the 20th centuries. With respect to the static permittivity, they obtained a function $\varepsilon_s = a\,e^{-b}$ with $a = 87.85306$ and $b = 0.00456992$, which predicts the value of ε_s at a given temperature to well within the limits of experimental accuracy for the range $-35^\circ C < t < 100^\circ C$. All high-frequency data (up to 1 THz) that met their selection criteria are tabulated. They stopped short of formulating models for the frequency dependence of the data; instead, they invited comments from the scientific community prior to the determination of what would probably be the ultimate model and spectral parameters for the dielectric properties of pure water, a finding that will greatly benefit this field of study. Already, other researchers have used this extensive survey. For example, Buchner et al. (1998) reported values for τ and ε_∞ of the principal water dispersion (Table 3.1) by fitting a two-Debye model to combined experimental data from Ellison et al. (1996) and other, more recent, studies (Barthel et al., 1995).

It is evident from Table 3.1 that the static permittivity and the relaxation time are fairly well-defined, less so the infinite permittivity. Fortunately, this parameter has little impact on the dielectric data in the gigahertz range because its value is only a small percentage of the permittivity in that frequency range. This relatively large uncertainty highlights the fact that even this most studied, pure substance is not a perfect reference liquid and that much remains to be done in the characterization of the dielectric properties of water at terahertz frequencies. Figure 3.11 is a plot of the dielectric properties of water at 20° tabulated by Ellison et al. (1996).

In biological materials, water is a solvent for salts, protein, nucleic acids, and smaller molecules. It is therefore important to study the effect of solutes on its dielectric response.

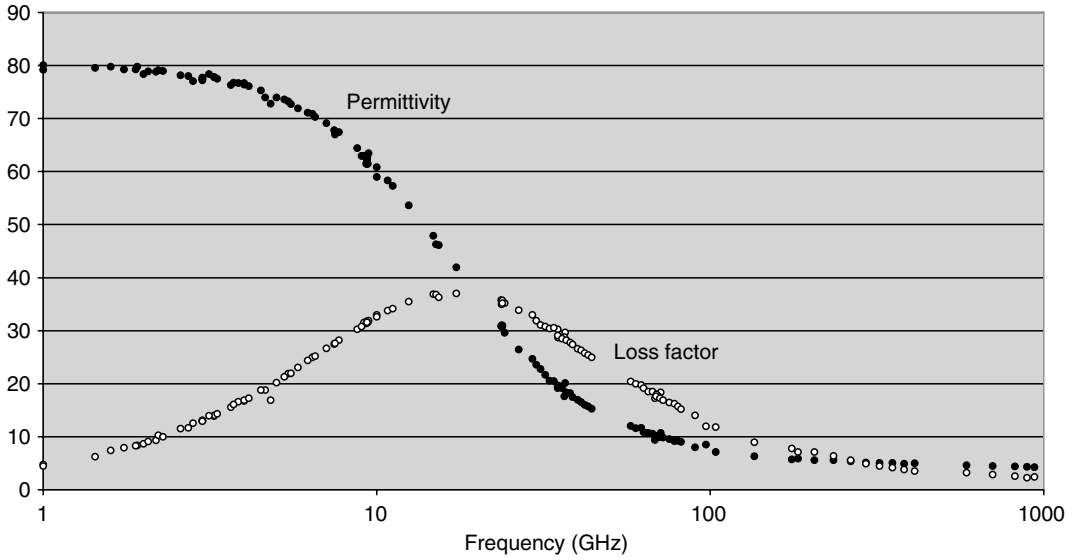

FIGURE 3.11
Experimental data from numerous sources reviewed and tabulated by Ellison et al. (1996).

3.5.2 Carbohydrates

In quantitative terms carbohydrates are not major constituents of animal cells; they are present at the surface of the cell membrane and are known to play a role in cellular communications. They are responsible for the gel consistency that gives certain body fluids such as vitreous humor and synovial fluid cushioning or lubricating properties. They are important constituents of certain tissues such as cartilage, tendon, and ligament. In terms of molecular structure, they vary in complexity and molecular size; they have in common the presence of one or more hydroxyl groups and the ability to hydrogen bond with each other or with water molecules. In aqueous solution they modify the principal dispersion of water to an extent that depends on the nature and concentration of the organic radical. In general, the dispersion is likely to be broader than a Debye, the static permittivity lower, and the relaxation time longer than for pure water, as observed and reported by Bateman and Gabriel (1987).

3.5.3 Proteins and Other Macromolecules

Protein constitutes the bulk of the organic matter in the body. Proteins are described as biopolymers, each molecule being a sequence of amino acids folded into a specific three-dimensional structure enclosing its hydrophobic sites within it. The surface has polar, hydrophilic groups with an affinity to bind water molecules from its surrounding aqueous environment. Part of the function of a protein resides in its structure; if the structure unfolds the protein is said to be denatured and is no longer functional. A good model for a globular protein in solution is that of a cluster of organic matter surrounded by a layer of strongly bound water; the solvent is referred to as free water to differentiate it from bound water. The size of the cluster depends on the molecular weight of the protein, which is typically of the order of tens or hundreds of thousands, that is, significantly larger than a water molecule. In an aqueous environment, most biological macromolecules including proteins act like polar molecules with permanent or induced dipole moment the magnitude of which depends on the molecular structure, configuration, and size.

Dielectric spectroscopy is therefore an important tool in the study of these molecular properties (Bateman et al., 1990, 1992). Typically, the dielectric dispersion of a protein will be in the megahertz frequency range, corresponding to a time constant of the order of microseconds. The dielectric spectrum of an aqueous globular protein solution will have two dispersion regions corresponding to the polarization of the protein and water molecules; the larger the protein the more clearly defined they will be. Conventionally, they are referred to as β and γ dispersions, respectively (Figure 3.12). Figure 3.12 shows a conceptual spectrum of a binary, protein–water system. In practice, to maintain the conformational stability of the biological molecules, inorganic ions, in the form of dissolved salts, must also be present. Table 3.2 has actual data, gathered from the literature, on the magnitude of the dielectric increment and the relaxation time for proteins of different shapes, sizes, and dipole moments. Many authors have reported the presence of a small dispersion that is attributed to bound water, described as molecules that are more or less strongly bound or otherwise affected by the presence of organic matter. When present, the spectral region of the bound water is termed δ dispersion. The book by Grant et al. (1978) is a good introduction to this important topic.

Larger biopolymers such as DNA, whose molecular weight may be of the order of several million, have more complex dielectric spectra with dispersions extending from kilohertz to megahertz. The elucidation of the polarization mechanisms responsible for

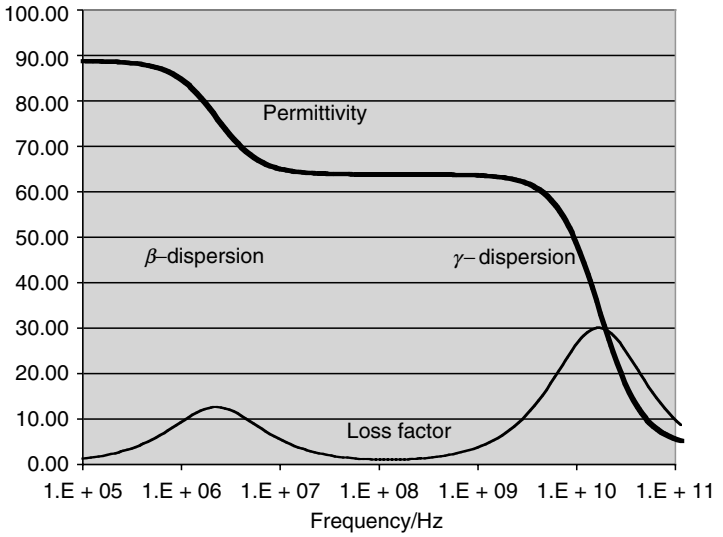

FIGURE 3.12
Conceptual representation of the dielectric spectrum of an aqueous protein solution. In practice, the two dispersions may overlap. The nearest to this picture is the complex permittivity spectrum of an aqueous solution of 1,2-dimyristoyl-L-3-phosphatidycholine reported by Kaatze and Giese (1980).

the dielectric spectrum of aqueous DNA solution is an area of active research. A good introduction to the subject is the book on biopolymers by Takashima (1989).

There is more than just academic interest in the study of biopolymers. Advances in nanotechnology are such that biological macromolecules are being considered as possible nanoscale electronic devices for fast information processing and transfer, a quest that will keep theoreticians and experimentalists busy for a long time.

3.5.4 Electrolytes

Electrolytes in the form of sodium, potassium, calcium, magnesium, chloride, and other ions play an important role in the function of biological systems. Many vital processes depend on a subtle balance being established between the concentration of electrolytes

TABLE 3.2

Dielectric Parameters of Various Proteins at 25°C

Protein	Mol wt. ($\times 10^3$)	$\Delta\varepsilon$	μ (D)	$\tau \times 10^8$ (s)	a/b
Myoglobin	17	0.15	170	2.9	—
β-Lactoglobulin (in 0.25 M glycine)	40	1.51	730	15, 5.1	4
Ovalbumin	44	0.10	250	18, 4.7	5
Horse carboxyhemoglobin	67	0.33	480	8.4	1.6
Horse serum albumin	70	0.17	380	36, 7.5	6
Horse serum pseudoglobulin	142	1.08	1100	250, 28	9

Notes: a/b is the axial ratio that determines the shape of the molecule. Where the shape deviates significantly from the spherical, two relaxation times are observed. The dielectric increment is $\Delta\varepsilon$, the dipole moment μ is given in Debye unit (1 D $= 3.33 \times 10^{-30}$ cm)
Source: From Foster KR, Schwan HP. 1989. *Crit Rev Biomed Eng* 17(1): 25–104. With permission.

inside and outside the cell. The cell membrane is, to a great extent, impermeable to the passive exchange of ions but allows directed movement under physiological control. In terms of dielectric properties, electrolytes have two effects. The direct effect, already mentioned, is the production of ohmic currents and energy loss in the system. This has the effect of making the static conductivity finite with a value commensurate with the ionic concentration and mobility. There are also important indirect effects whereby ionic charges contribute to the polarization of a biological system. One is interfacial polarization, whereby charge accumulation occurs at interfaces that are impermeable to ions. Another polarization mechanism is the ionic diffusion in electrical double layers adjacent to charged surfaces. Conduction, interfacial, and ion diffusion phenomena contribute significantly to the dielectric spectra of tissue.

3.5.5 Dielectric Dispersions in Tissue

The dielectric spectrum of a biological tissue (spleen at 37°C) is given in Figure 3.13 as an example of the response of a high water content tissue. Three main dispersion regions are immediately obvious and are referred to as α, β, and γ dispersions. The dispersions are rather broad, indicating the possible overlap of discrete relaxations arising from the polarization mechanisms encountered in the complex biological environment. Ionic conductivity contributes significantly to the loss factor, obliterating its features, and it is more

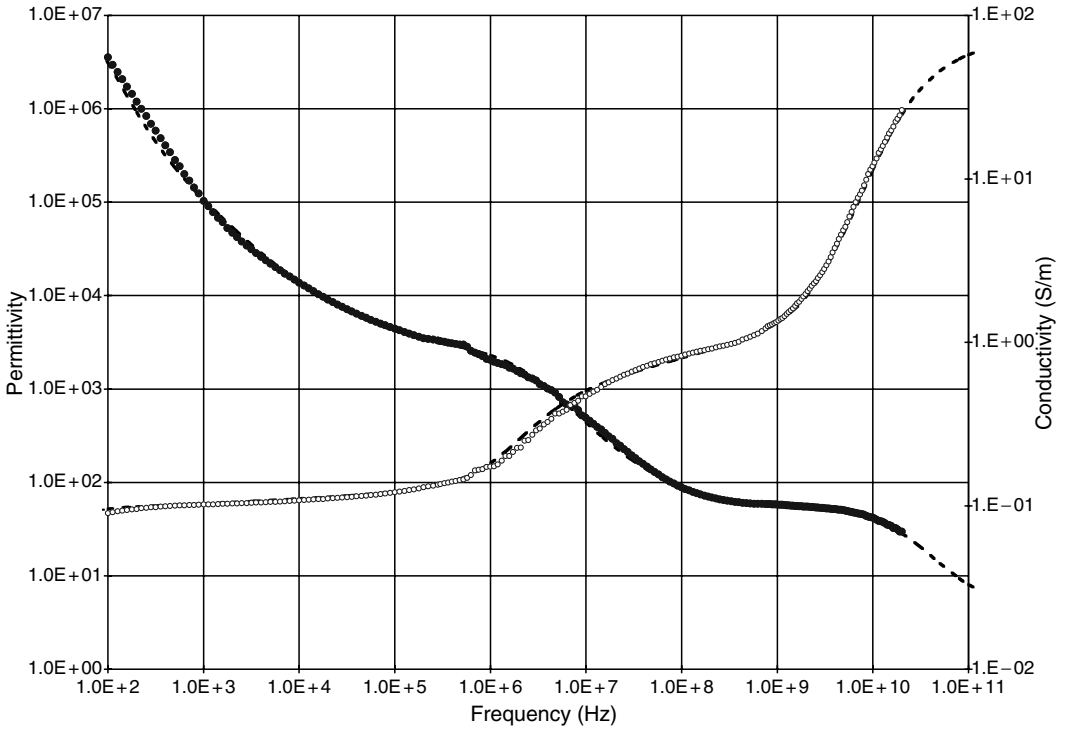

FIGURE 3.13

informative to express the dielectric properties of tissues as permittivity and conductivity as in Figure 3.13.

3.5.5.1 α Dispersion

The α or low-frequency dispersion is characterized by very high permittivity values and can be ascribed, at least partially, to counterion diffusion effects. Such large dispersions are predicted by theories of ionic diffusion in heterogenous media. While it is not possible to model the complexity of a tissue, simpler mixture models predict dielectric increments of the right order of magnitude. Other mechanisms were postulated to contribute to the α dispersion; many relate to interactions in the vicinity of the cell membrane. The cell membrane is a complex, dynamic structure comprising a phospholipid bilayer. The lipid, hydrophobic ends of the phospholipids form a middle layer; the hydrophilic groups cover the inner and outer surfaces. Embedded in the bilayer are proteins, transport organelles, and ionic channels that operate under physiological control. The ionic balance between the intra- and extracellular media maintains a 60- to 70-mV potential difference between them of about 10 kV/mm across the membrane, assuming a 6- to 7-nm thickness. Membrane-related mechanisms that are thought to contribute to the α dispersion include the charging of intracellular membrane-bound organelles and a frequency dependence in the impedance of the cell membrane itself. An important reason for the uncertainty in the understanding of this dispersion is the paucity of error-free dielectric data in its frequency range. The α dispersion has a very large permittivity increment. The corresponding decrement in conductivity is small; this, however, does not contravene the principle of causality and the Kramers–Kronig relations, which predict a change in conductivity of about 0.005 S/m for a 10^6 increment in permittivity and relaxation frequency of 100 Hz.

3.5.5.2 β Dispersion

The β dispersion occurs at intermediate frequencies and originates mostly from the capacitive charging of the cellular membranes and those of membrane-bound intracellular bodies. This phenomenon, also known as interfacial polarization, has been studied theoretically and experimentally. It was established experimentally that damage to the cell membrane changes the features of the β dispersion. Numerous biomedical applications are based on the variation of the parameters of the β dispersion with pathological conditions involving changes in cell physiology and morphology. Tissue with directed, anisotropic cellular structure would exhibit an anisotropic dielectric response in the frequency range of the β dispersion.

Modeling the electrodynamics of a simplified tissue-like system, for example, suspensions of spherical inclusions in conductive media, has established theoretical grounds for the presence of the β dispersions. It enables the computation of an effective permittivity of similar order of magnitude to the β dispersion. For a system of concentric shells in conductive media (Hanai et al., 1988; Irimajiri et al., 1991), it predicts the presence of dielectric dispersions equal in number to the number of interfaces. These interfacial polarizations are boundary effects that occur in addition to other polarizations that may occur in the components of the system. The multiplicity of mehanisms goes a long way toward explaining why the β dispersions in tissue are rather broad.

3.5.5.3 γ Dispersion

The γ dispersion is due to the dipolar polarization of tissue water. At frequencies in excess of a few hundred megahertz, where the response of tissue water is the dominant

TABLE 3.3

Dielectric Parameters of Water Dispersion in Tissues Obtained by Analysis of Experimental Results at 37°C

Tissue	ε_s	τ (ps)	α	σ (S/m)
Bone (cortex)	14.9	13.8	0.26	0.092
Bone (section)	22.1	14.4	0.22	0.208

Source: From Gabriel et al. (1996c).

mechanism, the complex permittivity may be expressed as Cole–Cole plus a conductivity term to simulate the dipolar dispersion of water and the contribution of the electrolytes; thus,

$$\hat{\varepsilon}(\omega) = \varepsilon_\infty + \frac{\varepsilon_s - \varepsilon_\infty}{1 + (j\omega\tau)^{1-\alpha}} + \frac{\sigma}{j\omega\varepsilon_0}$$

where σ is the conductivity due to ionic currents and to the lower-frequency polarization mechanisms. Table 3.3 gives the parameters of the γ dispersion of tissues modeled to the above expression. The water content of the tissues considered ranges from >95% for vitreous humor and >85% for retina to <20% for cortical bone. The correlation between ε_s and tissue water content is an obvious and expected result. The value of the distribution parameter α is significant for most tissues and negligible for body fluids (as for aqueous humor, for example). The mean relaxation time τ is generally longer than the value for water, indicating a restriction in the rotational ability of at least some of the tissue water molecules. The lengthening of the relaxation time of water in biological material is a well-studied hypothesis; the effect is common to most organic solutes, is known to increase with solute concentration (Grant et al., 1981; Bateman et al., 1990), and has previously been observed in tissues (Gabriel et al., 1983).

3.5.5.4 δ Dispersion

Tissues and other biological materials may exhibit dispersions other than the three main ones. The δ dispersion, identified in some protein solutions between the β and γ, dispersions may also occur in tissue in the hundreds of megahertz range; when present, its magnitude is small compared to the adjacent ones. Possible mechanisms include the dipolar relaxation of bound water, relaxation of small dipolar segments or side chains of biological molecules, and counterion diffusion along small regions of the charged surface. Under these conditions it is difficult to isolate and, in view of the multiplicity of possible mechanisms, difficult to interpret. It is often treated as the tail end of the β dispersion or a broadening of the γ dispersion.

3.5.6 Effective Complex Permittivity of a Heterogenous System

Where adequate experimental data are available, the complex permittivity of a tissue can be quite adequately modeled with four Cole–Coles and a static conductivity term:

$$\hat{\varepsilon}(\omega) = \varepsilon_\infty + \sum_{n=1}^{4} \frac{\Delta\varepsilon_n}{1 + (\mathrm{j}\omega\tau_n)^{(1-\alpha_n)}} + \sigma_\mathrm{s}/\mathrm{j}\omega\varepsilon_0 \tag{3.55}$$

This is a descriptive model, imparting no definite information on the polarization mechanisms; the measured dielectric properties represent the bulk response of the tissue. Assigning effective parameters to a heterogenous medium is equivalent to treating it as homogenous where these parameters are concerned; in this case, its structural components are much finer than the wavelength of the field probing it.

The derivation of a general formula for the effective permittivity of a system in terms of those for its constituents is based on the theory of the transport properties of mixtures (Reynolds and Hough, 1957). For example, in the case of a binary mixture where a medium with permittivity ε_1 has inclusions of permittivity ε_2 and assuming that v_1 andv_2 are their respective volume fractions such that $v_1 + v_2 = 1$, then the average electric displacement D is given by

$$D = v_1 D_1 + v_2 D \tag{3.56}$$

and the average electric field is given by

$$E = v_1 E_1 + v_2 E_2 \tag{3.57}$$

The effective permittivity ε of the mixture is given by

$$D = \varepsilon\varepsilon_0 E \tag{3.58}$$

and for each component, $D_1 = \varepsilon_1\varepsilon_0 E_1$ and $D_2 = \varepsilon_2\varepsilon_0 E_2$. Equation 3.56 and Equation 3.57 give

$$\varepsilon = \varepsilon_1 v_1 f_1 + \varepsilon_2 v_2 f_2 \tag{3.59}$$

where $v_1 f_1 + v_2 f_2 = 1, f_1 = E_1/E$, and $f_2 = E_2/E$, which gives two general formulations for the effective permittivity of the mixture:

$$\varepsilon = \varepsilon_1 + (\varepsilon_2 - \varepsilon_1) v_2 f_2 \tag{3.60}$$

or

$$(\varepsilon - \varepsilon_1) v_1 f_1 + (\varepsilon - \varepsilon_2) v_2 f_2 = 0 \tag{3.61}$$

The theoretical problem that needs to be resolved for specific mixtures boils down to the determination of the field ratios f_2 or f_2 and f_1. Theoretically, the two formulations are equivalent but, when approximations have to be made for the values of the field ratios, this is no longer true. Most of the published mixture equations differ from one another in the approximations considered appropriate. As for which of the two formulations to use as a starting point, it would seem reasonable to use Equation 3.60 for the case of sparse inclusions in a continuous medium and Equation 3.61 when the volume fractions of the

two components are comparable. In the general case, the dielectric properties (in Equation 3.60 and Equation 3.61) are complex. However, under static or quasistatic conditions, the mixture equations hold for either permittivity or conductivity.

Maxwell (1891) was the first to characterize the field ratios for a system of sparse spherical inclusions in a homogenous medium under static field conditions and obtained:

$$\frac{\sigma - \sigma_1}{\sigma + 2\sigma_1} = \nu_2 \frac{\sigma_2 - \sigma_1}{\sigma_2 + 2\sigma_1} \tag{3.62}$$

where the subscripts 1 and 2 refer to the suspending medium and inclusions, respectively. In terms of permittivity, Equation 3.62 is known as the Rayleigh formula; in its complex form it is attributed to Wagner and commonly known as the Maxwell–Wagner equation. Other well-known mixture equations for spherical inclusions include:

Böttcher equation:

$$\frac{\varepsilon - \varepsilon_1}{3\varepsilon} = \nu_2 \frac{\varepsilon_2 - \varepsilon_1}{\varepsilon_2 + 2\varepsilon_1} \tag{3.63}$$

Bruggeman equation:

$$\left(\frac{\varepsilon - \varepsilon_1}{\varepsilon_2 - \varepsilon_1}\right)^3 + (1 - \nu_2)\frac{\varepsilon}{\varepsilon_1} = 1 \tag{3.64}$$

Looyenga equation:

$$\varepsilon^{1/3} = \nu_1 \varepsilon_1^{1/3} + \nu_2 \varepsilon_2^{1/3} \tag{3.65}$$

To first-order approximation, the above mixture equations revert to the same expression irrespective of the formulation of the problem and of the technique used to solve it. This is because the conditions of infinite dilution and the spherical shape enable an almost exact solution to the field ratio to be obtained.

Other formulations exist for different shape inclusions such as oblate and prolate spheroids. The subject has been reviewed by, among others, Van Beek (1967), Hanai (1968), Dukhin (1971), and more recently, Greffe and Grosse (1992), Sihvola and Lindell (1992), and Tinga (1992).

It is possible to extend mixture equations to multiple inclusions by using an iterative procedure (Tamasanis, 1992). For example, if $\varepsilon(\varepsilon_1, \varepsilon_2, \nu_2)$ is the effective permittivity of a binary mixture of background of permittivity ε_1, inclusion of permittivity ε_2, and volume fraction v_2, then a mixture with two types of inclusions identified with subscripts 2 and 3, respectively, can be described as a binary mixture of background permittivity $\varepsilon(\varepsilon_1, \varepsilon_2, v_2/1 - v_3)$ and inclusion of permittivity ε_3 and volume fraction v_3. The effective permittivity of such a mixture will be

$$\varepsilon(\varepsilon_1;\, \varepsilon_2,\, v_2;\, \varepsilon_3,\, v_3) \approx \varepsilon\left[\varepsilon\left(\varepsilon_1;\, \varepsilon_2,\, \frac{v_2}{1 - v_3}\right);\, \varepsilon_3,\, v_3\right] \tag{3.66}$$

The contributions of the different types of inclusion are added recursively in order of increasing density.

Where the assumptions used in their derivation can be approximated in the tissue model, mixture equations can be used to analyze the dielectric properties of biological materials in terms of their constituents. A few examples are given here to illustrate their application.

If the ionic conductivities of the suspending phase and that of a protein solution are known, say, by measurement at a frequency below the protein β dispersion, and if an assumption is made about the conductivity of the protein molecules, an appropriate mixture equation can then be used to determine the volume fraction of the inclusions, which, in this case, is the hydrated protein. In turn, this enables the amount of bound water to be calculated given that the fraction of anhydrous protein is known. Bull and Breese (1969) followed this approach and calculated the bound water for a variety of proteins. They evaluated the water fraction to be 0.6 g/g of protein. Pauly and Schwan (1966), following a similar procedure, estimated the conductivity of the human erythrocyte to be 0.518 S/m at 25°C, compared to the value of 1.45 S/m calculated from the known ionic composition of the cell. They attributed the difference partly to excluded volume by the protein-bound water and partly to decreased ionic mobility due to hydrodynamic effects.

Bound water in biological systems including tissue was estimated by applying mixture equations in the near-plateau region between the β and γ dispersions of the permittivity spectrum. Assuming the tissue to be a suspension of hydrated organic matter in an electrolyte solution that is little affected by the presence of the organic matter, the measured permittivity at 1 GHz is a reasonable estimate of the effective static permittivity. Knowledge of the permittivity of the suspending medium and an estimate of the permittivity of the organic matter enables the volume fraction of the inclusion to be calculated. Comparison with the known organic content provides an estimate of bound water (e.g., Grant et al., 1984; Kaatze, 1990; Schaefer et al., 2003).

3.6 Dielectric Relaxation Mechanisms in Heterogenous Media

The description of a material as heterogenous is a matter of scale; in the context of dielectric relaxation, it refers to electrical heterogeneity or the presence of electrical boundaries or interfaces. Boundary conditions at and around the interfaces gives rise to dielectric dispersions quite apart from dipolar-type dispersions that occur in the surrounding media. In biological materials, cellular membranes provide such interfaces; their presence is associated with two major dispersion regions in the dielectric spectra of tissues, namely, α and β dispersions originating mainly from interfacial polarization and ionic diffusion effects. The main mechanisms giving rise to these phenomena will be briefly discussed in this section.

3.6.1 Interfacial Polarization

Interfacial polarization is due to the charging of interfaces between conducting media and is an important mechanism of interaction in biological material. The basic principles of this phenomenon are best illustrated in simple models first before discussing their occurrence in biological materials.

3.6.1.1 Interface between Two Media

The simplest model is that of an interface between two media, for example, two slabs of thickness d_1 and d_2 in contact with each other with their interface perpendicular to an external electric field (Figure 3.14a). If the static permittivity and conductivity of the two materials are ε_1, σ_1 and ε_2, σ_2, respectively, the boundary condition on the electric field component normal to the interface gives

$$E_1\varepsilon_1 = E_2\varepsilon_2 \tag{3.67}$$

If the current densities j_1 and j_2 are equal, there will be no charge accumulation at the interface; this, however, is hardly ever the case. The ratio of current densities at the interface is

$$j_1/j_2 = \sigma_1 E_1/\sigma_2 E_2 = \sigma_1\varepsilon_2/\sigma_2\varepsilon_1 \tag{3.68}$$

Therefore, if $\sigma_1\,\varepsilon_2 \neq \sigma_1\,\varepsilon_2$, the interface will be charged at a rate that is proportional to the difference between j_1 and j_2.

The effective permittivity ε and conductivity σ of the system are calculated from its effective capacitance. With the field across the interface, this is equivalent to capacitances in series combination; thus,

$$\frac{d_1 + d_2}{\varepsilon - \mathrm{j}\sigma/\omega\varepsilon_0} = \frac{d_1}{\varepsilon_1 - \mathrm{j}\sigma_1/\omega\varepsilon_0} + \frac{d_2}{\varepsilon_2 - \mathrm{j}\sigma_2/\omega\varepsilon_0} \tag{3.69}$$

This can be rearranged into a Debye type expression with a relaxation time of

$$\tau = \varepsilon_0 \frac{\varepsilon_1 d_2 + \varepsilon_2 d_1}{\sigma_1 d_2 + \sigma_2 d_1} \tag{3.70}$$

and limiting values for low and high frequencies

$$\varepsilon_s = \frac{(\varepsilon_2\sigma_1 - \varepsilon_1\sigma_2)^2 (d_1 + d_2) d_1 d_2}{(\varepsilon_1 d_2 + \varepsilon_2 d_1)(\sigma_1 d_2 + \sigma_2 d_1)^2} + \varepsilon_\infty \tag{3.71}$$

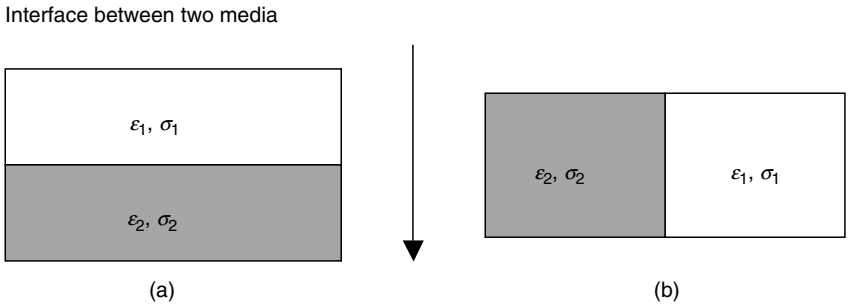

FIGURE 3.14
Two-media system; the arrow gives the direction of the electric field: (a) interface at right angle to the field and (b) interface along the field.

$$\sigma_s = (d_1 + d_2)\frac{\sigma_1\sigma_2}{\sigma_1 d_2 + \sigma_2 d_1} \tag{3.72}$$

$$\varepsilon_\infty = \frac{(d_1 + d_2)\varepsilon_1\varepsilon_1}{(\varepsilon_1 d_2 + \varepsilon_2 d_1)} \tag{3.73}$$

The polarization of the effective capacitance occurs in addition to any polarization process within the constituent phase, in which case the dielectric spectrum of the composite system will reflect the multiple dispersions.

If the field is along the interface (Figure 3.14b), no interfacial dispersion is observed, the effective permittivity is $\hat{\varepsilon} = (\hat{\varepsilon}_1 + \hat{\varepsilon}_2)/2$.

3.6.1.2 Suspension of Spheroids

The simplest system in this category is a dilute suspension of spherical inclusions in a continuum. Its effective complex permittivity is given by the formulation known as the Maxwell–Wagner equation, where the subscripts 1 and 2 refer to the suspending medium and inclusions, respectively:

$$\frac{\hat{\varepsilon} - \hat{\varepsilon}_1}{\hat{\varepsilon} + 2\hat{\varepsilon}_1} = v_2 \frac{\hat{\varepsilon}_2 - \hat{\varepsilon}_1}{\hat{\varepsilon}_2 + 2\hat{\varepsilon}_1} \tag{3.74}$$

This equation can be rearranged in the form of a dispersion equation with the following parameters:

$$\begin{aligned}
\varepsilon_\infty &= \varepsilon_2 \frac{2\varepsilon_2 + \varepsilon_1 - 2v_2(\varepsilon_2 - \varepsilon_1)}{2\varepsilon_2 + \varepsilon_1 + v_2(\varepsilon_2 - \varepsilon_1)} \\
\varepsilon_s - \varepsilon_\infty &= \frac{9(\varepsilon_2\sigma_1 - \varepsilon_1\sigma_2)^2 v_2(1 - v_2)}{[2\varepsilon_2 + \varepsilon_1 + v_2(\varepsilon_2 - \varepsilon_1)][2\sigma_2 + \sigma_2 + v_2(\sigma_2 - \sigma_1)]^2} \\
\sigma_s &= \sigma_2 \frac{2\sigma_s + \sigma_2 - 2v_2(\sigma_2 - \sigma_1)}{2\sigma_2 + \sigma_2 + v_2(\sigma_2 - \sigma_1)} \\
\sigma_s - \sigma_\infty &= \frac{9(\sigma_2\varepsilon_1 - \sigma_1\varepsilon_2)^2 v_2(1 - v_2)}{[2\sigma_2 + \sigma_1 + v_2(\sigma_2 - \sigma_1)][2\varepsilon_2 + \varepsilon_2 + v_2(\varepsilon_2 - \varepsilon_1)]^2} \\
\tau &= \varepsilon_0 \frac{2\varepsilon_2 + \varepsilon_1 - v_2(\varepsilon_2 - \varepsilon_1)}{2\sigma_2 + \sigma_2 + v_2(\sigma_2 - \sigma_1)}
\end{aligned} \tag{3.75}$$

The dispersion will occur when $\sigma_1\varepsilon_2 \neq \sigma_1\varepsilon_2$, which is practically always the case. The magnitude of the dispersion depends on the differences in dielectric parameters between the two phases.

In the context of mixture theory, sparse means $v_2 \leq 0.2$; to model the effective permittivity of more concentrated suspensions, it is necessary to take into consideration interparticle interactions. This becomes a very complex model; there are no rigorous solutions even for the relatively simple case of identical spherical inclusions. The Bruggeman–Hanai Equation 3.64 was formulated taking account of some interaction between particles and is therefore better suited than the Maxell–Wagner equation to model more concentrated suspension. In its complex form, it can be shown to predict the occurrence of a dispersion with the following limiting parameters:

$$\left(\frac{\varepsilon_\infty - \varepsilon_2}{\varepsilon_1 - \varepsilon_2}\right)\left(\frac{\varepsilon_1}{\varepsilon_s}\right)^{1/3} = 1 - v_2$$

$$\varepsilon_s\left(\frac{3}{\varepsilon_s - \sigma_2} - \frac{1}{\sigma_s}\right) = 3\left(\frac{\varepsilon_1 - \varepsilon_2}{\sigma_1 - \sigma_2} + \frac{\varepsilon_2}{\sigma_s - \sigma_2}\right) - \frac{\varepsilon_2}{\sigma_2}$$

$$\left(\frac{\varepsilon_s - \sigma_2}{\sigma_1 - \sigma_2}\right)\left(\frac{\sigma_1}{\sigma_s}\right)^{1/3} = 1 - v_2$$

$$\sigma_\infty\left(\frac{3}{\varepsilon_\infty - \varepsilon_2} - \frac{1}{\varepsilon_\infty}\right) = 3\left(\frac{\sigma_1 - \sigma_2}{\varepsilon_1 - \varepsilon_2} + \frac{\sigma_2}{\varepsilon_\infty - \varepsilon_2}\right) - \frac{\sigma_1}{\varepsilon_1} \tag{3.76}$$

In these expressions ε_s, ε_∞, σ_∞ are the limiting values of the corresponding parameters. The dispersion is characterized by a distribution of relaxation times.

The validity of the model has been verified experimentally for mixtures of known composition and geometry (Hanai et al., 1982; Ishikawa et al., 1982). The dispersion is broader than a single time constant because of the interactions between particles. Moreover, if the components of the heterogenous system exhibit molecular dielectric dispersion of their own, then these intrinsic dispersions will also appear, together with the interfacial dispersion, in the complete frequency spectrum of the system.

Fricke (1955), Sihvola and Kong (1988), Sihvola and Lindell (1992), and many others have extended the model to the more general case of a suspension of spheroids with any combination of axial ratios. Ultimately, the outcome is equivalent to introducing a parameter to account for the shape. The Maxwell–Wagner equation becomes

$$\frac{\hat{\varepsilon} - \hat{\varepsilon}_1}{\hat{\varepsilon} + F\hat{\varepsilon}_1} = v_2 \frac{\hat{\varepsilon}_2 - \hat{\varepsilon}_1}{\hat{\varepsilon}_2 + F\hat{\varepsilon}_1} \tag{3.77}$$

where F is the shape factor, equal to 2 for spheres, which reverts to Equation 3.74. In cases where the shape of the inclusion is not known, limiting values for the effective permittivity can be obtained using the shape factors in the extreme cases of infinitely long thin rods and infinitely thin circular disks.

An interesting case is that of ellipsoids with their axes aligned in the same direction. The permittivity would be different depending on the direction of the field; the mixture would be electrically anisotropic and the effective permittivity is represented by a tensor.

Another case of practical interest is that of layered spherical inclusions. This situation is required when modeling cellular structures surrounded by a membrane of finite thickness. Solutions for the effective permittivity of this model were provided by many researchers in this field (e.g., Schwan, 1957; Zhang et al., 1983; Grosse, 1988). These authors applied two mixture models, once to the concentric bodies, thus obtaining an effective permittivity for the inclusions, and then treating the mixture as a suspension of homogenous spheres. The parameters of the dispersion could be expressed in terms of the physical dimensions and electrical characteristics of the cell and cell membrane; simplified versions of these expressions are reported by Foster and Schwan (1989). Sihvola (1989) and Irimajiri et al. (1991), among others, extended the treatment to several concentric shells by using a recursive technique. These complex models are more relevant to the study of biological systems and to the understanding of the interactions at the cellular level. They are not sufficiently developed for the quantitative characterization of the interfacial polarization in biological systems, but do provide an insight into the factors that determine its characteristics. An example from the recent literature is the modeling of the dielectric response of heart tissue by Schaefer et al. (2002). The model is a function of the cell shape, electrical cell coupling and

polarization of cell membranes, and intracellular structure. It describes heart cells and subcellular organelles as rotational ellipsoids filled with electrolyte enclosed by an isolating membrane and is capable of reproducing the main features of the dielectric spectrum of heart tissue.

In recent years, statistical methods using probabilistic descriptions of the physical mixture in terms of a spatial density function have been developed to provide realistic bounds for the effective permittivity of mixtures. This approach, developed by, among others, Bergman (1978) and Milton (2002), provides an analytic integral representation of the effective permittivity $\hat{\boldsymbol{\varepsilon}}$ of an arbitrary binary mixture in terms of a spatial density function $g(x)$:

$$\frac{\hat{\boldsymbol{\varepsilon}} - \hat{\boldsymbol{\varepsilon}}_1}{\hat{\boldsymbol{\varepsilon}}_1} = \int_0^1 \frac{g(x)\,\mathrm{d}x}{x + \hat{\boldsymbol{\varepsilon}}_1/\hat{\boldsymbol{\varepsilon}}_2 - \hat{\boldsymbol{\varepsilon}}_1}$$

where, as before, the subscripts 1 and 2 refer to continuum and dispersed phases, respectively, and the integration is over all possible positions. Depending on the choice of distribution function $g(x)$, it is possible for the above equation to revert to some of the well-known binary mixture equations. Recursive application is possible; modeling biological systems remains challenging.

A new tool for the study of mixtures, including biological materials, has evolved with the development of increasingly powerful numerical modeling packages for the propagation of electromagnetic fields in complex structures from full solutions of Maxwell's equations. With structures being defined at the nanoscale, the characterization of fields within cells and subcellular structures appears to be within reach (Gimsa and Wachner, 1998, 1999, 2001a,b; Bianco et al., 2000; Sebastian et al., 2001; Munoz et al., 2003).

3.6.2 Counterion Polarization Effects

Another important polarization phenomenon in electrically biological materials originates from ionic diffusion effects near charged surfaces and the formation of counterion or electric double layers. The distribution of ions in the vicinity of charged interfaces is subject to concentration and electric field gradients; an equilibrium is reached with the ions continuously distributed over the volume of the electrolyte solution. The time constant associated with this mechanism is longer than that of the Maxwell–Wagner effect, it is of the form L^2/D, where L is the length over which diffusion occurs and D is a diffusion coefficient (Schwarz, 1962).

Counterion phenomena are difficult to analyze rigorously; they involve coupled electrodynamic and hydrodynamic mechanisms. The theories are complex, but good reviews are available as an introduction to the subject (Dukhin, 1971; Dukhin and Shilov, 1974; Fixman, 1980, 1983; Mandel and Odijk, 1984). Relatively simple models that provide exact solutions have been proposed (Grosse and Foster, 1987; Grosse, 1988), whereby coupled differential equations for the ion concentrations and current densities are obtained for a macroscopic sphere of radius a in an ionic medium. Their solution yields a broad, asymmetrical, low-frequency dispersion. The time constant of this dispersion is a^2/D, where D is the diffusion coefficient of ions in the bulk electrolyte.

To visualize the effect, consider the motion of an ion in the bulk electrolyte near the particle, it will be conducted away or excluded depending on whether its sign is the same or opposite that of the ions in the counterion layer. Thus, for an ion in the electrolyte, the particle acts either as a good conductor or as an insulator depending on its charge

compared to that of the counterion. A cloud of charge accumulates within a Debye length of the charged surface; for physiological saline (0.15 N NaCl) the Debye length is very small, <1 nm, resulting in a very large induced capacitance and hence a large permittivity dispersion.

3.7 Dielectric Properties of Tissue—State-of-Knowledge

Research into the dielectric properties of biological materials and their variation with frequency has been ongoing for most of the past century. Early studies went a long way toward understanding and establishing the principles of interaction and the corresponding features of the highly frequency-dependent spectrum of a tissue. In the last few decades, the research was driven, above all, by the need to establish a credible database of dielectric properties of all body tissues for use in electromagnetic dosimetry studies, where the object is to quantify the exposure of people to external electromagnetic fields from knowledge of the effective internal fields and currents induced in them. In these studies, tissues are characterized by their measured dielectric properties. In the last decade, most dosimetric studies drew on data published in the scientific literature in 1996 and made widely available on the Internet thereafter (Gabriel et al., 1996; Gabriel and Gabriel, 1997).

3.7.1 1996 Database

The backbone of the 1996 database is a large experimental study providing data pertaining, almost exclusively, to excised animal tissue at 37°C. For most tissues, the characterization was over a wide frequency range, 10 Hz to 20 GHz, using three previously established experimental setups with overlapping frequency ranges. The following are some of its characteristics:

- The data are presented in the context of a review covering all relevant publications in the preceding half-century. By and large, the experimental data were well within the confines of corresponding values from the literature.
- The data showed good internal consistency, that is, good agreement between data obtained with different experimental setups in a common frequency range.
- Finally, an element of great practical importance, the dielectric spectra were parametrized using a multidispersion model consisting of four Cole–Cole terms and one ionic conductivity term. For each tissue, the parameters of the model enable the reconstruction of its spectrum, a procedure that could easily be incorporated in numerical studies to provide dielectric data that are broadly in line with the vast body of literature on the subject.
- The fact that the complex permittivity data could be fitted to Cole–Cole dispersions implies that they also agree with the Kramers–Kronig relation in accordance with the principle of causality for a linear system. This imparts another level of consistency to the data.

Examples are given here to illustrate the extent of the available data in the literature for certain tissues at certain frequencies in contrast to the scarcity of data elsewhere

(Figure 3.15 through Figure 3.17). No attempt is made at a quantitative or mechanistic analysis.

While useful, the 1996 database has several limitations, as pointed out by its authors:

- Most measurements were carried out on excised tissue, while data pertaining to live tissue would have been more relevant in bioelectromagnetics studies.
- For most tissues, the predictions of the model can be used with confidence for frequencies above 1 MHz because of the availability of supporting data in the literature.
- At lower frequencies, where the literature values are scarce and have larger than average uncertainties, the model should be used with caution in the knowledge that it provides a ''best estimate'' based on the then available knowledge. This is particularly important for tissues where there are no data to support its predictions.
- Electrode polarization, an inevitable source of error at low-frequencies, was not totally accounted for. It affects the data at frequencies below 100 Hz.
- Because of the geometry of the sampling probe, it was not possible to orient the field along and across directed structure to demonstrate the anisotropy of the dielectric properties.

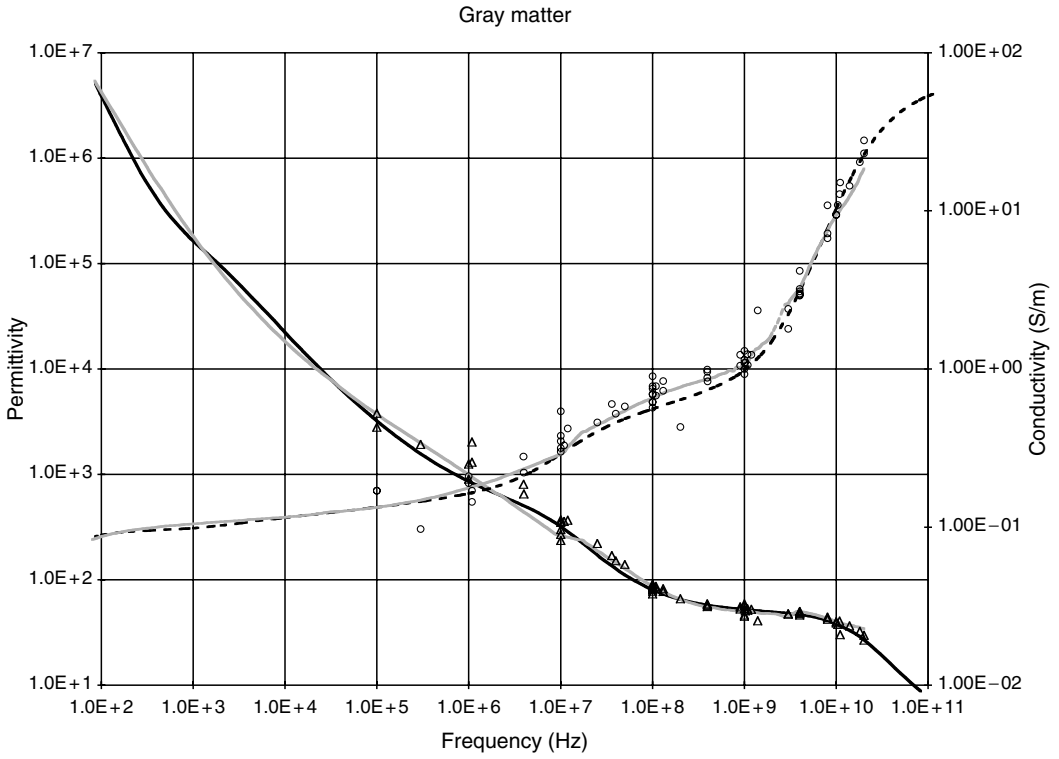

FIGURE 3.15
Permittivity and conductivity of gray matter at 37°C; gray lines are experimental data from Gabriel et al. (1996), triangles and circles are permittivity and conductivity values from the pre-1996 literature, black solid and dashed lines are the predictions of the model.

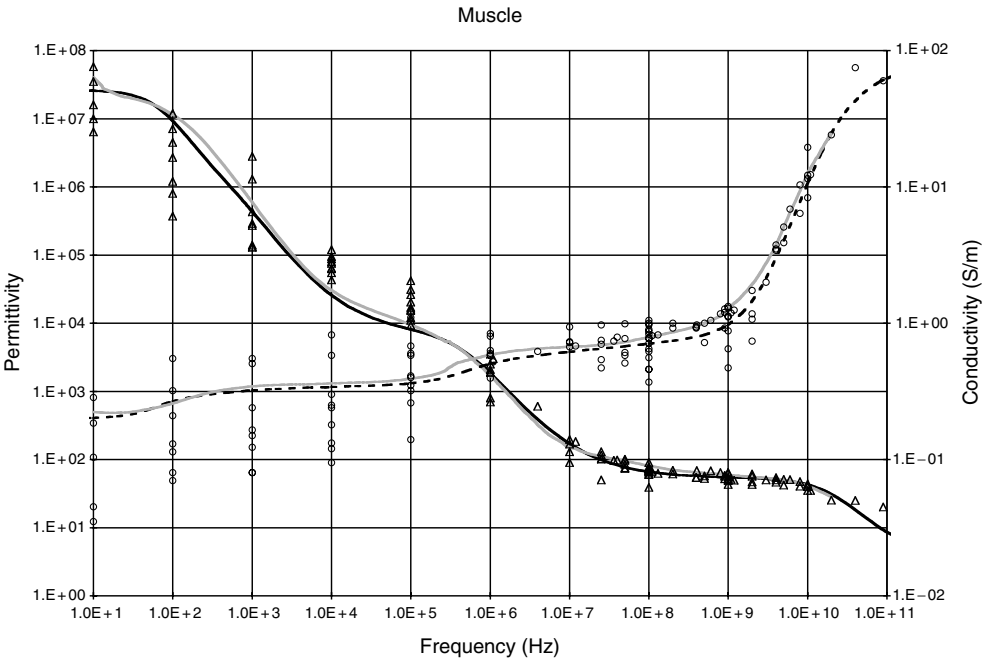

FIGURE 3.16
Permittivity and conductivity of skeletal muscle at 37°C; legend as in Figure 3.15. The very wide spectrum of data below 1 MHz is, at least partially, due to the anisotropy in the dielectric properties of muscle tissue. The literature data pertain to measurement along and across the muscle fibers and to measurements where the direction was not specified.

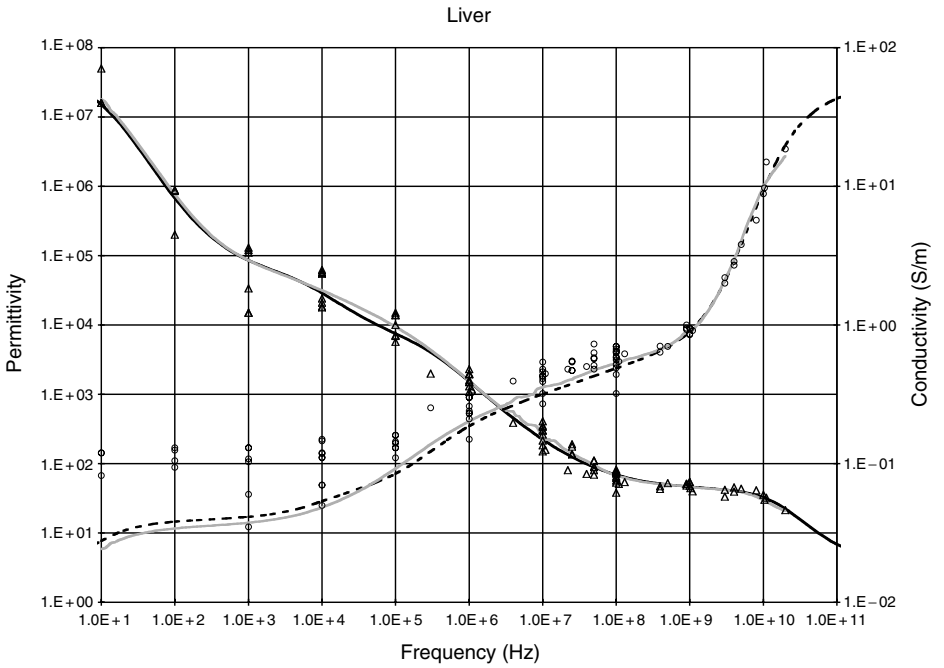

FIGURE 3.17
Permittivity and conductivity of liver tissue at 37°C; legend as in Figure 3.15. Liver tissue exhibits no significant anisotropy in its dielectric properties, but as with all tissue, the characteristics of the β dispersion and the static conductivity are sensitive to the viability and time after death when the measurements were made.

Evidently, much remains to be done, in particular with respect to reducing the uncertainty in the data and filling in the gaps identified. Ten years on, the recent literature is reviewed to update the state-of-knowledge on the subject.

3.7.2 Literature After 1996—A Brief Review

The review is carried out per tissue type or thematic underline. In some cases, data from recent studies are compared with the model in the 1996 database and with data from a recent study, where the dielectric properties of over 40 tissues were characterized *in vivo* and *in vitro* in the frequency range 10^2 to 10^4 MHz (Peyman et al., 2005).

3.7.2.1 Brain Tissue: Gray and White Matter

At microwave frequencies, three studies reported new data for brain tissue (Bao et al., 1997; Schmid et al., 2003a,b). Data tabulated by the authors are given in Figure 3.18. Data by Peyman et al. (2005) are in reasonable agreement with the database, while data by Bao and coworkers and Schmid and coworkers are higher for both permittivity and conductivity.

It is important to find a reason as to why carefully conducted studies, using adaptations of a conceptually similar experimental procedure, are still coming up with different results. In terms of explanation we note the handling of the sample by Bao et al., in which the whole brain is excised, immersed in saline, temperature regulated, and measured while immersed. The authors give good reasons for following this procedure.

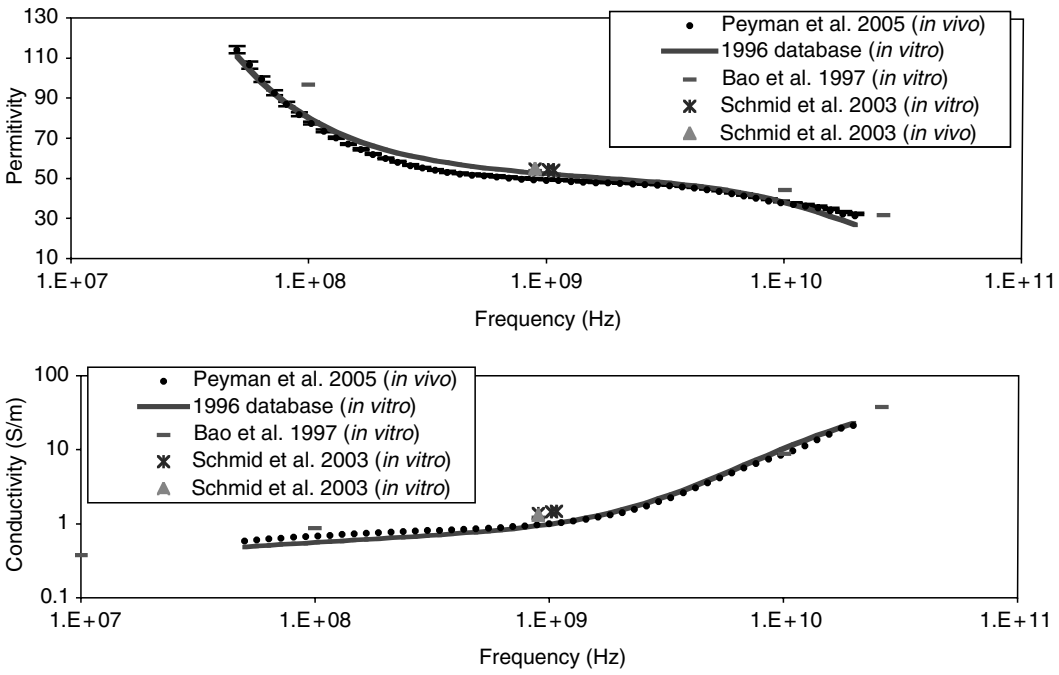

FIGURE 3.18
Dielectric properties of gray matter at 37°C. Data from recent studies compared to the prediction of the 1996 database.

It is inevitable, however, that one should expect their data to fall on the high side of average because of the presence of saline. Schmid et al. published data on porcine (*in vivo*) and human gray matter (*in vitro*). Their porcine gray matter data were obtained under conditions designed for the study of variation with time over a period spanning the time of death and beyond. Presumably, this is why their measurements were carried out over a narrow frequency range with the measurement probe held in position for the duration of the experiment (150 min). One might speculate that the amount of pressure used to maintain constant contact between the probe and the live brain could cause local oozing of fluid and higher conductivity values.

Conjecture apart, these data are valuable additions to the literature, but one must be cautious not to generalize on the basis of such limited data that measurement *in vitro* underestimates the dielectric properties of living tissues at microwave frequencies. Differences between tissue properties obtained *in vivo* and *in vitro* are to be expected at lower frequencies, in the range of α and β dispersions, in view of the sensitivity of their causal mechanism to the physiological state of the tissue. Differences between *in vivo* and *in vitro* data are much less likely in the frequency range of the γ dispersion, where water content is the most important determinant factor, and as recently reported by Stauffer et al. (2003), for liver tissue, and by Peyman et al. (2005), for many tissues including gray matter. Measurements *in vivo* are fraught with difficulties. For example, Burdette et al. (1986) measured the gray matter, *in vivo*, through the pia matter and directly beneath it. Of the two sets of data obtained, one is similar to that of Schmid et al., and the other is significantly lower.

In their human study, Schmid et al. measured the dielectric properties of gray matter in the frequency range of 800 MHz to 2450 MHz on 20 human brains immediately after excision. The measurements were carried out at room temperature in the range 18°C to 25°C and extrapolated to 37°C using experimentally determined thermal coefficients. Nevertheless, the dielectric properties at 900 MHz were in very good agreement with their data for porcine gray matter *in vivo*. It is understandably frustrating to realize that the bounds of uncertainty remain high when comparing data from different laboratories, even for those tissues that have been widely measured and reported.

Latikka et al. (2001) reported conductivity values at 50 kHz for gray matter (0.28 S/m), white matter (0.25 S/m), cerebrospinal fluid (1.25 S/m), and tumors (0.1 S/m to 0.43 S/m). They used a monopolar needle electrode during brain surgery on nine patients who had deep brain tumors. The technique is not geared toward making directed measurement and detecting anisotropy in the electrical properties, although those are anticipated on theoretical grounds and are known to be present in the hertz to kilohertz frequency range (Nicholson, 1965; Ranck et al., 1965; Yeldin et al., 1974; Nicholson and Freeman, 1975). Observed differences in the conductivity along and across the cellular structure were factors between 2 and 10 depending on the tissue. Clearly, this is an area of importance to electrophysiology, among other applications; it is also an area where data are scarce.

Peyman et al. (2001) reported variation in the dielectric properties of rat brain tissue as a function of age, at microwave frequencies. Their data pertained to the whole brain. The observed variation was ascribed, at least partially, to the change in the ratio of gray to white matter, which is known to occur throughout the developmental stage. In a recent study on porcine tissues (Peyman et al., 2005), they were able investigate gray and white matter separately. In this case, no variations were observed in the dielectric spectrum of gray matter, while statistically significant variations were observed in the dielectric spectrum of white matter (Figure 3.19). The observed variations are probably related to the process of myelination, which begins at birth and lasts to maturation. Similar variations were observed in the dielectric properties of the spinal cord.

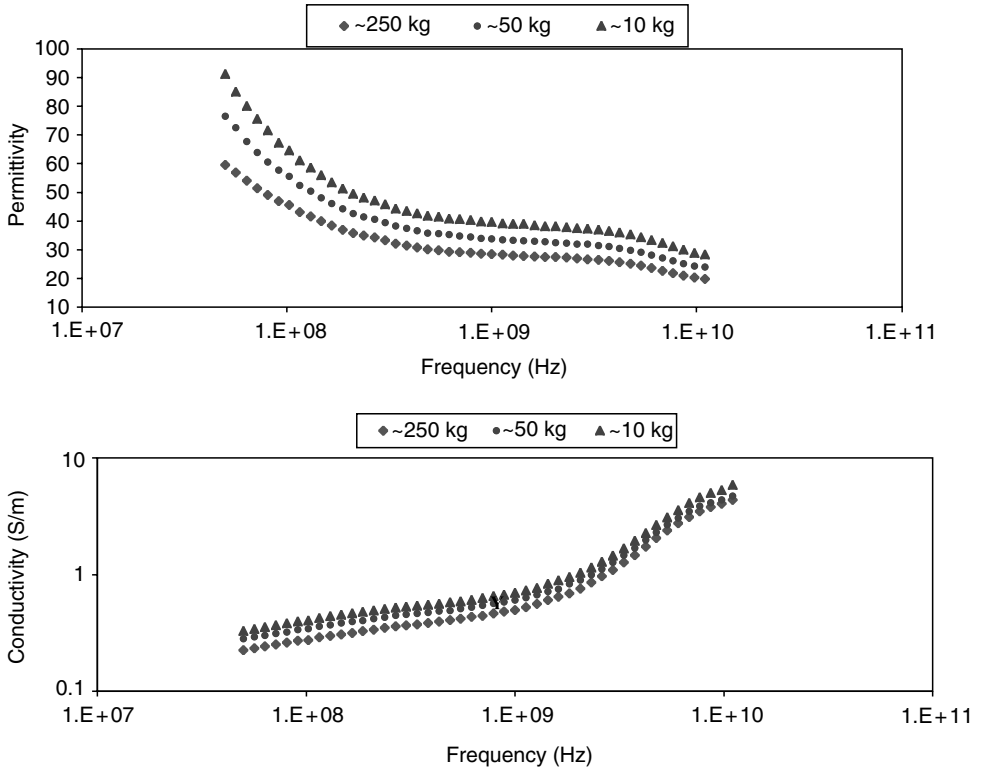

FIGURE 3.19
Permittivity and conductivity of white matter as a function of animal growth. The measurements were made *in vitro* at 37°C. The lowest permittivity and conductivity spectra pertain to a fully grown, 250-kg sow, the highest to a 10-kg piglet. (Data are from Peyman A, Holden S, Gabriel C. 2005. Dielectric Properties of Biological Tissues at Microwave Frequencies. Final technical report, MTHR Department of Health, U.K.)

3.7.2.2 Liver

Dielectric data for liver tissue were reported in several studies carried out under different conditions for a variety of reasons. For example, Riedel et al. (2003) developed a contact-free inductive measurement procedure and demonstrated the system by carrying out conductivity measurements on liver tissue between 50 and 400 kHz as a function of time after death. Stauffer et al. (2003) characterized the dielectric properties of normal and cancerous liver tissue in the frequency range of 0.3 to 3 GHz and reported higher permittivity and conductivity for tumor tissue. Chin and Sherar (2001) observed irreversible changes in the dielectric properties of liver tissue at 915 MHz because of excessive heating causing protein denaturation. Haemmerich et al. (2002) reported changes in the electrical resistivity of liver tissue during induced ischemia and postmortem. They observed increases in resistivity *in vivo* during occlusion. They analyzed the data in terms of intra- and extracellular resistance and cell membrane capacitance.

Valuable contributions by Raicu et al. (1998a,b) have provided data for rat liver tissue, measured *in vivo*, in the frequency range of 10^2 to 10^8 Hz. This is an eventful part of the dielectric spectrum of a tissue where contributions from interfacial and counterion interaction mechanisms occur. The measured data were corrected for electrode polarization and found to be in reasonable agreement with some previous studies (Surowiec et al., 1986; Foster and Schwan, 1996; Gabriel et al., 1996c). As expected, the data obtained traced a broad dielectric dispersion curve over the range of 10^3 to 10^8 Hz, suggestive of the

involvement of widely distributed relaxation times. In the second of their 1998 papers, they provide a mechanistic analysis. A simple application of the Maxwell–Wagner interfacial polarization theory could not fully explain the observed dielectric behavior, especially at frequencies below 1 MHz. The Bruggeman–Hanai-type effective medium theory (EMT) was better, but not perfect, at simulating the observation at low-frequencies. A better simulation of the effective permittivity was obtained when second-order corrections, for possible dipole–dipole interaction (DDI) effects, were introduced to the classical EMT for a concentrated suspension of particles. Application of the new EMT-DDI model enabled reasonable estimates to be made of the following: effective size and shape of hepatic cell; specific capacitance for the plasma, nuclear, and mitochondrial membranes associated with the hepatocyte; and cytosolic as well as nucleoplasmic conductivities of physiological interest.

3.7.2.3 Muscle

Muscle tissues, be it skeletal, myocardial, lingual, or other, exhibit large anisotropy in their electrical properties. This is to be expected from the tissue structure and was observed at frequencies below 1 MHz (Epstein and Foster, 1983; Fallert et al., 1993). The static conductivity value measured along the muscle fiber may be up to an order of magnitude higher than when measured across. The α dispersion is more prominent and the β dispersion less defined in the longitudinal direction in accordance with the predictions of effective permittivity modeling of elongated structures. For example, Semenov et al. (2002) evaluated anisotropy of the myocardium using a cellular model of the myocardial tissue and concluded that at frequencies lower than 10 MHz, myocardial dielectric properties are highly anisotropic (up to a factor of 10). Reliable, low-frequency data are very scarce, and there is a wide range in what is available in the literature, partly due to the fact that many authors do not specify the measurement orientation. The situation is not helped by the fact that the apparent anisotropy depends on the measurement procedure, in particular the interelectrode distance in relation to the size of the muscle fiber. Some of the problems associated with obtaining good data at frequencies below 1 MHz have been described by Tsai et al. (2000, 2002) in the context of their *in vivo* measurement of swine myocardial resistivity. In their study, they report changes in the myocardial resistivity as a function of time after death. The postmortem resistivity at 1, 10, and 100 Hz increased to about three times their original *in vivo* value and at 500 kHz and 1 MHz increased less than 15%, 6 h after death.

Most recent studies on the electrical properties of muscle tissue focused on the differences between normal and ischemic or hypoxic tissue. One of the drivers is to investigate the possibility of using *in situ* impedance measurements to map the histological changes in tissue *in vivo*. There is also potential for noninvasive imaging provided that the electrical characteristics of both normal and scar tissue are well-defined. Miyauchi et al. (1999) and Schaefer et al. (1999) observed changes in the α and β dispersions of normal and ischemic skeletal muscle. Ischemia in myocardial muscle is a matter of clinical importance in the assessment of myocardial infarction and has been the subject of many dielectric investigations. Schwartzman et al. (1999) investigated the properties of the border zone, which were found to be intermediate between healthy and infarcted tissue in the case of chronically infarcted ventricular myocardium. Semenov et al. (2002) observed the dielectric properties of canine myocardium during acute ischemia and hypoxia to explore the potential of these observations for the clinical assessment of myocardial tissue using electrical impedance and microwave tomography. One of the problems identified is the need to know and take into consideration the tissue electrical anisotropy.

3.7.2.4 *Skin*

Skin is the interface of the body with environmental agents including electromagnetic fields; knowledge of its dielectric properties is of importance in the assessment of human exposure and in numerous biomedical applications. Data from *in vivo* measurements are now available, obtained using noninvasive, open-ended coaxial probes (Gabriel et al., 1996c; Gabriel, 1997; Raicu et al., 2000). However, the interpretation of such topical measurements as effective permittivity of the skin is far from straightforward. Lahtinen et al. (1997) and Alanen et al. (1998) advocate an analysis based on a quasistatic approximation of the fringing field of the probe penetrating a layered structure. Gabriel (1997) drew attention to the effect on the dielectric spectrum of the degree of hydration of the stratum corneum (Figure 3.20), which also affects penetration of the field into the tissue. Joining the discussion, Raicu et al. (2000) carried out *in vivo* measurements on dry skin and on skin moistened with physiological saline, in the frequency range of 100 Hz to 100 MHz. They analyzed the data using the dispersion model comprising a Debye-type and ''universal'' responses (Equation 3.53) and a conductivity term. Comparing the parameters of the model for dry and saline-moistened skin, they noted a fivefold increase in the dispersion magnitude. One possible explanation they provide is that the ''effective penetration depth'' increases and contributions from the innermost skin layers become evident. This statement appears paradoxical; in fact, it is due to the reduction in the layering effect; when moistened, the skin appears more homogenous and behaves like a high water content tissue.

Raicu et al. (2000) further speculate that an interfacial polarization originating from the stratum corneum–epidermis interface occurs in the case of dry skin, as suggested by Alanen et al. (1999), but not in that of the saline-moistened skin. In support of this argument, they refer to the change in one of the distribution parameters, β, which decreases from 0.152 to 0.076 after the skin is hydrated with aqueous NaCl solution. It therefore appears that topical measurement on dry (normal) skin *in vivo* may not be proportionately representative of the inner layers. On the other hand, the use of an aqueous coupling agent that is likely to hydrate the stratum corneum affects the results of the measurements. In practice, the use of a coupling agent gives more reproducible results and leads to better agreement between data from the recent literature, as is evident in Figure 3.21 through Figure 3.23, which contain such data (Gabriel, 1997; Ghodgaonkar et al., 2000; Raicu et al., 2000; Sunaga et al., 2002; Hwang et al., 2003; Petaja et al., 2003) and collectively cover the frequency range of 100 Hz to 100 GHz.

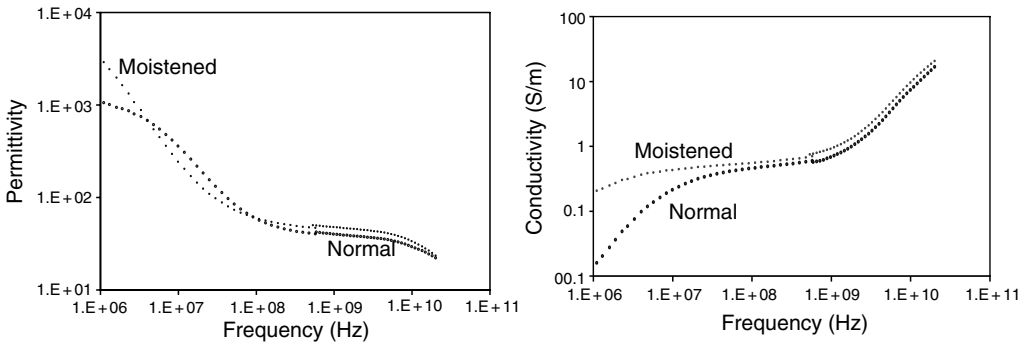

FIGURE 3.20
Permittivity and conductivity of skin (ventral forearm) illustrating the effect of moistening the skin on the dielectric spectra (Gabriel, 1996).

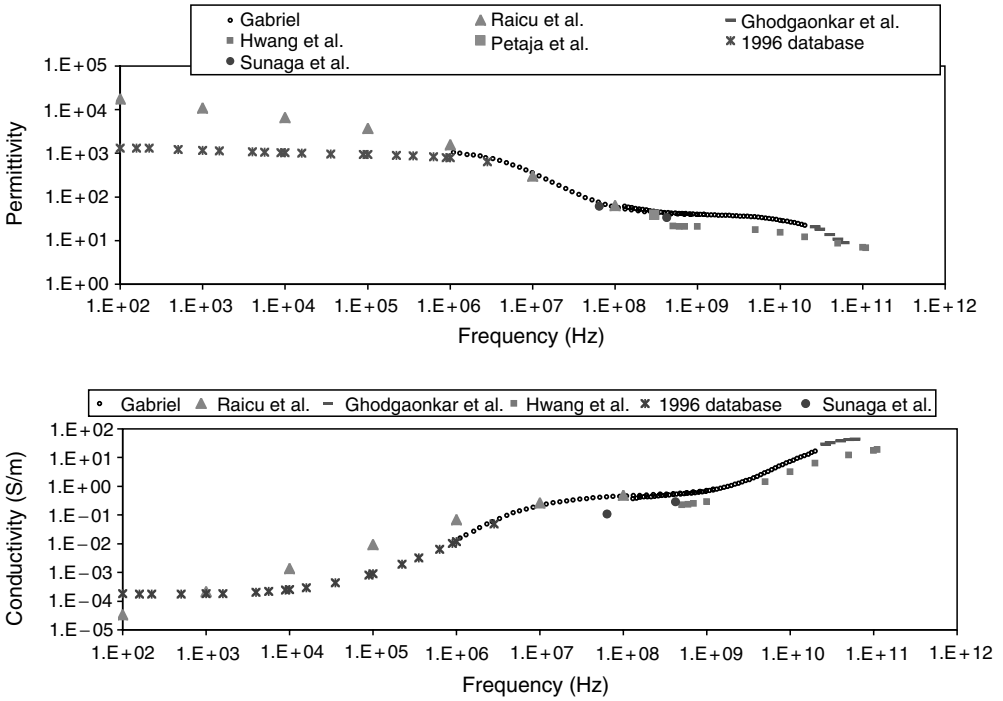

FIGURE 3.21
Permittivity and conductivity of skin (different parts of the body, excluding palms and soles). No moistening or contact gel was used. Different measurement techniques were used including open-ended coaxial probes of vastly different sizes.

The dielectric properties of skin have been widely investigated as monitors of various pathological conditions. Hayashi et al. (2005) investigated the dielectric properties of human skin *in vivo* at frequencies up to 10 GHz to monitor the progress of the healing process of skin burns using water content as the determinant factor. Their measurement technique, time domain spectroscopy and open-ended probe, is similar to that used by

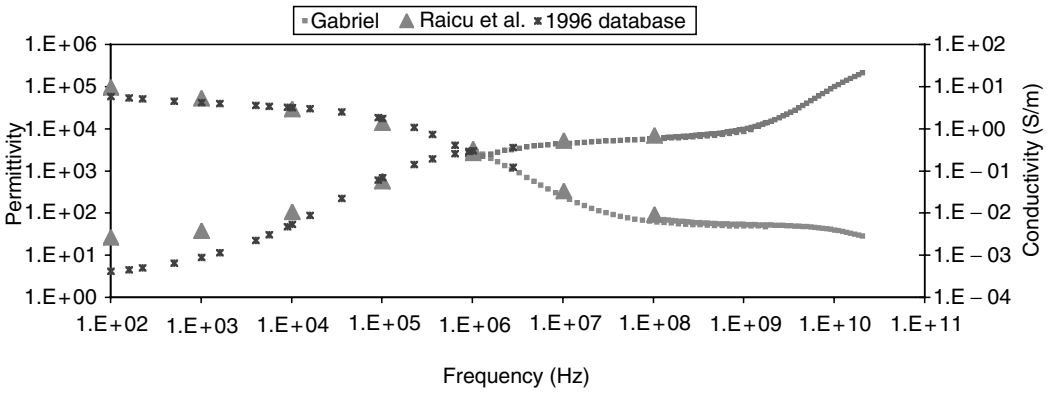

FIGURE 3.22
Permittivity and conductivity of skin (Raicu et al.: back of neck, moistened with physiological saline; Gabriel and database: ventral forearm, moistened with water). Open-ended coaxial probes of vastly different sizes were used.

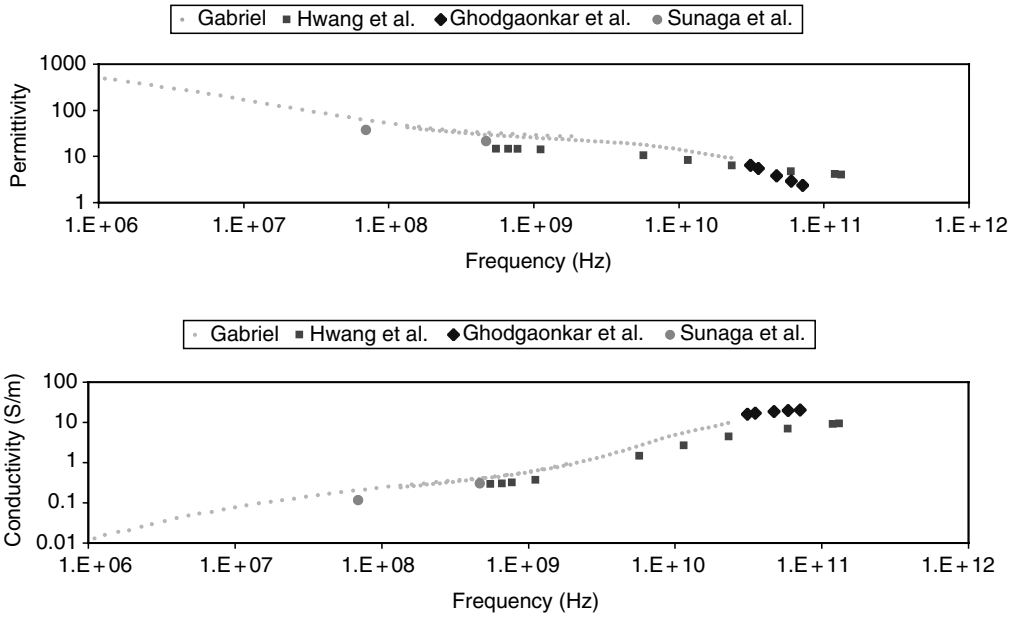

FIGURE 3.23
Permittivity and conductivity of palm, from recent studies.

Gabriel et al. (1997), who reported the dielectric spectra of normal and wounded tissue and ascribed the differences to water content.

Petaja et al. (2003) attempted to correlate the dielectric properties of skin at 300 MHz to body fluid changes after cardiac surgery and report limited success. Sunaga et al. (2002) investigated the variability in the dielectric properties of human skin of healthy volunteers, collagen disease patients, and dialysis patients over the frequency range of 1 to 450 MHz. No significant difference was detected in the dielectric properties among the three groups; some regional (abdomen, thigh, and forearm) dependence was observed. Marzec et al. (1999) measured the conductance and susceptance of soles and calves in leg skin from healthy controls and patients with ischemia in the frequency range of 100 Hz to 100 kHz. Ischemia was found to have no effect on the admittance at frequencies lower than 10 kHz, where the effect of the stratum corneum is dominant. Observed differences at frequencies in excess of 10 kHz are ascribed to ischemia in the underlying skin tissue.

Lindholm-Sethson et al. (1998) investigated the potential of using noninvasive skin impedance spectroscopy for the early detection of diabetic changes. They implemented a multivariate data analysis procedure to demonstrate how a regression model between the skin impedance and other diagnostic data for diabetic and control groups can be developed into a novel diagnostic tool for the early discovery of possible complications in diabetic patients. Statistical procedures are increasingly being applied to correlate dielectric parameters to structural or compositional elements of biological material, particularly in cases where there is a physical mechanism underpinning the effect that is obscured by noisy data (Kent et al., 2002).

The use of dielectric spectroscopy to monitor damage to the skin caused by ionizing radiation is an active field of research aiming at monitoring the side effects of clinical radiotherapy objectively and quantitatively. It appears that the changes to the skin during

the acute stage cause both permittivity and conductivity to decrease (Tamura et al., 1994; Nuutinen et al., 1998), while the reverse happens when radiation-induced fibrosis finally sets in (Lahtinen et al., 1999). The initial decrease in permittivity, which also means a decrease in skin water, may be due to damage to skin capillaries resulting in swelling of the cytoplasm, with narrowing or occlusion of capillaries and a reduction in the effective microcirculation of the skin. In the long term, an increase in collagen and collagen-bound water is a likely explanation for the observed increase in the permittivity in line with a clinical indicator of subcutaneous fibrosis (Nuntineu, 1998).

3.7.2.5 Bone

Peyman et al. (2001) observed variation in the dielectric properties of rat skull bone as a function of developmental stage from neonate to 70 days old. They reported lower permittivity and conductivity values across the spectrum (100 MHz to 20 GHz). Similar results were recently reported for porcine skull, cortical bone, and bone marrow (Peyman et al., 2005).

3.7.2.6 Dielectric Properties of Cancerous Tissue

The pathological differences between normal and cancerous cells affect their composition and morphology and shape their dielectric spectrum. Interest in this field of study is driven by biomedical applications where such differences can be exploited for the treatment or diagnosis of cancer. Most of the clinical applications are based on hyperthermia, whereby electromagnetic energy is preferentially applied to the cancerous tissue, usually as an adjunct to radiotherapy. Electromagnetic hyperthermia was an active field of study in the 1980s, and it remains the domain of specialist medical centers. In contrast, there is a growing interest in applications geared toward the detection of cancerous regions using three-dimensional microwave tomography procedures and signal analysis (Hagness et al., 1998, 1999; Bulyshev et al., 2001; Wersebe et al., 2002). In cases where the suspect region is accessible for dielectric measurements, the procedure relies on the characterization and comparative analysis of the dielectric spectrum (Walker et al., 2000). The ultimate goal is to detect changes at the precancerous stage prior to their visibility by x-rays and to the emergence of serious clinical symptoms.

There is evidence that tumors have higher water content than the corresponding normal tissue; for certain types of tumor, such as breast carcinoma surrounded by fatty tissue, the difference could be considerable. In terms of dielectric properties, one would expect cancerous tissue to have higher permittivity and conductivity at microwave frequencies compared to normal tissue, as observed and reported by Schepps and Foster (1980), Foster and Schepps (1981), Rogers et al. (1983), and more recently, Stauffer et al. (2003).

Morphological changes affect the dielectric properties in the frequency range of the β dispersion and can be quite significant (Smith et al., 1986). Walker et al. (2000) used a finite element analysis to model the differences in impedivity between normal and precancerous cervical cells in the frequency range of 100 Hz to 10 MHz. Their results showed significant differences at frequencies lower than 10 kHz, basically in line with measurements carried out *in situ* with a four-electrode pencil probe. Polevaya et al. (1999) used time domain dielectric spectroscopy to study the differences between normal and malignant white blood cells. They used a Maxwell–Wagner mixture formulation and a double-shell cell model to determine differences in cellular and nuclear membrane characteristics between normal and malignant cells. Their detailed analysis reflects on some functional differences between membranes and provides some insight into the etiology of cancer.

The use of the electrical characteristics of tissue to understand, image, or treat cancerous tissue relies on the availability of good representative data across the spectrum but particularly in the frequency range of the β dispersion, where the changes are specific to the cellular transformation as well as the water content.

3.7.2.7 Conductivity of Tissue at Low-Frequency

There are limited, reliable dielectric data for body tissue at frequencies below 100 kHz. Some of the reasons relate to the dependence of the dielectric properties on the physiological state, degree of perfusion, time after death, and other biological parameters. There are also experimental difficulties, in particular electrode polarization, which is a major source of systematic error at frequencies below 100 Hz, even when precautions are taken to minimize its effects. Based on typical tissue dielectric data and a simple model for the electrode polarization, it is possible to estimate that it affects the permittivity more than the conductivity and that for body tissue, the conductive rather than the capacitive component dominates its electrical admittance (Schwan, 1992). For this reason, at extremely low-frequencies, the conductivity of tissue is considered real rather than complex, and the body is modeled as a resistive network the parameters of which are determined by the conductivity of the various tissues.

The conductivity of body tissue can be estimated by modeling on a cellular scale and applying appropriate mixture equations. Using this approach, Peters et al. (2001) evaluated the effective conductivity of several tissues such as cerebral cortex, liver, and blood. Such studies help to place upper and lower bounds on the conductivity values based on cellular parameters and knowledge of the conductivity of the phases.

Faes et al. (1999) carried out a meta-analysis of review studies (Geddes and Baker, 1967; Stuchly and Stuchly, 1980; Duck, 1990; Gabriel et al., 1996a,b) of tissue conductivity in the frequency range 100 Hz to 10 MHz. To make relative comparisons between different tissues, they calculated the mean and 95% confidence interval. They found large confidence intervals such that the conductivities of most high water content tissues (skeletal and cardiac muscle, kidney, liver, lung, and spleen) were not statistically different from one another at that level of significance. In contrast, blood has higher conductivity, while bone and fat have demonstrably lower conductivities. The insignificance of differences in high water content tissues could, of course, imply an equality of their conductivities, but it could also point at a large source of experimental variation that obscures real differences.

The conductivity of the body, or body parts, can be obtained by volume averaging using anatomical models and individual tissue conductivity as in Table 3.4, where the conductivity of the whole and the various parts of the body is given based on tissue conductivity in Gabriel (2000) and a voxel anatomical human model (Dimbylow, 1996).

At 50 Hz, the calculated conductivity values are comparable to the commonly used estimate of 0.2 S/m for the effective permittivity of a homogenous body model. When dielectric data become available, it would become imperative to reexamine the whole

TABLE 3.4

Conductivity (in S/m) of the Whole and Parts of the Body Obtained by Volume Averaging

Frequency	Whole Body	Head	Torso	Arm	Leg	Neck
50 Hz	0.22	0.25	0.22	0.19	0.20	—
10 kHz	0.28	0.28	0.26	—	0.24	0.22
100 kHz	0.29	0.30	0.33	—	0.24	0.24

Source: From Gabriel (2000).

question of whether or not there is sufficient justification for neglecting the contribution of the capacitive element of the body's electrical properties.

3.7.2.8 Nonlinear Dielectric Properties

The polarization mechanisms discussed so far occur from interactions with weak fields eliciting linear responses. At high field strength, nonlinear molecular and cellular polarization phenomena are predicted on theoretical grounds, on the basis of induced dipolar properties and classical electrodynamics. The threshold for initiating such effects is system and frequency dependent. As a general rule, as the frequency increases, so does the field level required to cause an effect. In general, at frequencies below the manifestation of the β dispersion, field strengths of the order of 10^6 V/m may be capable of initiating polarization mechanisms that affect the cellular function; higher fields may cause dielectric breakdown within the membrane, ultimately leading to cell destruction.

Under controlled conditions, high field strength, nonlinear effects are the focus of numerous applications in biotechnology. For example, dielectrophoresis, or the motion of particles caused by electrical polarization effects in nonuniform fields, is used to separate and manipulate cells. For a review of this subject, see Pethig (1996). Another nonlinear phenomenon, electroporation, is a consequence of the electrical breakdown of biological membranes, resulting in the formation of pores and a significant increase in the membrane permeability to external ions and molecules. Under controlled conditions, electroporation could be reversible and used to advantage in therapeutic, drug delivery applications. The basic principles can be found in mechanistic studies by Plickett and Weaver (1996), Prausnitz et al. (1999), and many others.

The hypothesis that weak fields may trigger nonlinear effects in cells has been investigated in theory and practice (Weaver and Astumian, 1990; Woodward and Kell, 1990). The generation of harmonics is one aspect that can be used to monitor their occurrence (Woodward and Kell, 1990); it also means that the dielectric properties are nonlinear, responding to harmonics as well as to the fundamental frequency. The study of harmonics is a subtle and clever tool; it has yet to prove its effectiveness in monitoring physiological responses to weak fields.

More recently, Balzano (2002) proposed to use a similar approach to test whether biological cells exhibit nonlinear responses to weak fields, at microwave frequencies. His idea hinges on the possibility of detecting a microwave signal at 1.8 GHz (second harmonic of 900 MHz) as weak as one microwave photon per cell per second. An experimental project based on this hypothesis is currently under way (see MTHR Web site: http://www.mthr.org.uk/research_projects/HO_funded_projects_excell.htm, accessed August 5, 2005). It will help to clarify the issue of nonlinear dielectric properties.

Magnetic Properties of Biological Material

Jon Dobson

CONTENTS

4.1 Introduction

Magnetism arises from the movement of electrical charges, such as the oscillation of electrons in a conducting wire, the flow of ions in an organism or the orbital, and spin motions of electrons in an atom. Since all materials contain moving subatomic particles (electrons and protons), all materials are, in some sense, ''magnetic.'' In order to understand more about the role of magnetic materials in organisms, it is first necessary to examine what is meant by the various types of magnetic behavior of materials.

The magnetic properties of materials are dominated by the electron spin motion. In quantum mechanical terms, electrons may assume two possible spin states: spin $+1/2$ or spin $-1/2$. These may also be referred to as ''spin up'' and ''spin down.'' The Pauli exclusion principle states that no two electrons may occupy the same energy state in an atom. This means that no two electrons may have the same set of values for the quantum numbers as they would then be indistinguishable. As electrons are added, they fill up each possible state in a given shell before filling the shell associated with the next higher energy state. The filling of the shells is governed by Schrödinger's wave equation and the quantum numbers.

Electrons are added to subshells in parallel spin configurations first according to Hund's rule. If all electrons are paired, there is no ''spin'' magnetic moment. These materials are still magnetic though, because of the electron's orbital motion. In most materials of biological origin, however, electron spin motion is cancelled, allowing electron orbital motion to dominate.

The spin structure of the transition series elements (iron in particular) is most important for the magnetic properties of biological materials. This is due to the presence of uncompensated spins in the 3d orbital, which gives rise to a spin magnetic moment. The spin moment is much stronger than the orbital moment and is aligned parallel to an applied field.

All materials, including biological materials, fall into one of the three categories of magnetic materials based on the spin and orbital motion of electrons: (1) diamagnetic, (2) paramagnetic, and (3) ferromagnetic.

4.2 Diamagnetic Materials

Diamagnets are materials in which all electron spins are paired (i.e., there are no uncompensated spins). Therefore, the magnetic properties of diamagnets are determined by the electron orbital motion.

According to Faraday's law, in the presence of an applied magnetic field there is an electric field induced that is acting on the orbiting electron. The induced electric field produces a torque on the electron, which gives the electron extra angular momentum. This extra angular momentum produces a magnetic moment, the sign of which is negative (i.e., antiparallel to the induced or applied magnetic field). Therefore, diamagnetic materials are repelled in magnetic fields (they have weak, negative magnetic susceptibility).

4.3 Paramagnetic Materials

Paramagnetic materials are those in which individual atoms, ions, or molecules have some number of uncompensated spins and thus a permanent net spin magnetic moment. As we have stated before, the spin moment is much larger than the orbital moment, so we would therefore expect that the behavior of paramagnetic materials when placed in a magnetic field will be governed by the behavior of the spin magnetic moments. This is indeed the case.

When paramagnetic substances are placed in an external magnetic field, the uncompensated spin moments tend to align, to some degree, parallel to the applied field direction (Figure 4.1). The magnetic energies involved in this alignment are relatively

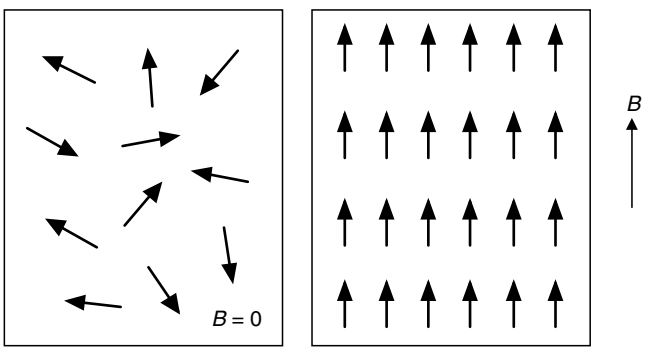

FIGURE 4.1
Orientation of spins in a paramagnet in the absence of a magnetic field ($B = 0$; left) and in the presence of a strong magnetic field (right)

small, and the energy associated with thermal agitation tends to work against the alignment, having a randomizing effect. The degree of alignment of the uncompensated spins with the applied magnetic field depends, therefore, on the strength of the field (the stronger the field, the greater the degree of alignment up to very high fields) and the temperature (the hotter the material, the lower the degree of alignment in the same applied field).

Since the spin moments in paramagnetic materials align with the applied field in this classical model, they add to it, so that the net effect is that these materials are attracted to a magnetic field (and they have a positive magnetic susceptibility). The linear temperature dependence of the magnetic susceptibility in paramagnetic materials was worked out by Pierre Curie and is known as Curie's law:

$$M/H = \chi = C/T$$

where M is the magnetization, H is the applied magnetic field, χ is the magnetic susceptibility, T is the temperature, and C is the Curie constant and is related to the magnetic properties of the material.

In paramagnetic materials, the individual dipole spin moments of the ions may be thought of as noninteracting (in other words, the magnetic moment of one atom has no effect on its neighboring atoms in the material). Because of the noninteraction of the magnetic moments, this fairly weak effect (paramagnetism) is lost upon removal of the external field. Therefore, when a paramagnetic material is not in an external magnetic field, the net magnetic moment in the material is zero because of the randomizing effects of thermal agitation.

4.4 Ferromagnetic Materials

As in paramagnets, in ferromagnetic materials, there are also uncompensated spins; however, these spins are coupled, giving rise to strong magnetic effects. Ferromagnetism may be thought of as a ''group phenomenon,'' where groups of spin moments act in concert, whereas paramagnetism may be thought of as an ''individual phenomenon,'' where the moment of one atom has little or no effect on the moment of neighboring atoms.

In ferromagnetic materials, as in paramagnets, the magnetic susceptibility is positive, and these materials acquire a positive magnetization when placed in an applied field because of alignment of the spin moments in the material with the field. Unlike paramagnets, however, the net magnetization is not lost upon removal of the field (as long as the material is below a certain temperature, which will be discussed in a moment), and the induced moment in the material may be very strong (Figure 4.2). This is to say that ferromagnetic materials exhibit ''hysteresis.''

The mechanism responsible for coupling of the spin magnetic moments in neighboring atoms in a material is due to quantum mechanical phenomena and is governed by the Pauli exclusion principle. The uncompensated spins in individual atoms of a ferromagnetic material may couple either directly (direct exchange) or through an intermediate anion—usually oxygen (superexchange). In ferromagnetic materials, this gives rise to a net magnetic moment because of the coupling of spins in a preferred orientation. Keep in mind that this coupling is quantum mechanical in nature and not purely due to magnetic forces acting between uncompensated spins in neighboring atoms.

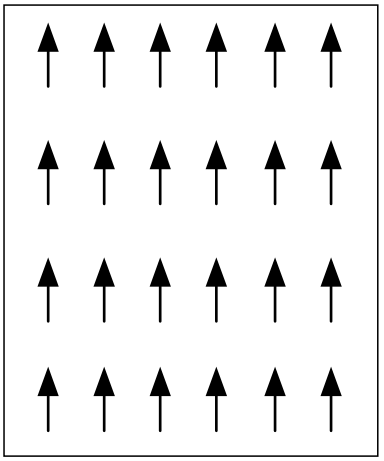

FIGURE 4.2
In ferromagnets, all spins are coupled and aligned, even in the absence of an applied field. This is the origin of remanent magnetization (i.e., hysteresis) in materials.

There are also special cases of ferromagnetism in which neighboring spins are coupled, but not necessarily in the same direction. We will examine two of these cases, antiferromagnetism and ferrimagnetism, as they are important to biological materials, though there are others.

4.4.1 Antiferromagnetism

For some ferromagnetic materials, the exchange coupling between neighboring lattice elements is such that the spins are aligned opposite to each other. This is called antiferromagnetism, and the exchange coupling arises from super exchange according to the Pauli exclusion principle and Hund's rule (Figure 4.3).

In this case the spin moments will still align themselves to an external applied field, only some will be parallel to the applied field and those exchange coupled to them will be antiparallel. This would normally give rise to a material with no net magnetic moment if for every spin up, it was coupled to a spin down. This is not, however, always the case. In some materials, there is a canted antiferromagnetic spin structure (Figure 4.3) or lattice defects and frustrated surface spins (in very fine particles), which can give rise to a net moment in the absence of an applied field.

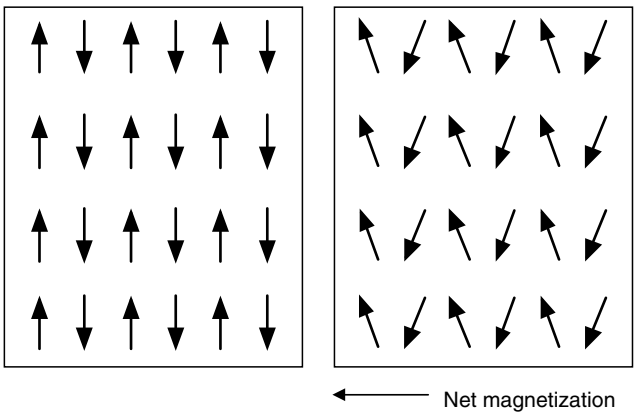

FIGURE 4.3
Pure antiferromagnetic behavior in which spins are coupled antiparallel to each other (left) and an antiferromagnet with a canted spin structure that gives rise to a net magnetization even in the absence of an applied field (right).

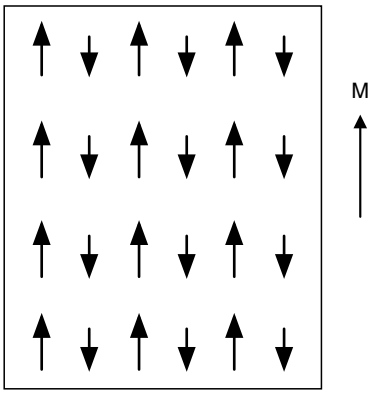

FIGURE 4.4
Electron spin configuration for a ferrimagnet. M = magnetization.

4.4.2 Ferrimagnetism

In addition to antiferromagnetic materials, it is also possible for the neighboring lattice subunits to have unequal numbers of uncompensated electrons coupled antiparallel to each other. This is the case for magnetite (Fe_3O_4), which contains both Fe^{2+} and Fe^{3+} in its lattice structure. The unequal distribution of the two neighboring iron ions gives rise to a net moment (again, even in the absence of an applied field) since one sublattice will have a magnetic moment of greater magnitude than the other, as shown in Figure 4.4. This type of material is called ferrimagnetic.

4.4.3 Temperature Dependence of Ferromagnetism

Since ferromagnetism results from the interaction of atomic moments in materials, there is an exchange energy associated with coupling of the spin moments. At room temperature, this exchange energy is much greater than the energy due to randomizing thermal effects (kT). If thermal energy exceeds the spin coupling (exchange) energy, the coupling breaks down, and the material behaves as a paramagnet. This temperature is dependent on the material and is called the Curie temperature (or, in the case of antiferromagnetic materials, the Néel temperature) (Figure 4.5).

Finally, materials that are superparamagnetic are generally very small (on the order of nanometers), and the electron spins may be coupled either parallel (ferromagnet) or

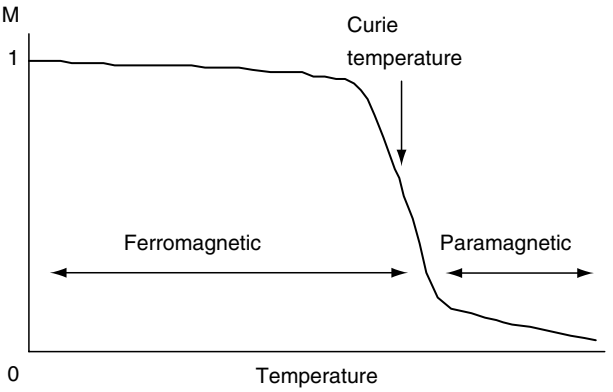

FIGURE 4.5
Magnetization as a function of temperature for a ferromagnet. Above the Curie temperature, spin coupling breaks down, and the material behaves as a paramagnet.

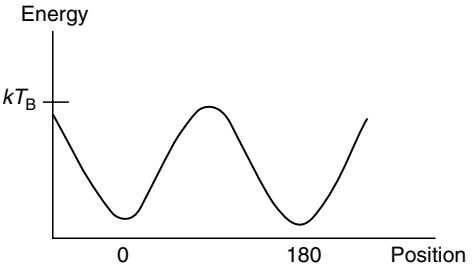

FIGURE 4.6
Schematic of the energy barriers in a superparamagnet. If thermal energy is above a given temperature—the blocking temperature (T_B)—the spins will be able to very rapidly flip between 0° and 180° along the easy axis of magnetization. If the particle becomes larger or the temperature is lowered, the height of the energy barrier constrains the orientation of the electron spins to one or the other of the easy axis energy wells.

antiparallel (ferri- or antiferromagnet). In the case of these materials, however, thermal considerations are dominant. Superparamagnetic materials are named as such because thermal energy causes them to behave—even though this is a special class of ferromagnetism—like a paramagnet. The difference is that, because of coupling of the spin moments, thermal energy causes the spins to flip rapidly as a group rather than individually, as is the case for paramagnetism. On a macroscopic level, the behavior of the two is very similar, except at low temperatures when the thermal energy is sufficiently reduced.

If the superparamagnetic particles are placed in an applied field, the energy of the field will cause the spins to align themselves parallel to it, just as with a normal ferromagnet or paramagnet (the degree of alignment depending on the strength of the field and the temperature—as with paramagnets). If the field is taken away, thermal fluctuation causes a ''relaxation'' of the spins, and they begin to flip rapidly between parallel and antiparallel orientations along the easy axis of magnetization (determined by magnetocrystalline or shape anisotropy). This has the effect of causing the material to appear paramagnetic when the magnetization is examined on timescales longer than the flipping frequency (generally $\sim 10^{-9}$ s). The remanent magnetization (which is the magnetization left in the material after removal of the field) decays with time according to the equation:

$$\tau = f_0 \exp\left(\frac{\nu M_s H_c}{2kT}\right)$$

where τ = relaxation time, f_0 = lattice vibration frequency, ν = grain volume, M_s = spontaneous magnetization, H_c = coercivity, k = Boltzmann's constant, and T = temperature.

The relaxation time depends on the height of the energy barrier—which is a function of grain volume and the magnetic properties of the material—and the amount of thermal energy (kT) required to overcome it (Figure 4.6). Using this equation, it is possible to calculate grain volumes above which the magnetization becomes stable or ''blocked'' (i.e., decays over very long periods of time at a given temperature).

4.5 Biological Magnets

For most biological materials, the magnetic permeability is close to that of free space (i.e., diamagnetic), which implies that there is no direct interaction with the magnetic component of electromagnetic fields at low field strengths. However, this is not the case for all biological materials.

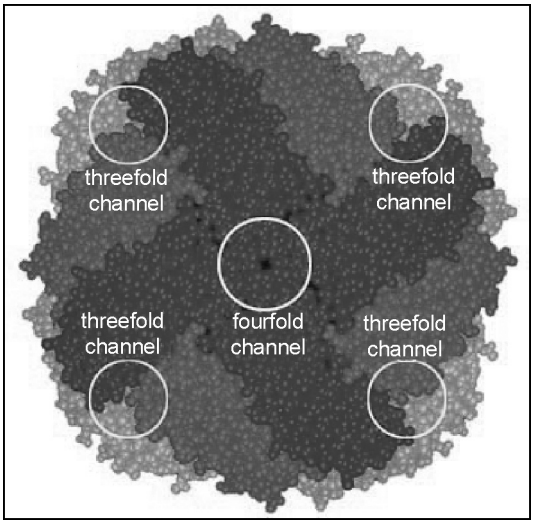

FIGURE 4.7 (See color insert following page 380.) Model of the ferritin protein showing the peptide subunits and iron transport channels. (From www.chemistry.wustl.edu/~edudev/LabTutorials/Ferritin/FerritinTutorial.html. With permission.)

Most magnetic (paramagnetic and ferromagnetic) materials in organisms are compounds of iron—and in particular, iron oxides. Virtually all organisms require iron to function normally. This is mainly due to its redox activity, which allows it to play an important role in energetic biochemical reactions. In organisms, iron is stored as the mineral ferrihydrite ($5Fe_2O_3 \cdot 9H_2O$) within the iron storage protein ferritin. It consists of a 12-nm hollow spherical protein shell made up of 24 subunits (Figure 4.7). The core of ferritin protein is 8 nm in diameter, and it can hold up to 4500 iron atoms in the form of ferrihydrite. Iron is transported into and out of the core through three- and fourfold channels in the shell. During transport, highly toxic Fe(II) is oxidized to Fe(III) for storage as ferrihydrite (Harrison and Arosio, 1996). The specific iron biochemistry of ferritin is complex and is not completely understood (e.g., Yang et al., 1998; Zhao et al., 2001).

Ferrihydrite is a superparamagnetic antiferromagnet at body temperature, and as such, its magnetic properties are potentially important for understanding the environmental consequences of electromagnetic field exposure, including exposure to strong fields within magnetic resonance imaging (MRI) scanners. In fact, the development of pulse sequences for MRI of ferritin is leading to novel ways of assessing iron concentrations in the liver and examining iron associated with neurodegenerative disorders such as Alzheimer's and Parkinson's diseases (Clarke and St. Pierre, 2000; Bartzokis et al., 2004; St. Pierre et al., 2004, 2005). These techniques rely on the magnetic fields generated by ferritin to produce contrast in ferrihydrite-rich tissue in much the same way as synthetic superparamagnetic iron oxide contrast agents do (for a review, see Pankhurst et al., 2003).

In addition to ferrihydrite in ferritin, in 1992 Joseph Kirschvink's group at the California Institute of Technology discovered that biogenic magnetite is produced in the human brain (Kirschvink et al., 1992). Later work demonstrated that this magnetic iron biomineral is present in several organs in the human body, including the heart, liver, and spleen (Schultheiss-Grassi et al., 1997).

Magnetite (Fe_3O_4)—a ferromagnetic iron oxide—is also known as lodestone and is a mineral more commonly associated with sedimentary rocks and volcanics. However, it is also found in many organisms. Probably, the most well-known example is the magnetotactic bacterium. These bacteria use chains of single-domain, biogenic magnetite arranged in chains in order to sense the geomagnetic field and use it for navigation—much like a

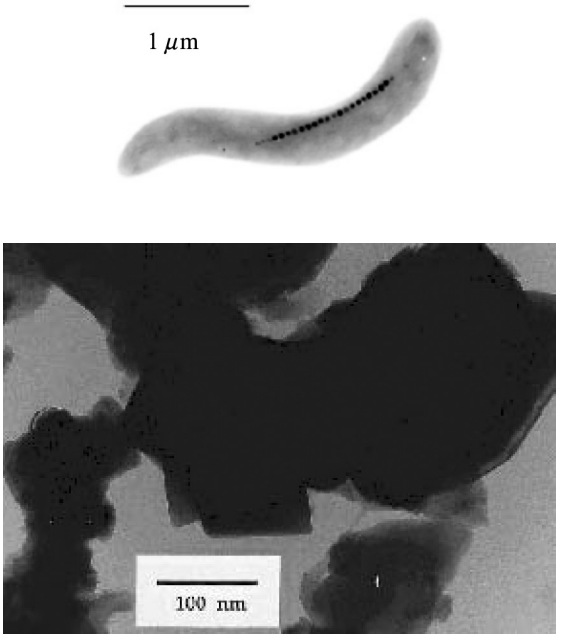

FIGURE 4.8
Transmission electron micrograph of the magnetotactic bacterium MS-1 (top). (From www.calpoly.edu/~rfrankel/mtbphoto.html) Biogenic magnetite extracted from the human hippocampus (bottom). (From Schultheiss-Grassi, PP, R Wessiken, and J Dobson (1999) *Biochim. Biophys. Acta* 1426: 212–216. With permission.)

compass needle (Blakemore, 1975) (Figure 4.8). Although the mechanism by which these organisms produce perfect magnetite crystals is not well understood, it has recently been shown that the process appears to be mediated by specific proteins (Arakaki et al., 2003). Since Blakemore's early discovery, magnetite has been found in a wide variety of animals from bacteria to humans, and in some cases, as with magnetotactic bacteria, it appears to be used for navigation (e.g., Walker and Bitterman, 1989; Walker et al., 1997; Wiltschko and Wiltschko, 2002; for a review, see Kirschvink and Hagadorn, 2000).

Although by 1992, magnetite was known to occur in many organisms, the discovery of biogenic magnetite in the human brain proved controversial. Further work in this area confirmed and extended Krischvink's results, examining not only the occurrence of magnetite in the brain but also its potential role in neurophysiological processes (Dunn et al., 1995; Dobson and Grassi, 1996; Schultheiss-Grassi and Dobson, 1999; Dobson 2001, 2002, 2004; Hautot et al., 2003; Collingwood et al., 2005) (Figure 4.8).

One area of research where the presence of biogenic magnetite in the brain may provide answers to some controversial questions is in the examination of potential mechanisms for the interaction of environmental electromagnetic fields with humans. Two theoretical models have been proposed to demonstrate how biogenic magnetite could act as a transducer of both low-frequency magnetic fields and radio frequency (RF) fields emitted from mobile phones and base stations (Kirschvink, 1992, 1996; Dobson and St. Pierre, 1996). These models rely on the fact that magnetite will couple strongly to the magnetic fields from electrical devices and, either through ferromagnetic resonance effects or through mechanical effects on membrane ion channels, can disrupt the normal functioning of cells in the brain.

Early tests of these models indicate that low-frequency, pulsed magnetic fields from mobile phones may have an influence on cellular activity (including cell death), whereas effects due to ferromagnetic resonance in RF fields are less clear (Cranfield et al., 2003a,b). In addition, magnetite contamination and the presence of biogenic magnetite in model organisms have also been highlighted as potential confounders that could influence the results of studies on the effects of environmental magnetic fields on organisms (Kobayashi and Kirschvink, 1995; Cranfield et al., 2004).

Although magnetite and ferrihydrite are two of the most ubiquitous magnetic materials in organisms, they are not the only ones. Greigite (Fe_7S_8) is a ferrimagnetic iron sulfide found in some iron-reducing bacteria (Posfai et al., 1998). It has a strong magnetic moment similar to magnetite and is thought to be produced as a by-product of iron reduction. Hematite (Fe_2O_3) and wüstite-like (FeO) iron phases also have recently been found within human ferritin (Quintana et al., 2004). And hemosiderin (FeOOH) is a goethite-like iron oxyhydroxide that is antiferromagnetic and is found primarily in pathogenic liver tissue (St. Pierre et al., 1998). In addition to these ferromagnetic materials, other ions and iron compounds, such as hemoglobin, are paramagnetic.

4.6 Magnetic Iron Compounds Related to Pathogenesis

Though iron is an important component of normally functioning organisms, in some cases, it can also be toxic. Because of its redox potential, Fe(II) generally has the potential to do more damage than oxidized Fe(III). For this reason, iron is primarily stored as Fe(III) within ferritin in organisms.

Disruption of the body's normal mechanisms for iron storage can lead to iron overload diseases such as hemochromatosis and β-thalassemia and the deposition of significant amounts of magnetic iron compounds (St. Pierre et al., 1998; Chua-anusorn et al., 2000). These diseases result in the formation of significant iron deposits, predominantly in the liver, which consist mainly of the iron biomineral hemosiderin (FeOOH). Hemosiderin is antiferromagnetic, but can occur as large particles in the body. As with ferrihydrite, both these antiferromagnets contain only Fe(III) and as such have a relatively weak magnetic moment primarily due to lattice defects and, for very fine particles, to frustrated spins on the particle's surface. As mentioned earlier, the presence of these magnetic iron compounds is being exploited for the development of noninvasive MRI monitoring of liver iron in order to track the effectiveness of chelating compounds that are used to treat these diseases (Clarke and St. Pierre, 2000; St. Pierre et al., 2004, 2005). In the brain, disruption of normal iron metabolism results from either disease or trauma and can often lead to pathogenesis (Beard et al., 1993). The accumulation of excess iron is known to induce epileptic activity, primarily as a result of intracranial bleeding due to head trauma. The model of iron-induced epilepsy was first introduced by Willmore et al. (1978), and the electrophysiological responses have been characterized in many studies since then (e.g., Ueda and Willmore, 2000; Engstrom et al., 2001). More recently, evidence shows that iron overload diseases may even predispose a person to epilepsy (Ikeda, 2001).

Although the initial seizure response to trauma and excess iron is relatively swift (Ueda et al., 1998), the long-term consequences of intracranial bleeding on the formation of various magnetic iron compounds in the brain are unclear. Little is known about the formation of iron compounds in the brain of epileptic patients, other than that there appears to be a relationship with an increase in iron (e.g., Willmore et al., 1978; Ueda and

Willmore, 2000; Engstrom et al., 2001). This increase may lead to increased iron loading in the ferritin core or the sequestration of free iron in another form, which could have significant consequences for disease progression. A preliminary correlation between magnetite particle packing geometry and epileptogenic tissue has been demonstrated; however, there is as yet no indication of an increase in magnetite biomineralization associated with temporal lobe epilepsy (Schultheiss-Grassi and Dobson, 1999).

The association of abnormal accumulations of iron with neurodegenerative disorders such as Alzheimer's, Parkinson's, and Huntington's diseases has been known for over 50 y (Goodman, 1953). Although this relationship has been studied extensively, it is not yet clear which iron compounds are present and what their role in these diseases is; however, evidence is mounting that there are likely synergistic mechanisms related to iron and amyloid-β (Aβ, the principal component of Alzheimer's plaques) and other disease-related proteins (e.g., Sayre et al., 2000; Rottkamp et al., 2001; Atamna and Frey, 2004]. Recent work seems to confirm that iron plays a role in disease progression as iron chelators appear to have neuroprotective effects in rat models of Parkinson's disease (Ben Shachar et al., 2004).

Various forms of iron may play a significant role in the biochemical processes that lead to the progression of neurodegenerative diseases. Although there is much speculation on that role, the primary mechanism is thought to be the result of oxidative stress—the generation of free radicals via the Fenton reaction (Connor and Menzies, 1995; Markesbery, 1997; Koppenol, 2001). Recently, Floor (2000) demonstrated the connection between high levels of iron in the basal ganglia and oxidative stress in Parkinson's patients. A disruption of iron metabolism and increased iron in the same region of the brain also has been implicated in Alzheimer's and Huntington's diseases (Bartzokis and Tishler, 2000). Furthermore, iron accumulation has been associated with microgliosis and correlated with increased damage to the CA1 region of the hippocampus via iron–zinc interactions in models of neurodegenerative diseases (Shoham and Youdim, 2000).

It should be noted, however, that some results have shown that the presence of oxidized nucleosides in neurons does not appear to be related to senile plaque material or neurofibrillary tangles in Alzheimer's (Nunomura et al., 1999). In some cases, free radical damage has even been reported to be reduced by Aβ deposition because of the inhibitory role of Aβ-related Zn^{2+} in H_2O_2-mediated toxicity (Cuajungco et al., 2000; Nunomura et al., 2000). More recently, it has been noted that in transgenic mouse models of Alzheimer's, neurogenesis was related to increased deposition of Aβ (Jankowsky et al., 2003). It has been postulated that this may be due to a possible neuroprotective role of Aβ in binding excess redox active iron, which is deposited because of the increased need for iron during neurogenesis (Dobson and Batich, 2004).

Recently, state-of-the-art superconducting quantum interference device (SQUID) magnetometry, nuclear forward scattering, and synchrotron x-ray fluorescence imaging have been employed to evaluate which specific iron compounds are present in these diseases and to map them to structures in the tissue (Hautot et al., 2003; Collingwood et al., 2005; Mikhailova et al., 2005). Early results of these studies indicate that several magnetic iron compounds are associated with these diseases—ferrihydrite (from ferritin), biogenic magnetite, α-iron, and hemosiderin. These results represent a major step toward our understanding of the origin and role of magnetic iron compounds in these diseases.

The role of the various magnetic materials in many organisms, particularly in humans, is only just beginning to be unraveled. After more than two decades of research on magnetic biominerals, it is clear that in many cases they play an important role in biological processes and may provide us with insights into mechanisms of interaction of environmental electromagnetic fields and organisms.

Interaction of Direct Current and Extremely Low-Frequency Electric Fields with Biological Materials and Systems

Frank S. Barnes

CONTENTS

5.1 Introduction

The fact that electrical currents can affect the behavior of biological systems has been known for more than 2000 years. Electric shocks have been used to treat a wide variety of ailments since the eighteenth century. However, our knowledge of how these fields and the resulting currents influence biological systems is surprisingly incomplete. Electrical signals are clearly important in the control of biological processes and in carrying information from one part of the body to another. Nerve cells propagate electrical signals from sensors of pressure, temperature, light, sound, etc., to the brain and return control signals to muscles and other tissue. Yet, if we choose to stimulate these processes with external electrical inputs, we have a relatively limited understanding of how a given electrical signal will affect various biological organs; what the safe limits of exposure are (particularly overextended periods of time); and how electrical signals are carried across cell membranes, are propagated along nerves, or affect growth processes and cell division.

The purpose of this review is to bring together some of the physical concepts that underlie the interaction between electric fields and biological materials with the objective of providing background for determining safe levels of exposure and new applications for the use of electricity in therapy. This is the first step in a long chain of events that lead from externally applied electric field forces to significant biological changes. An objective of this chapter is to provide a background for some of the other chapters that cover both possible health effects and some therapeutic applications of electric and magnetic fields.

The approach that will be taken is to start with Maxwell's equations and couple them to the bulk electric and magnetic properties of the materials. These equations allow us to calculate the values of the electric and magnetic fields as a function of time and space given the values for the dielectric constant and the conductivity. The techniques for the solution of these equations for a wide variety of biological systems are covered in Chapter 10 in this volume by J. Lin and P. Bemardi and for imaging see Chapter 12 in this volume by W.T. Joines, O.H. Liu and G. Ybarra. From the solutions of these equations for the electric and magnetic fields, the conservation of energy, and charge, expressions can be obtained for the current density and other parameters of interest.

Next, the force equations are used to develop equations for the conductivity and the dielectric constant. This section is organized to begin at the lowest level of complexity by examining some of the forces that are exerted on charged particles in fluids, and it then proceeds to some of the effects of electric fields on chemical reaction rates and membranes. At the next level of complexity, some effects of externally applied electric fields on currents through membranes and membrane nonlinearities are described. Some effects of high-level fields and electroporation are described in Chapter 9 in *BMA* by Weaver and Chizmadzhev [112]. This is followed by a discussion of some long-term adaptive processes and secondary effects of current flow due to heating and by a description of a few effects on whole animals. This information is presented with the objective of specifying the general level or intensity of fields, currents, and temperatures where one can expect to observe a given class of biological responses. Much more data are presented in Chapter 3 in *BMA* by Anderson et al. [113]. The next section contains data on the levels of typical naturally occurring and man-made fields. This section also includes a comparison of some externally applied fields, fundamental noise levels, and signals generated in the body. J. Weaver and M. Bier present a more complete treatment of some of the noise sources in biological cells in Chapter 7 in this volume.

5.2 Maxwell's Equations and the Properties of Materials

Maxwell's equations can be written in both differential and integral form, and solutions to them under a variety of boundary conditions are extensively covered in Chapter 10 in this volume by James C. Lin and Paolo Bernardi. In differential form they are given by [1]

$$\vec{\nabla} \times \vec{H} = \vec{J} + \frac{\partial \vec{d}}{\partial t} \tag{5.1}$$

$$\vec{\nabla} \times \vec{E} = -\frac{\partial \vec{B}}{\partial t} \tag{5.2}$$

$$\vec{d} = \varepsilon_0 \vec{E} + \vec{p} \tag{5.3}$$

$$\vec{B} = \mu_0 \vec{H} + \vec{M}_B \tag{5.4}$$

where $\vec{H}$ is the magnetic field, $\vec{J}$ is the current density, $\vec{d}$ is the displacement vector, t is time, $\vec{E}$ is the electric field, $\vec{\nabla}$ is the partial differential operator, del, $\vec{B}$ is the magnetic flux density, ε_0 is the dielectric constant for free space, $\vec{p}$ is the electrical polarization per unit volume, μ_0 is the magnetic permeability in vacuum, and $\vec{M}_B$ is the magnetic polarization per unit volume. It is often convenient to expand the electrical polarization in a power series:

$$\vec{p} = \vec{p}_0 + \varepsilon_0 X_e \vec{E} + \varepsilon_0 X_2 \vec{E}^2 + \cdots \tag{5.5}$$

where $\vec{p}_0$ is the permanent polarization, X_e is the linear electric susceptibility, and X_2 is the quadratic coefficient. X_2 is significant for nonlinear optics and very large values of the electric field. For most of the exposure conditions described in this volume it is convenient to express the induced polarization in terms of the dielectric constant ε

$$\varepsilon = \varepsilon_0 (1 + X_e) \tag{5.6}$$

Note that in anisotropic materials, both ε and X_e may be tensors and complex numbers. The imaginary part of ε is associated with the loss or dissipation of energy by the bound charges. The solutions to Maxwell's equations for $\vec{E}$ and $\vec{B}$ are given for a variety of boundary conditions and under the assumption that values for $\vec{J}$, $\vec{p}$, and $\vec{M}_B$ are known (given in Chapter 10 in this volume by James C. Lin and Paolo Bernardi). These fields, in turn, determine the forces on the components of the biological material.

5.3 Physics of the Interactions of Electric Fields with Biological Materials

Biological systems consist of complex physical subsystems. In an attempt to understand them, we will start at the most elementary level. Perhaps the simplest level—which is already surprisingly complicated—is the effect of electric fields on biological fluids. These fluids contain a large number of components, including ions, polar molecules such as water, proteins, lipids, hormones, and colloidal particles. Current flow in these fluids is given by the sum of the drift and diffusion currents for each component. At low current densities the system is linear; however, at moderate to high current densities nonlinearities are observed [2]. In addition, the fields can change the orientation of molecules with dipole moments, induce dipoles by distorting electron orbits, and change the relative positions of some of the atoms within the molecule. This, in turn, leads to changes in the dielectric constant. The next level of complexity involves the interaction of the fields with membranes that behave like porous solids for fields applied perpendicularly to their surface and like viscous liquids for fields in the plane of the membrane [3,4]. Membranes are inhomogenous so that different portions of them may be affected differently by the perturbing fields. Additionally, membranes are involved in active chemical reactions that change their porosity to various ions selectively. Both electrical potentials and chemical signals may change the membranes' conductivity by orders of magnitude and transmit signals across membranes. The next level of complexity occurs in the interactions between

the biological fluids and the membranes in the presence of electric fields. Electric fields affect the selective transport of ions or molecules through the membrane. They change the buildup of charged ion layers at the surface and change the way new molecules are incorporated into the membrane or are bound to its surface. The result of changes in the transport of molecules or ions across cell membranes is changes in the performance of the cells and, in turn, of the organs of which they are a part. They can also lead to changes in the rate of exchange of electrons between molecules in the membrane and ions or molecules in the fluid [5]. For example, a biasing electric voltage across a pacemaker cell in the heart will change its firing rate and thus the pumping rate of the heart.

The fundamental law describing the forces on charged particles is given by

$$\vec{F} = q(\vec{E} + \vec{v} \times \vec{B}) \tag{5.7}$$

where $\vec{F}$ is the force, q is the charge on the particle, and $\vec{v}$ is the velocity of the particle. $\vec{E}$ and $\vec{B}$ are coupled by Maxwell's equations so that a time-varying magnetic field generates an $\vec{E}$ field and vice versa. This force may lead to ion currents and changes in the orientation of dipoles in molecules, and it may also lead to transitions between energy levels, to shifts in their spacing and induced dipole moments, $\vec{P}$. Additionally, if nonlinearities or time-varying impedances are present, alternating current (AC) fields can be rectified to produce direct current (DC), frequencies at the second and higher harmonics, and sum and difference frequencies with biological or molecular oscillations. Direct magnetic field effects may occur through the term $\vec{v} \times \vec{B}$. For example, for a Na^+ moving at a thermal velocity of 4×10^2 m/sec in the earth's magnetic field of about 5×10^{-5} T, this term has a magnitude of 2×10^{-2} V/m, and the force is at right angles to the field and the velocity.

In addition to the forces on charged particles, electric fields can induce forces on polarizable atoms, molecules, ions, and molecules with dipole moments. To first order these forces are described by

$$\vec{F}_{\mathrm{d}} = (\vec{P}_0 \cdot \vec{\nabla})\vec{E} \tag{5.8}$$

$$\vec{F}_{\mathrm{L}} = \boldsymbol{\alpha} V(\vec{E} \cdot \vec{\nabla})\vec{E} \tag{5.9}$$

where $\vec{F}_{\mathrm{d}}$ is the force on a molecule with a permanent dipole moment $\vec{P}_0$, and $\vec{\nabla}\vec{E}$ is the gradient of the electric field. $\vec{F}_{\mathrm{L}}$ is the force on a molecule with an induced dipole moment $\vec{P}_{\mathrm{i}} = \boldsymbol{\alpha} V\vec{E}$, where α is the tensor polarizability and V is the volume [6]. Note that biological materials are highly inhomogenous and that there are large electric field gradients at the boundaries between the fluids and membranes. Additionally, for induced dipole moments, when the sign of the dipole reverses with an alternating field the force along the gradient of the field can be in a constant direction.

The current flow $\vec{J}_{\mathrm{i}}$ of a given molecule or ion, in molecules or ions per second per meter square, has both drift and diffusion components that may be given by

$$\vec{J}_{\mathrm{i}} = N_{\mathrm{i}}\mu\vec{F} + qD\vec{\nabla}N_{\mathrm{i}} \tag{5.10}$$

where N_{i} is the ion concentration, μ is the mobility in seconds per kilogram, D is the diffusion constant in meter square per second, and $\vec{\nabla}N_{\mathrm{i}}$ is the gradient of the concentration. For charged particles, the force has two components [7]:

$$\vec{F} = q\vec{E} + (\vec{M} \cdot \vec{\nabla}\vec{E}) \tag{5.11}$$

where $\vec{M}$ is the sum of the permanent and induced dipole moments.

The drift portion of the ion currents takes the form

$$\vec{J} = \sum q_i N_i \mu_i \vec{E} + \sum N_i \mu_i (\vec{M} \cdot \vec{\nabla}) \vec{E} \tag{5.12}$$

The conductivity $\sigma = \sum q_i N_i \mu_i$, and N_i is the concentration of each ion, μ_i is the mobility, and $\vec{M}_i$ is the dipole moment. Table 5.1 shows some typical values of mobility.

The conductivity of biological fluids such as blood, which contains cells, is in the vicinity of $\sigma = 0.6\,\mathrm{S/m}$, while for physiological saline it is approximately $1.4\,\mathrm{S/m}$. For more detailed material on the conductivities and dielectric constants of biological materials, see Chapter 3 in this volume by C. Gabriel. If the fluid channels between cells are relatively thick and the fluids are relatively good conductors, the channels tend to short circuit the voltages that might otherwise appear across membranes that typically have conductivities at least a thousand times smaller.

The total dielectric constant for a material includes the sum of the induced polarizabilities of the components and interaction terms between them. It is sometimes useful to think of the dielectric constant as a way of describing the fraction of the electric field that is shorted out by the bound charges. This can be shown by considering an ideal parallel plate capacitor where the outside plates are separated by a distance l. The capacity for these plates is given by

$$C_0 = \frac{\varepsilon_0 A}{l} \tag{5.13}$$

If an ideal thin metal plate of thickness w is inserted halfway between these plates, then the resulting capacity is given by

$$C = \frac{C_0}{(1 - w/l)} = \frac{\varepsilon A}{l} \tag{5.14}$$

The corresponding dielectric constant is given by

$$\varepsilon = \frac{\varepsilon_0}{(1 - w/l)} \tag{5.15}$$

In this example it is apparent that as the fraction of the field that is shorted out by the metal plate of thickness w increases, so does the effective dielectric constant. The electrons or ions forming an induced dipole moment can be thought of as doing the same thing. If there is a significant time lag for the movement of the charge, the effective value of w is reduced. The very large values of the dielectric constants of some tissues at low-frequencies can be thought of as the resulting motion of ions that are trapped inside highly

TABLE 5.1

Typical Values of Biological Ionic Mobilities

Particles	Mobilities	Ions	Mobilities
Proteins	$\mu = 10^{-10}$ to $10^{-8}\ \mathrm{m^2/V\,sec}$	Ca^{2+}	$\mu = 6.2 \times 10^{-8}\ \mathrm{m^2/V\,sec}$
Na^+	$\mu = 5.2 \times 10^{-8}\ \mathrm{m^2/V\,sec}$	Mg^+	$\mu = 5.4 \times 10^{-8}\ \mathrm{m^2/V\,sec}$
K^+	$\mu = 7.6 \times 10^{-8}\ \mathrm{m^2/V\,sec}$	Cr^+	$\mu = 1.9 \times 10^{-8}\ \mathrm{m^2/V\,sec}$

resistive membranes. At higher frequencies, the ions can no longer move fast enough to fully charge the surfaces of the membranes, and the effective dielectric constant for the tissue decreases. If energy is absorbed in inducing the dipole moments, then the dielectric constant becomes a complex number.

The forces applied by an electric field superimpose a drift velocity on the much larger random thermal velocity in the opposite directions for positively and negatively charged particles. These forces can lead to a redistribution of ions or molecules as a result of the differential mobilities and to an increase in the concentration of ions at interfaces. The average drift velocity $\vec{v}$ for a charged particle is given by

$$\vec{v} = \mu_i \vec{E} \tag{5.16}$$

The separation of molecules as a result of the different velocities in a DC electric field is known as electrophoresis and is frequently used to identify large molecules or charged colloidal particles [8]. The separation of particles in an AC field gradient is known as dielectrophoresis [5].

For a spherical particle in a homogenous insulating fluid the mobility μ_i is given by

$$\mu_i = q/6\pi\eta a \tag{5.17}$$

provided that the particle is significantly larger than the background particles of the fluid, where η is the viscosity of the fluid and a is the radius of the particle. In a conducting medium, counterions, or ions with a charge opposite to that of the particle, and molecules with dipole moments are attracted to it. They change the effective radius of the particle and then partially shield its charge. Additionally, small counterions may flow in the direction opposite to the particle motion, exerting a viscous drag. The theory for motion of a rigid sphere through a conducting liquid is complicated if all these effects are taken into account. Often some of the parameters, including the charge on the sphere, are not measurable. However, a relatively simple expression for the electrophoretic mobility is often used:

$$\mu_i = \frac{\varepsilon_i \zeta}{4\pi\eta} \tag{5.18}$$

where ε_i and η are the dielectric permittivity and the viscosity of the fluid (in kg/m sec), respectively, and ζ is the electrical potential drop from the particle surface across the bound fluid to the interface where the liquid begins to flow under the shear stress. Stated another way the ''zeta potential,'' ζ, is the potential at the surface boundary between the stationary fluid and the liquid that is moving with the particle. It should be noted that ζ is less than the total potential ψ across the charge double layer surrounding the charged particle. Also, note that water molecules bind to the ions, increase the effective diameter, and reduce the effective charge. This, in turn, makes the mobility less than that which might be expected at first from the atomic size and Stokes' law.

In a uniform AC field a charged particle oscillates about its mean position, and the electrical energy added to the solution is largely converted to heat. If there is a gradient in the field, as is to be expected in biological materials that are highly inhomogenous, then the gradient of the field can lead to a net charge displacement if the fields are large enough to lead to nonlinearities in the mobility or induced dipole moments. For large $\vec{E}$ the velocity saturates and mobility varies as

$$\mu_i = \frac{\mu_0'}{\left|\vec{E}\right|} \tag{5.19}$$

and Equation 5.16 yields

$$|\vec{v}| = \mu_0'$$

Most biological systems are highly inhomogenous, and the induced currents will vary rapidly in space. For the case of an induced dipole moment and an ideal dielectric sphere with a permittivity ε_2 and a conductivity $\sigma_2 = 0$ in an ideal dielectric fluid with a dielectric permittivity ε_1 and a conductivity $\sigma_1 = 0$ and a nonuniform electric field prior to inserting the sphere, the force

$$\vec{F}_{\mathbf{L}} = \boldsymbol{\alpha} V(\vec{E} \cdot \vec{\nabla})\vec{E} = 4\pi a^2 \varepsilon_1 \left\{ \frac{\varepsilon_2 - \varepsilon_1}{\varepsilon_2 + 2\varepsilon_1} \right\} \{(\vec{E}_1 \cdot \vec{\nabla})\vec{E}_1\} \tag{5.20}$$

where $\vec{E}_1$ is the field in the fluid prior to insertion of the sphere. Written another way

$$\vec{F}_{\mathrm{L}} = (3/2)V\varepsilon_1 \left\{ \frac{\varepsilon_2 - \varepsilon_1}{\varepsilon_2 + 2\varepsilon_1} \right\} \vec{\nabla} \left| \vec{E}_1 \right|^2 \tag{5.21}$$

If we assume that the viscous drag on a spherical particle is given by Stokes' law, then

$$\vec{F}_{\mathrm{d}} = 6\pi a \eta \vec{v} \tag{5.22}$$

and the mobility μ_{i} is given by

$$\mu_{\mathrm{i}} = (2a^2/3\eta)\varepsilon_1 \left\{ \frac{\varepsilon_2 - \varepsilon_1}{\varepsilon_2 + 2\varepsilon_1} \right\} \vec{\nabla}\vec{E}_1 \tag{5.23}$$

Dielectrophoresis may also be used for identifying molecules, and a more general treatment of the forces needs to take into account the conductivity or a complex dielectric constant for both the fluid and the particle [9].

For particles with dipole moments to change their distribution under the influence of an electric field gradient the force $\vec{F}$ must be large enough to overcome other forces. One of these forces that frequently must be overcome is due to osmotic pressure or diffusion. The osmotic pressure can be thought of as the force per unit area arising from diffusion or the random motion of the particles and is given by

$$\Pi = N_{\mathrm{i}} kT \tag{5.24}$$

where k is Boltzmann's constant and T is the absolute temperature [10]. The average differential force on a particle is proportional to the gradient of the osmotic pressure and is given by

$$\vec{F}_{\mathrm{os}} = -\frac{1}{N_{\mathrm{i}}} \vec{\nabla}\Pi = \frac{kT\vec{\nabla}N_{\mathrm{i}}}{N_{\mathrm{i}} - k\vec{\nabla}T} \tag{5.25}$$

If we consider the case of a spherical volume with a radial concentration gradient at constant temperature, the force is given by

$$\vec{F}_{\mathrm{os}} = -kT \frac{\Delta N_{\mathrm{i}}}{N_{\mathrm{i}}} \cdot \frac{r_0}{\Delta r} \tag{5.26}$$

where r_0 is the unit vector, ΔN_i is the incremental change in concentration, and Δr is the incremental change in distance. The maximum change is given by

$$\frac{\Delta N_i}{N_i} = 1 \tag{5.27}$$

when the presence or absence of a particle occurs at a distance $\Delta r = 2a$, where a is the particle radius. In this case, we get the maximum force

$$\left|\vec{F}_{os(max)}\right| = -\frac{kT}{2a} \tag{5.28}$$

To get an idea of the size of these forces, consider a particle of fat with $a = 1\,\mu m$ in water. The maximum osmotic pressure at $T = 300\,K$ is $|\vec{F}_{os(max)}| = 2 \times 10^{-13}\,N$. The dielectric constant for water is approximately $\varepsilon_1 = 80\varepsilon_0$ and for a fat particle, $\varepsilon_2 = 2\varepsilon_0$, where $\varepsilon_0 = 8.854 \times 10^{-12}\,F/m$. To get a dielectric force greater than the maximum osmotic force, we need a value of $\vec{\nabla} \mid \vec{E}_1 \mid^2 > 10^{12}\,V^2/m^3$. This is given approximately by a voltage of 100 V across a 5 mm gap when the $\vec{E}$ field goes from zero to a peak value of $5 \times 10^4\,V/m$ over the same gap. For a particle with a single charge in a uniform field, we would need a field of $E = 1.3 \times 10^4\,V/m$ to get an equal force.

The electric current densities generated by a concentration gradient are given by

$$\vec{J}_d = -qD\vec{\nabla}N_i \tag{5.29}$$

where D is the diffusion constant and is given by

$$D = \upsilon kT \tag{5.30}$$

where $\boldsymbol{\upsilon}$ is the hydrodynamic mobility with the dimensions of velocity/force and D has the dimensions of meter square per second. For rigid spherical particles of radius a, where $a \gg a_{H_2O}$, the Einstein–Stokes equation gives

$$D = \frac{kT}{6\pi\eta a} \tag{5.31}$$

This is only a first-order approximation because D varies slightly with concentration, departure of the molecule from a spherical shape, and other factors. η is the viscosity (in kg/m sec).

It is sometimes of interest to estimate the ratio of the drift to the diffusion current in order to estimate the level of the applied fields or the applied field gradients that lead to biological changes. This ratio is approximately given by [6]

$$\frac{\vec{J}_{i,diffusion}}{\vec{J}_{i,drift}} = \left(\frac{kT}{F_i}\right)\cdot\left(\frac{\Delta N_i}{N_i}\right) \tag{5.32}$$

where $\vec{F}_i$ is the force on the particle due to both the charge on the particle and the gradient of the field on the dipole moment. If we now assume that the maximum change in N_i goes from N_i in the solution to 0 at the membrane surface over a distance of the diameter of the

molecule of N_i and that this is the same distance over which the field goes from the field in the fluid to the field in the membrane, then

$$\frac{\vec{J}_{i,\text{diffusion}}}{\vec{J}_{i,\text{drift}}} = \frac{kT}{W_i} \tag{5.33}$$

where W_i is the energy acquired by the particle moving through the field and its gradient. At room temperature the thermal energy $kT \cong 0.026\,\text{eV}$. A voltage drop from an externally applied source across the membrane liquid boundary on the order of $2 \times 10^{-3}\,\text{V}$ would be required in order to make the drift current significant with respect to the total diffusion current under these assumptions. One way in which smaller drift currents and smaller voltages could be significant is if the ions with low velocities perpendicular to the membrane are the most important in binding to the membrane. Slow molecules stay close to the membrane for longer times, and these molecules are most affected by the applied forces [6].

For different boundary conditions the results will be quite different. If, for example, the boundary was nearly perfectly reflective, then the concentration gradient would be nearly 0, and so would the net diffusion current. Additionally, the gradient in the concentration may occur over a larger distance than the gradient of the electric field. At steady state the concentration at the membrane can be expected to increase until the diffusion current and the drift current balance each other so that the net current is equal to the rate at which the molecules are bound to the membrane or pass through it.

There are four forces that may become important when considering the interaction between two particles in a fluid. These are the osmotic diffusion force, the electrostatic force, the van der Waals force, and the hydration force [9]. These forces may all become important in considering the interaction between particles or bilipid membranes in an aqueous fluid. Electrostatic or coulomb forces between particles of like charge are repulsive. Because the charged particles attract free ions of the opposite sign—which produces a double layer—they are effectively shielded or are screened by the charged ions of the opposite sign when immersed in a conducting fluid. This force decays exponentially or

$$\vec{F}_c = \vec{F}_0 \exp - \frac{r}{\lambda_d} \tag{5.34}$$

where λ_d is known as the Debye screening length [11]

$$\lambda_d = \left[\frac{2q^2 n}{\varepsilon kT}\right]^{1/2} \tag{5.35}$$

where n is the density of the ion species doing the shielding, q is the charge and ε is the dielectric constant of the solution, k is Boltzmann's constant, and T is the absolute temperature. For physiological saline solution of approximately 0.14 M, the Debye length is approximately 0.83 nm [12]. Thus, the electrostatic forces are important only at very short ranges.

For like particles, the forces are repulsive at short distances (0.1 to 0.2 nm) and attractive at longer ranges. These forces may be thought of as being generated by transient electromagnetic fields because of fluctuations that occur as a result of thermal agitation or natural uncertainties in the position and momentum of the electrons and atomic nuclei.

If one thinks of the local transient fluctuations in terms of the underlying contributions from oscillations at all possible frequencies, it can be shown that the strength of the contributions due to the local fluctuations at a given frequency is proportional to the absorption of light at that frequency by the material. For an individual atom these forces fall off very rapidly as $1/r^7$ [7]. However, when they are integrated over the surface of a membrane, which is thick compared to an atomic layer, they are correlated over many atoms, as the wavelengths are large compared to an atomic diameter.

A calculation of these fields has been performed starting with quantum field theory [13]. The size of the forces and the rate at which they decay depend on the distance between the membranes and the difference of the bulk polarizability of the membrane and the aqueous gap in a complex way. All frequencies of the charge fluctuations contribute to the attraction, and each gives rise to a different relationship between energy and the distance of separation. For many simple cases and for a classical explanation of these forces and potential distributions, see Ref. [14].

One case of interest is for two membranes with a distance d_w across the aqueous gap between them. The thickness of the membranes is assumed to be large compared to the spacing. The force between these two membranes is approximately given by

$$\vec{F}_w = \frac{H}{6d_w^3} \tag{5.36}$$

where H is the Hamaker coefficient [9]. In a typical situation, the distances over which the van der Waals force is estimated to be important extend out to separations of 10 to 20 nm, which is substantially longer than a Debye length or the rate of falloff for the electrostatic or coulomb forces. The hydration forces are repulsive forces that rise extremely rapidly as the membrane bilayers approach a separation distance of approximately an atomic spacing. Experimentally, these forces can be expressed in the form [9]

$$\vec{F}_H = \vec{F}_{H_0} \exp -d_w/\Lambda \tag{5.37}$$

where Λ is a scaling constant. In the case of egg phosphomonoesterase bilayers, $\vec{F}_{H_0} \approx 7 \times 10^{-13}$ N/m^2 and $\Lambda = 0.256$ nm. This force may be important up to about 2 nm and is assumed to come about as a consequence of the work required to remove water from the hydrophilic surface of the membrane.

Long-range attractive forces have been observed between hydrophobic surfaces [15]. These forces are proportional to the contact area and may be the orders of magnitude larger than the van der Waals forces. They may also have decay lengths up to 25 nm. The magnitude and range of these forces depends on the temperature and the length of the surfactant's chain, and they appear only when the chains are in a fixed ordered state. These forces appear to be generated when the fields emanating from one surface induce a larger polarization in the other surface layer than in the intervening medium. Some relatively complex expressions for these attractive forces have been worked out [14].

These forces are important in self-organizing processes such as protein folding, ligand binding to hydrophobic receptor sites, and transformation of membrane structures. All these forces act over relatively short ranges in typical biological fluids. The ion densities are so large that charge neutrality is maintained everywhere except very close to charged surfaces.

The effect of an electric field, or an electric field gradient in a fluid, is to superimpose a small drift velocity on a relatively large random thermal velocity. For example, if

we apply an electric field of 10^3 V/m to a Na^+ ion, we would expect a drift velocity of about 5×10^{-5} m/sec as compared to a thermal velocity of about 4×10^2 m/sec. For a protein, we would expect a drift velocity approximately one tenth of the speed of the Na^+ ion, although at higher fields. This means that if we are to transport proteins or other small charged particles over appreciable distances of a few millimeters, we can expect it to take minutes or longer. In the case of bacteria, we have measured drift velocities of 10^{-6} m/sec at 100 Hz in fields of about 10^4 V/m and gradients of 5×10^6 V/m^2 or about 0.2% of the velocity of the Na ions in the same field [5,16].

This drift velocity may also change chemical reaction rates if the rate is limited by the availability of one of the charged components. Consider the case of a chemical reaction that takes place in a homogenous fluid if the chemical reaction has the form

$$(A) + (B) \underset{k_2}{\overset{k_1}{\leftrightarrows}} (C) \tag{5.38}$$

where (A) and (B) are the concentrations of the two input chemical reactants and k_1 is the reaction rate for A + B to C and k_2 is the rate for the back reaction of C to A and B. If we simplify the system and let k_2 be small, then the initial reaction rate may take the form [17,18]

$$k_1 = k(A)^n(B)^m \tag{5.39}$$

where n and m refer to the order of the reaction. In order to find the values of n and m, one can make the concentration of one of the reactants small so that it takes the form

$$k_1 = k(A_0)^n(B)^m \tag{5.40}$$

where we have made the concentration (A_0) large enough so that it is approximately constant, and the changes in the reaction rate can be measured by varying (B). The value of k is given by

$$k = zpe^{-\Psi/RT} \tag{5.41}$$

where z is the collision frequency and p is the steric factor, which is <1 and reflects the fact that not all collisions occur with the right orientation of the molecules to react. ψ is the activation energy, R is the gas constant, and T is the absolute temperature. For many cases the collision frequency is proportional to the current density, and thus there are terms that are proportional to both the drift and the diffusion currents. For example, consider the case of an enzyme reaction on a charged substrate such as a biological membrane. The total current density for a given ion in the fluid incident on the membrane is given by Equation 5.10.

If the chemical reaction rate is limited by the number of ions arriving at the membrane surface with enough energy to overcome the barrier required to initiate the reaction, then a DC drift current may either add to or subtract from the diffusion current. If the field direction is such that it prevents the ion from reaching the surface, then the chemical reaction is blocked. If the direction is reversed, the rate can grow exponentially. These changes in chemical reaction rates with the direction of the electric field are likely to be responsible for changes in the growth and reabsorption of neuritis [19]. They are also likely to be involved in the mobility of cells such as leukocytes and fibroblasts [20,21].

An AC drift current will add to the diffusion current. For the AC fields, the drift current can be thought of as increasing the volume covered by a particle executing a random walk as a result of Brownian motion. Thus, in an asymmetrical environment an electric field oscillating in the x direction may increase the number of particles that will strike the $y-z$ plane in a fixed period of time and can increase the chemical reaction rate for a catalytic reaction at the $y-z$ plane. Seto and Hsieh show that AC fields as low as 5 V/m can increase enzyme reaction rates by a factor of 5 [22]. For a 60 Hz field, the peak-to-peak displacement for Ca^{2+} resulting from this field is estimated to be about 1.6 nm or about twice the thickness of the Debye layer. AC magnetic fields have also been shown to change the growth rate of corn roots at fields levels of 5×10^{-3} T. It is likely that these fields are inducing significant currents [23].

An additional mechanism by which AC or DC electric or magnetic fields can effect chemical reactions is by shifting the energy level and the distribution of particles in them. DC electric fields can shift the energy level by an amount that is given by the change in the dipole moment, $\Delta\vec{M}$, and in the polarizability, $\Delta\alpha$, associated with the transition. A DC field can either stretch or compress a dipole depending on its orientation with respect to the field, thus increasing or decreasing the energy levels for atoms or molecules with different orientations. It also can modify its rate of rotation, speeding it up when the dipole is pointed in the direction of the field and slowing it down when it is pointed away from the field [24]. In a vacuum the modifications of the rotational states have been worked out from the quantum mechanics for relatively simple molecules and can lead to a relatively complex set of allowed energy states that are a function of the applied field [23]. In a solid or a membrane the energy levels between the states corresponding to the different orientations shift, by different amounts, for each state as a function of the applied field. This is known as the Stark effect [25]. The frequency corresponding to this energy shift with a fixed orientation is given by

$$h\Delta f = -\Delta\vec{M} \cdot \vec{E} - \frac{1}{2}\vec{E} \cdot \Delta\alpha \cdot \vec{E} \tag{5.42}$$

where Δf is the frequency splitting between levels, $\Delta\vec{M}$ is the change in the dipole moment, $\Delta\alpha$ is the change in polarizability, and h is Plank's constant. These terms give the linear and quadratic Stark effects for a transition in a uniaxially oriented system. These energy levels will be inhomogenously broadened by the random orientation of the dipoles with respect to the applied field and by the thermal energy. Since the quantum of energy, hf, at microwave and lower frequencies is very much smaller than a quantum of thermal energy, low-lying energy levels are approximately equally populated. However, higher-energy states may be preferentially excited by chemical reactions or optical photons so that different excited states may contain different populations. These states may be further defined by the magnetic field and separated by a Zeeman splitting. Thus, radio- and low-frequency fields corresponding to energy separation between these states may excite transitions between levels that are separated by the Stark splitting and change the population distribution in these excited states. The transition rate between an excited molecule and its final product depends on the overlap between the energy levels of the two states. Thus, the application of an electric field can shift the energy levels so as to either increase or decrease this overlap and the transition rate. This has been discussed at length in Ref. [23] for the case of Zeeman splitting of the energy levels by a DC magnetic field and free radicals [26]. See also Chapter 6 in this volume by S. Engstrom.

5.4 Biological Amplification

Biological systems are not in a state of thermal equilibrium. In a typical cell, energy is supplied by hydrolysis of an ATP molecule, which leads to the pumping of three sodium ions out of a cell and two potassium ions into the cell. The net result is creation of potential difference between the inside and outside of a cell in the range of 50 to 100 mV so that the interior of the cell is at a negative potential with respect to the external environment [27]. This potential difference can be used to amplify a variety of external signals just as a typical electronic amplifier can use a small AC signal to convert DC energy into a larger AC signal. For example, the input from many dentric junctions can be summed in a pyramidal cell to trigger an action potential that is larger than any of the input signals [28]. The input from a single synaptic junction might change the cell resting potential by 0.5 to 1 mV, and 10 to 20 inputs might be required to fire an action potential of 50 to 100 mV [27]. Additionally, subthreshold inputs can lead to the release of neural transmitters that, in turn, can release from 2 to 10,000 Ca^{2+} ions from internal stores. These neural transmitters may remain bound to the postsynaptic membrane for up to 4 sec and reduce the threshold for the firing of successive pulses [29]. Feedback from the postsynaptic membrane to the presynaptic membrane can further reduce the firing potential for the synaptic junction.

Another mechanism of amplification that may be of interest is the extraction of energy from a high-frequency signal. If a low-frequency electric field is added to a higher-frequency field and is incident on a nonlinear reactance, then the low-frequency signal may be amplified parametrically. This mechanism for amplification is valuable in the optical region for the generation of tunable signal sources and for low-noise microwave amplifiers [1,30]. In a biological system the low-frequency signal might be generated by an ongoing process such as the heart and amplified by mixing with an external signal from a power line field.

An additional mechanism for amplifications is stochastic resonance. Stochastic resonance differs from the foregoing mechanisms of amplification in that the energy is extracted from the noise. Consider, for example, a small, externally applied sinusoidal electric field incident on an ion in a potential well. If the energy acquired from the external signal is not large enough to exceed the potential barrier, the ion stays trapped in the potential well. However, if noise is added to the system, then when the sum of the applied electric field and the noise are large enough to provide enough energy to exceed the height of the potential barrier, the ion may escape the potential well. This happens most frequently at the peaks of the applied electric field so that the signal is amplified at the applied frequency. Gains on the order of 20 to 30 dB and increases in the signal-to-noise ratio of 18 dB have been observed for stochastic resonance amplifiers [31]. For an extensive review of this subject and some application neuronal systems, see Gammaitoni [32]. For a bistable system, such as a pacemaker cell that is driven by both noise and a periodic signal, it has been shown that the signal-to-noise ratio can be enhanced by the addition of noise to a weak periodic signal and that power can be extracted from the noise. A strong periodic signal can be generated at signal-to-noise ratios <1 [31,33]. This phenomenon occurs when two energy states are separated by a barrier, and the probability of a transition increases exponentially with increasing noise power. For periodic signals that are insufficient to cause a transition over the barrier but periodically increase the energy of the particle, the transition rate at the signal frequency first increases with increased noise power up to some maximum. When the noise power is increased above this level, the output signal becomes more random (see also Chapter 9 in this volume by Weaver and Bier).

5.5 Effects of Electric Fields on Cell Membranes

Electric fields play a very important role in the normal biological functioning of membranes. Membranes are complex structures containing lipids, voltage-activated ion channels, and proteins. It would be surprising if externally applied fields did not affect the membrane behavior. First, an electric field exerts a mechanical force on a membrane by means of the force exerted on charges in the Debye layer on either side of it and on charged proteins that may protrude from the lipid bilayer. Note that although as a first approximation the membrane is often modeled as a smooth planar or spherical surface, it is highly inhomogenous, and the charges are sparsely disturbed. Thus, the field on a protein may be widely different from the average field. See Figure 5.1a. and b for a partial indication of a membrane and cell complexity. The effects from fields in the plane of the membrane, where large molecules such as proteins are free to move as in a viscous fluid, are significantly different from the effects of fields in the transverse direction, where the membrane components are bound in a layer typically 5 to 15 nm thick.

The field distribution incident on a particular part of a cell membrane is a function of its geometry, frequency, and the cells around it. As can be seen from the models in Figure 5.1d, a wide variety of environments may exist. The currents that flow through and along the membranes are dependent on the geometry and frequency. A variety of equivalent circuits have been used to model both the impedance of the membrane and the extracellular fluids. The simplest of these are a resistor and capacitor in parallel. At very low-frequencies a collection of cells can be modeled with resistors as indicated in Figure 5.1c.

The interiors of cells are normally negatively biased in relation to the surrounding fluid by 50 to 150 mV, which leads to average transverse electric fields up to tens of millions of volts per meter [34]. The effective membrane resistance (R_m) per unit area takes on values of 0.14 to 15 Ω/m^2 in the transverse direction. This corresponds to resistivities in the range of $\rho_m = 10^7$ to 10^9 Ω m. The relative dielectric constant for the membrane is typically in the range of 2 to 4. Both the surrounding fluid and the interior of a cell have resistivities ρ_f of about 2 Ω m and a relative dielectric constant of 50 to 80. This means that the cell membrane tends to shield the interior of a cell very effectively from externally applied fields at frequencies below a few kilohertz and becomes almost a short circuit in the multimegahertz region of the spectrum. In most cells the interior of the cell contains complex structures that are functions of time as the cell grows and divides. See Figure 5.1b.

Consider the case of an oversimplified hypothetical rectangular cell as shown in Figure 5.1c. At low-frequencies, an external field $\vec{E}$ causes a current density $\vec{J}_f = \vec{E}/\rho_f$ to flow in the external medium, where ρ_f is the resistivity of the fluid. The corresponding voltage drop is $V = \vec{E}L = \vec{J}_f\rho_f L$, which we can consider to be applied to the cell. This voltage is distributed across the cell length as

$$V = [\rho_m 2t + \rho_f(L - 2t)]|J_m| \tag{5.43}$$

where $\vec{J}_m$ is the current density through the cell and ρ_m is the resistivity of the membranes. Typical cell membrane thicknesses are 6 to 10 nm, and typical dimensions are 10 to 150 μm. Setting $L = 100$ μm and

$$\rho_m 2t = 10\,\Omega m^2 \tag{5.44}$$

$$V = (10\,\Omega m^2 + 2 \times 10^{-6}\,\Omega m^2)|J_m| \tag{5.45}$$

(c) Current distribution in a hypothetical rectangular cell. (d) Partition of 60-Hz currents through and around cells for an average current density $J = 10^2$ A/m^2. J_c is the current density between cells, and J_m is the current density through the membrane. (From Wachtel, H., private communication. With permission.)

This shows that essentially all of the transverse voltage drop occurs across the membrane at low-frequencies and the interior of the cell is almost completely shielded from external fields. A more complete theory for long cells that accounts for the internal resistance of the cell is given by Cooper et al. [35]. See also Chapter 11 by Pila [114]. Note that muscles, nerves, and a number of other cells may be much longer than 100 μm and may have dimensions in centimeters. Additionally, blood vessels form long, low-resistance paths that may concentrate currents due to externally applied fields. The anisotropic characteristics of cells are reflected in an anisotropy of the dielectric and conductive properties of tissue, which may give variations of as much as 10 to 1 in conductivity, depending on the direction of measurement relative to cell orientation [36]. A number of fish, including sharks, have been shown to use very long cells and to sum signals in both series and parallel to increase the voltage drop across a sensitive membrane in order to sense fields as low as 10^{-6} V/m [37–39]. The long cell may be thought of as an antenna that concentrates the field across a very thin, voltage-sensitive detector membrane. This membrane appears to have a built-in amplifier that allows detection of signals that are only a little above the natural electrical noise.

Membranes are not just simple linear resistors, but they usually are nonlinear and, in the case of nerve cells, are time varying as well. For a passive membrane in which the membrane potential is primarily determined by the concentration gradient of a single ion such as K^+, the Nernst equation predicts a diode-rectifying characteristic of the form [31]

$$I = I_0\left[\exp\left(\frac{V_m}{\eta V_T}\right) - 1\right] \tag{5.46}$$

where V_T is given by

$$V_T = \frac{kT}{q} = 0.026\,\text{V} \tag{5.47}$$

at $T = 300\,\text{K}$. q is the charge on the electron, V_m is the voltage across the membrane, I_o is the current for ideal back-biased current in amperes, and η is a dimensionless constant. Thus, for currents flowing through a membrane in one direction, the current is nearly constant, whereas for flow in the other direction the currect increases exponentially with voltage. In addition to passive currents, cells also use the energy from metabolic processes for the active transport of ions against the fields established by the concentration gradients. These processes are usually modeled as current sources and described as pumps [31]. A thermodynamic approach to pumping shows that ions can be pumped if they form a compound with a material that can flow through the membrane and that is created on one side of the membrane and destroyed on the other [40]. A large variety of models have been generated to characterize the effects of externally applied fields on the transport of ions through membranes [41–43]. However, the details of the pumping process are not well understood. In addition to ion transport, electrical fields can change the binding of ions or molecules to the membrane surface.

In the case of pacemaker cells, there are also feedback processes that lead to an oscillating membrane potential and a membrane resistance that is a function of time. The current flow for these cells is described empirically by the Hodgkin–Huxley equation [31]. An alternate approach that treats the nerve pulse like a plasma instability has been proposed by Triffet and Green and Vaccaro and Green [44,45]. Na^+ and K^+ currents are the dominant carriers for the propagation of nerve impulses along a cell. It is generally believed that the Na^+ and K^+ currents that flow through the membrane in opposite directions are carried through separate channels. Ca^{2+} ion currents are involved in the activation of at least a portion of the K^+ currents and are voltage gated. By activating the K^+ currents, the Ca^{2+} ions shorten the length of time the cell is depolarized and thus speed up the firing cycle [46]. A statistical approach to the formation of protein channels in the membrane by Baumann and Easton predicts many of the observed characteristics [47–49].

During the firing of a nerve cell, the Na^+ current pulse precedes the K^+ current pulse, which returns the cell to its resting potential [31]. The overall concentration balances are maintained by active ion pumps. Cl^- Mg^{2+}, and possibly OH^- and H^+ ions may also be involved in the current flow across a cell membrane.

The firing of a nerve cell typically involves voltage spikes of $10^{-1}\,\text{V}$ and peak current densities of $1.5\,\text{A/m}^2$. Changes in the firing rate can be induced by the injection of charge through a microelectrode of $<10^{-9}\,\text{A}$ for a few milliseconds. However, in cases where electrodes are used to stimulate muscles or to control epilepsy, the current is injected through a series of cell membrane fluid boundaries at a distance from the controlling nerve fiber. Thus, typical injected currents to produce behavioral changes in cells are in milliamperes, and current densities are $10\,\text{A/m}^2$ or higher.

For fields parallel to the plane of the membrane, it is possible to obtain electrophoresis or a rearrangement of charged particles. This has been shown by Poo in a striking fashion in cultured embryonic *Xenopus* myotomal muscle cells [50,51]. Receptors on the surface of the cell were labeled with a fluorescent dye and allowed to uniformly distribute themselves. Exposures to electric fields of 10^2 to $10^3\,\text{V/m}$ were sufficient to concentrate the

fluorescent-labeled receptors on the side of the anode in about 10 min. After shutting off the field, diffusion returned the dye to its uniform distribution in about 2 h. This corresponds to an in-plane diffusion constant of about $3 \times 10^{-12}\,m^2/sec$. The force on the receptor molecules or particles in the membrane includes not only $q\vec{E}$ but also any viscous drag that may be generated by the flow of ions of the opposite sign moving along the surface in the opposite direction. The direction of motion for a given charged particle seems to depend on whether it has a larger or smaller zeta (ζ) potential than the potential across the charged double layer at the interface between the cell surface and the fluid (see Equation 5.16).

Additional work has shown that the distribution of acetylcholine (ACh) receptors is changed by external fields [48,49]. These receptors are concentrated on the cathode-facing surface of the cell in fields of $10^3\,V/m$ over a period of 30 min by literally rearranging channels already existing in the cell membrane. The concentration or clustering persists for at least 5 h after the field has been turned off, indicating that the clustering is relatively stable. Single-channel patch measurements show both a higher density of ACh channels in the clusters near the cathode and a longer mean duration of the pulses through the transmembrane channels. The length of the current pulse near the anode does not differ from the controls, indicating that the field itself does not have a direct effect on the channel kinetics. The lateral diffusion coefficient, D, of ACh receptors in the plasma membrane of cultured *Xenopus* embryonic muscle cells is estimated to be $2.6 \times 10^{-6}\,m^2/sec$ at 22°C [48,49]. Lateral concentration gradients in lipid monolayers have been shown to be induced by externally applied electric field gradients. For binary mixtures of dihydrocholesterol and dimyristoylphosphatidylcholine, the application of an electric field gradient at pressures below the critical pressure produces a liquid–liquid phase separation in a monolayer that is otherwise homogenous [52]. This separation occurs at field levels on the order of $10^7\,V/m$ and gradients of 10^9 to $10^{11}\,V/m^2$.

5.6 Nonlinear Effects of AC Fields on Cells

5.6.1 Introduction

The application of an AC electric field to nonlinear systems, which can be described by either a nonlinear resistance or capacitance, leads to at least partial rectification of the input signal and the generation of harmonics. If two or more signal frequencies are applied, it also leads to frequency mixing of the form

$$f_o = \pm mf_1 \pm nf_2 \tag{5.48}$$

where f_o is the output frequency, f_1 and f_2 are input frequencies, and m and n are integers. The rectified component of the AC current can, in turn, lead to ion accumulation at interfaces, which results in changes in ion concentration [53,54]. These changes in ion concentration, in turn, can affect biological function. Another important additional effect is the dependence of the dielectric constant on frequency. This leads to changes in the electric field distributions in tissue with frequency. Thus, both the electrophoretic and the dielectrophoretic forces become both size and frequency dependent. A third—possibly important—additional effect is the excitation of frequency-sensitive biological systems in a resonant manner. By driving systems near their resonant frequency, we may change the effective amplitude of the stimulating signal and change the frequency of the nerve cells firing.

In this section we will review the rectification process at the cell membrane in some detail. Additionally, we will show that cell nonlinearities lead to frequency-dependent effects such as injection phase locking of pacemaker cells. We will also briefly examine some problems associated with the exposure of cells to very low, extremely low-frequency (ELF) fields and the application of large ELF fields to biological systems.

5.6.2 Rectification by Cell Membranes

The rectification of currents flowing across membranes has been studied by many authors, beginning with Katz in 1949. Much of this work is referenced by Hayashi and Fishman in their paper on the inward rectifier K^+ channel kinetics [53].

For many passive cell membranes, an approximate relation for the transmembrane current can be derived from the Nernst equation as given in Equation 5.41 [31]. If we apply an AC signal across the membrane of the form $V_M = V_0 + V_1 \cos \omega t$, the resulting current can be approximated for small values of V_M (i.e., $qV_M < \eta kT$) by a Taylor series yielding

$$I = \frac{I_0}{\eta V_T}\left(V_0 + \frac{V_1^2}{4\eta V_T} + V_1 \cos \omega t + \frac{1}{4\eta V_T} V_0 V_1 \cos \omega t + \frac{V_1^2}{4\eta V_T} \cos 2\omega t + \cdots\right) \tag{5.49}$$

It is to be noted that the second term in the expression is the first approximation to the fraction of the applied AC voltage V_1 that yields a DC current component ΔI,

$$\Delta I = \frac{I_0}{4}\left(\frac{V_1}{\eta V_T}\right)^2 \tag{5.50}$$

or an offset voltage V_{DC} given by

$$V_{DC} \approx \frac{I_0}{4}\left(\frac{V_1}{\eta V_T}\right)^2 R_m \tag{5.51}$$

where R_m is the membrane impedance. This predicted voltage offset for an applied AC current has been measured by Montaigne and Pickard [55]. In their experiments, an AC signal was applied to a large plant cell by a strip line, and the measured voltage shift was obtained through microelectrodes located outside the applied AC fields. For an applied AC field of about 0.2 V, they measured a DC offset of 1 to 2 $\times$ 10^{-4} V. For frequencies above 2.5 kHz, the effects of the membrane capacitance must be taken into account, and the effective driving voltage is reduced to

$$(V_1)_{eff} = [\sqrt{2}\, a\sigma_e\, \vec{E}_{1rms}][(\sigma_e + aG)^2 + (a\omega C)^2]^{-1/2} \tag{5.52}$$

where a is the cell radius, σ_e, is the conductivity of the medium $\vec{E}_{1rms}$, is the electric field strength in the medium surrounding the cell, G is the membrane conductance per unit area, ω is the frequency, and C is the membrane capacitance per unit area [56]. This leads to the usual roll-off in the measured DC offset with increasing frequency. Note that the DC effect gets still smaller at higher frequencies (above 1 MHz) because of transit time limitations for ion flow across the membrane [57].

The relaxation times for a typical K^+ channel in an *Aplysia* membrane has been measured to be from 2 to 8 ms [51]. Rectification has also been demonstrated in thin lipid membranes [58]. In these systems, both the conductivity of the membrane and the ion concentration differences across it can be controlled. The Nernst equation was shown

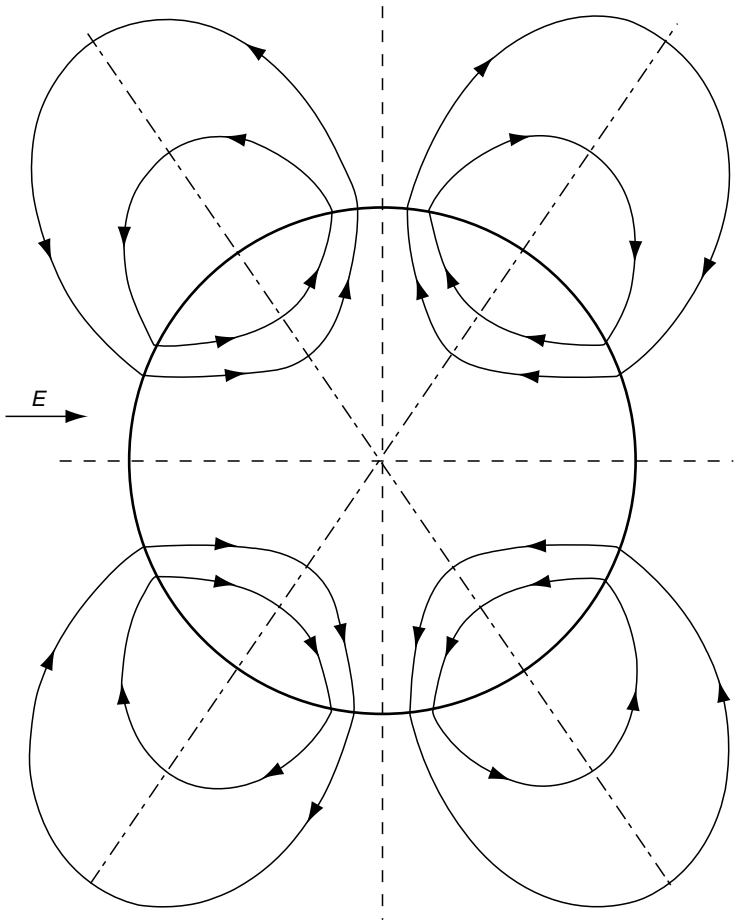

FIGURE 5.2
Induced DC current distribution in a spherical cell. (From Bisceglia and Pinto, I., personal communication, 1984. With permission.)

to apply to the I vs. V curve over a range of voltages from -60 to $+40$ mV. Depending on the ion concentration and membrane doping, the values of η ranged from 1 to 0.25.

A different treatment of the nonlinear response of passive cell membranes to an applied AC field has been carried out by Franceschetti and Pinto and by Casaleggio et al. [59,60]. Both these groups have expanded the Nernst equation in a Volterra series that takes into account memory of the preceding state of the cell. They have also treated the cell in spherical rather than planar geometry. The inclusion of a spherical cell requires that the total current into and out of the cell be equal to zero, and thus loops are formed circulating through the cell membrane (see Figure 5.2). All the theoretical treatments predict a DC component that varies as the square of the input signal V and tends to hyperpolarize the cell or make the interior of the cell more negative.

Cain has considered the effects of an AC field on nonlinearities of the nerve cell by numerical analysis of the Hodgkin–Huxley equation [61].* He applied a voltage

*Bisceglia and Pinto have applied a Volterra series expansion to the Hodgkin–Huxley equations. This approach gives an alternate method to Cain's of computing the current shifts resulting from applied AC signals [62].

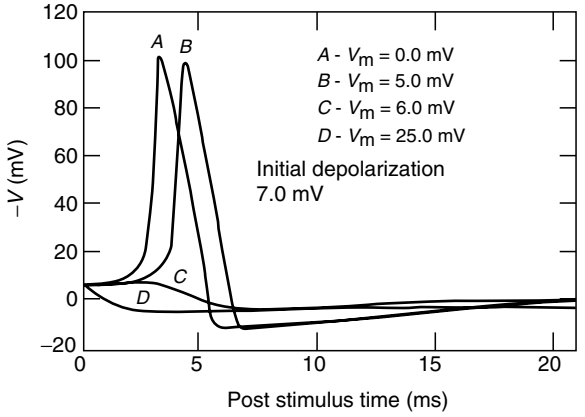

FIGURE 5.3
Computed membrane action potentials in response to an initial membrane depolarization of 7 mV for different values of V_m. Curves are solutions to the Hodgkin–Huxley equations. (From Cain, C.A., *Bioelectromagnetics*, 2, 23, 1981. With permission.)

$$V_m = V_0 + V_1 \cos \omega t[u(t) - u(t - \tau)] \tag{5.53}$$

across the membrane, where $u(t)$ and $u(t - \tau)$ are unit step functions that define an AC pulse of length τ. For the case where the AC frequency is large compared to the reciprocal of the pulse length, if a 7 mV depolarizing pulse is also applied to the membrane, the action potential is obtained as shown in Figure 5.3. Cain has assumed coefficients appropriate to the giant squid axon. Increasing V_1 first delays, and then suppresses, the action potential. If no depolarizing pulse is applied, the predicted changes in g_{Na} and g_K and the deviation V from the resting potential are as shown in Figure 5.4 for a 10 msec AC pulse with $V_1 = 25$ mV. Note that the applied AC frequency is assumed high enough not to be resolved in these figures. From these results, it is clear that AC signals can induce substantial changes in the operating characteristics of nerve cells at moderate to high levels of applied voltage. Although the appropriate coefficients were not measured in order to make a direct comparison between theory and experiments, Wachtel's results on *Aplysia* at frequencies above the lock-in range would appear to support Cain's theoretical predictions [63].

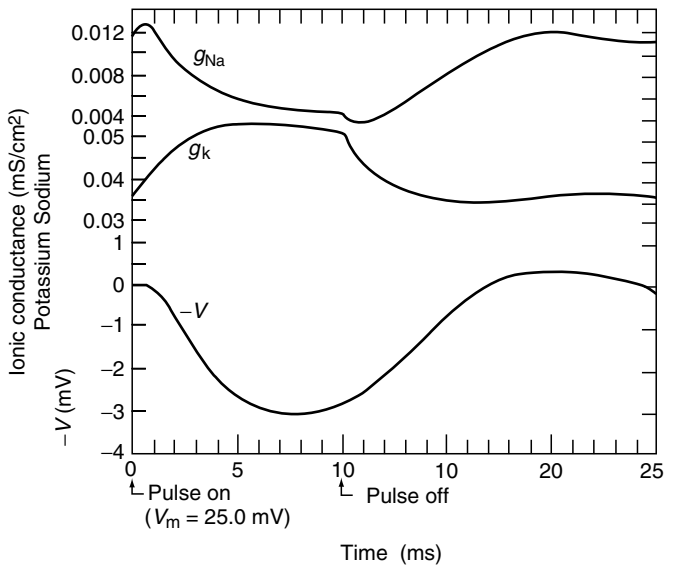

FIGURE 5.4
Response of model axon to a pulsed oscillating component of membrane electric field (10-ms pulse, V_m = 25 mV). The membrane potential and the sodium and potassium conductances are shown. These curves are solutions of the Hodgkin–Huxley equations. (Note: 1 mS/cm^2 = 10 S/m^2.) (From Cain, C.A., *Bioelectromagnetics*, 2, 23, 1981. With permission.)

Wachtel has made a series of measurements that demonstrate the nonlinear characteristics of pacemaker cells from *Aplysia* [61]. First, he measured the current input through a microelectrode that changed the firing rate of the cell. The current threshold for a minimum detectable change was approximately 6×10^{-10} A at frequencies between 0.8 and 1 Hz (see Figure 5.5). The natural firing rate for this cell is about 0.8 Hz, and an increasing current is required to synchronize the cell to the injected signal as the frequency deviates from the natural firing rate. A theory for injection locking of electronic oscillators predicts that the signal required for locking an oscillator to an external signal increases linearly as the difference between the two frequencies $\Delta\omega$ increases [64]. The signal required for lock-in according to this theory is given by

$$I_t \approx |A\Delta\omega|\ I \tag{5.54}$$

where I_t is the injected signal current and I is the peak unperturbed oscillator current. $A = \partial\phi/\partial\omega$ is the rate of change of phase with respect to frequency in the unperturbed oscillator. $\Delta\omega_0$ is equal to the difference between the frequency of the free-running oscillator and the injected signal. This expression is applicable as long as

$$\Delta\omega_0 \leq \frac{2\pi}{\tau} \tag{5.55}$$

where τ is the time constant for adjusting the gain of the circuit. The time constant τ for the *Aplysia* cells varied between 0.1 and 0.5 sec, and this corresponds to a maximum measured lock-in frequency of about 10 Hz. The results in Figure 5.5 show the threshold for one-to-one locking up to about 2 Hz. In the range from 2 to 10 Hz, Wachtel observed a lower threshold for subharmonic locking than one-to-one locking. At frequencies above 80 Hz, he observed a constant shift in the firing rate of the neuron in response to the injected transmembrane AC signal. The natural firing rate would be restored by also injecting a transmembrane DC signal equal in amplitude to about 1% of the peak-to-peak value of the AC current. This DC current was in the depolarizing direction, making the exterior of the cell more negative with respect to the cell cytoplasm to increase the firing rate (i.e., to restore it to its natural value). Apparently, the applied transmembrane AC current was partially rectified so as to hyperpolarize the membrane (making the interior of the cell more negative with respect to the external fluid). The details of how the applied field modifies the ion flow are only partially understood, but one characteristic is an increase in the conductivity for K^+, which increases its flow out of the cell. Wachtel also

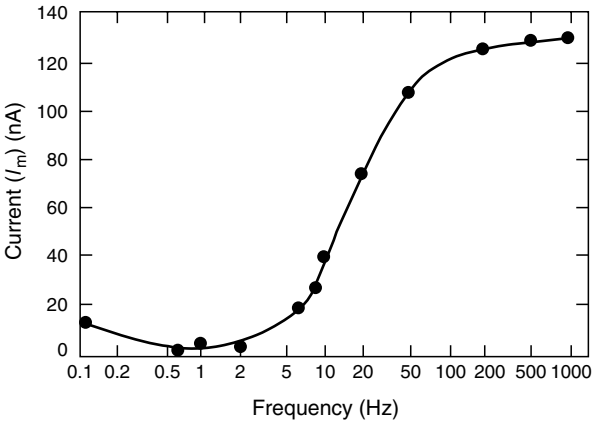

FIGURE 5.5
Intracellular (transmembrane) currents I_m (in nA) needed at different frequencies to produce firing-pattern changes (in a pacemaker neuron). Note that the detectable changes take on different forms at different frequencies. (From Wachtel, H., *Proceedings of the 18th Annual Hansford Life Science Symposium*, Technical Information Center, U.S. Department of Energy, Richland, WA, 132, 1978. With permission.)

injected low-frequency currents into the seawater surrounding the cell preparation through external electrodes [61]. In this case, the minimum current densities flowing in the vicinity of the cell preparation for injection locking were estimated to be about $10^{-2}\,\mathrm{A/m^2}$, and there was about a 30 to 1 variation between the maximum and minimum sensitivities for changes in angle between the applied field and the cells. At frequencies above 100 Hz, a minimum of about $0.35\,\mathrm{A/m^2}$ was necessary to obtain a detectable change in firing rate.

These studies have been extended by Barnes et al., and injection locking at harmonic and subharmonics has been shown to occur. It is suggested that phase locking may provide a mechanism for narrow banding or time averaging so that a weak coherent signal may be distinguished from noise by a cell. In an electronic circuit model we showed we could phase lock an oscillator at signal-to-noise ratios <1 [65]. Extensive modeling of phase locking for a squid axon using two versions of the Hodgkin–Huxley equations has been carried out by Fohlmeister et al. [66]. They show that phase locking can occur for a wide variety of frequencies with AM-modulated signals at injected current densities greater than $0.1\,\mathrm{A/m^2}$ [67]. For natural oscillation frequencies less than the externally applied signal, the system may be treated as a parametric process. For parametric amplification, a phase stability such that

$$\frac{\mathrm{d}\Phi}{\mathrm{d}t} < \Delta\omega - KV_\mathrm{s} \tag{5.56}$$

is required for injection locking of the frequency of oscillation to an external signal, where $\mathrm{d}\Phi/\mathrm{d}t$ is the rate of change of the phase, $\Delta\omega$ is the frequency offset, K is the linear control characteristic in units of $(2\pi\,\mathrm{Hz/V})$ and is closely related to the loop gain, and V_s is the injected signal [68]. Stated in words, this equation requires that the amplified signal, KV_s be large enough to correct for the random frequency fluctuations $\mathrm{d}\Phi/\mathrm{d}t$ generated by the noise for the system to become phase locked to a signal that is displaced by $\Delta\omega$ (see Figure 5.6 for some examples of injection locking of pacemaker cells to an external signal) [65]. An increase in the sensitivity to electromagnetic fields has also been shown in isolated frog hearts for signals that approach the natural resonant frequency or firing rate [69]. In these experiments, the firing rate of the heart was shown to increase as much as 30% when a signal in the vicinity of 10 to 20 V/m was applied through Ringer's solution to the isolated frog hearts at a frequency between 0.5 and 1 Hz. The natural firing rate of these excised hearts started out at approximately 1 Hz and dropped to about 0.5 Hz

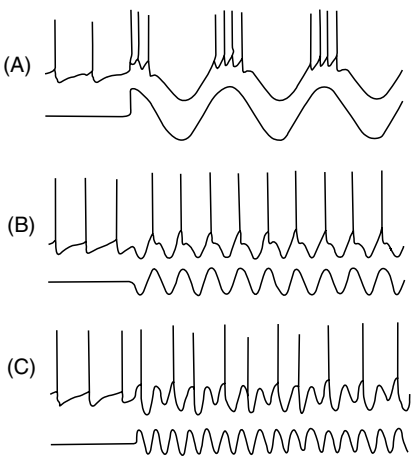

FIGURE 5.6
Examples of several modes of synchrony between an imposed ELF field and neuronal patterns. In each case the ELF current is shown below the transmembrane potential recording. (A) For ELF frequencies well below FR_0, several nerve impulses (spikes) are locked to each ELF half cycle. (B) ELF frequencies slightly above FR_0 are effective in phase locking the rise of neuronal spikes on a one-to-one basis. (C) For ELF frequencies several times greater than FR_0, phase locking can take the form of spikes occurring on alternate cycles (two-for-one synchrony). (From Barnes, F.S., *Bioelectromagn. Suppl.*, 1, 67–85, 1992. With permission.)

over a period of 2 h, where they remained stable for at least 5 h. To get a 30% increase in firing rate at 60 Hz, it was necessary to apply field strengths of 60 to 80 V/m. Thus, we have additional evidence that electric fields with repetition rates near the natural biological signaling frequencies are more likely to induce changes than those of higher frequencies and that signal strengths required for a given shift increase approximately linearly up to some cutoff, as shown in Figure 5.5.

For weak fields, it has been shown that cells can respond differently to signals that are both space and time coherent than they do for signals that look like the background noise. Litovitz et al. have shown that the application of 10 μT magnetic fields at either 55 or 65 Hz doubles the specific activity of ornithine decarboxylase (ODC) in L929 cells if the signals are coherent for periods of 10 sec or longer during the course of a 4 h exposure [70]. The applied signal and the corresponding ODC response as a function of the coherence time are shown in Figure 5.7. The ODC response of the cell can be fitted to an exponential curve of the form

$$(\text{ODC}) = 1 + 1.26\left[1 - \exp\left(\frac{\tau_{\text{coh}}}{\tau_{\text{cell}}}\right)\right] \tag{5.57}$$

where τ_{coh} is the length of the time between shifts in frequency and the introduction of a random phase shift and τ_{cell} is the effective time constant of the cell [70]. τ_{cell} has a value of about 8 sec for these cells. If a spatially coherent noise signal with a power spectral density ranging from 30 to 90 Hz is superimposed on the coherent signal, the increased ODC response decreases with a decreasing signal-to-noise ratio and is less than 10% at a signal-to-noise ratio of 1 [71]. This work has been extended to show that temporally incoherent magnetic fields inhibit 60 Hz-induced changes in the ODC activity of developing chick embryos [72].

For the exposure geometry used in these experiments, the magnetic field induced a corresponding electric field of 4 μV/m. This signal is well below the calculated thermal noise field of 0.02 V/m for a 20 μm cell diameter. The combined results of the experiments cited above indicate that both space and time coherence may be used by cells to separate useful signals from larger natural background noise signals. For example, to get a significant biological response, some threshold number of channels or receptor molecules may need to be activated within a given period of time; this, in turn, requires nearly

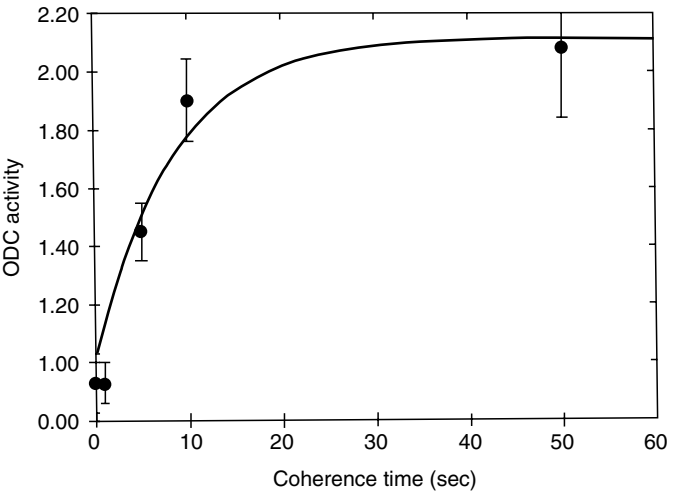

FIGURE 5.7
Plot of the enhancement of ODC activity (exposed/control) as a function of the coherence time, τ_{coh}, of the applied field. The solid line is the best fit to the mathematical function given by Equation 5.44, where τ_{cell} is found to be 8.2 sec. The experimental points shown represent a minimum of six different exposures. (© Academic Press; From Litovitz, T.A., Krause, D., and Mullins, J.M., *Biochem. Biophys. Res. Commun.*, 178, 3, 862, 1991. With permission.)

simultaneous activation over a significant fraction of the cell surface. Similar results have been obtained for developing chick embryos, where weak coherent signals lead to an increased incidence of abnormalities [73]. In this work, Litovitz and his colleagues show an increase in the incidence of abnormalities of approximately a factor of 3 for White Leghorn chicken embryos incubated in periodic magnetic fields with peak field strength of 1 μT (100 Hz repetition rate, 500 μs pulse duration, 2 μs rise, and decay times) when compared with the controls. This increased rate of the incidence of abnormalities was nearly eliminated with the addition of band-filtered noise with a spectrum running from 30 to 100 Hz and a root mean square value of 1 μT. Thus, Litovitz makes a strong case for a requirement of both space and time coherence for biological systems to detect signals below the natural noise environment.

A number of experiments indicate that at least two mechanisms are involved in the effects of low-level time-varying magnetic fields on membrane transport. The first of these is through Faraday's law or the induced electric field, which, in turn, induces electric currents. In these experiments, one would expect to get the same effects by introducing electric fields with electrodes at levels that induce the same current densities. The second group of experiments indicates that the background DC magnetic field is also important and that the combined effects of AC and DC magnetic fields are observed.

The initial experiments by Walleczek and Liburdy showed an enhanced uptake of Ca^{2+} in Con. A-activated rat thymocytes with exposures of 1 h to 60 Hz magnetic fields of 22 mT and induced current densities of 0.16 A/m^2 [74]. In this paper the exposure system consisted of concentric rings on cell culture plates, which, in turn, were placed in a water-cooled solenoid that produced a uniform magnetic field. This was followed by a group of experiments by Liburdy on Ca^{2+} transport across mitogen-activated lymphocyte membranes [75]. In these experiments, both the DC and the AC magnetic fields were controlled so that the DC geomagnetic field and the ambient 60 Hz fields were perpendicular to the exposed and control plates. The results show an increase in the Ca^{2+} influx during the plateau phase of the calcium signaling for Con. A-activated lymphocytes, which was a function of the induced electric field and which could be reproduced by applying the electric fields across the cells with a salt bridge at levels between 0.1 and 0.17 V/m. This corresponds to induced current levels of 0.168 to 0.28 A/m^2 in the fluid surrounding the cells, which had a conductivity, $\sigma = 1.68$ S/m, that is approximately a hundred times larger than the current densities observed around growing cells. Thus, the approximately 20% to 25% increase in the initial Ca^{2+} uptake is the result of a relatively large external current. In other experiments it was also shown that the response is dependent on the age of the animals from which cells are taken [76].

Most other reported experiments have not been done in a way to sort out the differences between possible direct effects of the magnetic fields and the induced electric fields. Yost and Liburdy [77] have also conducted experiments in the same system that show a direct dependence of the calcium uptake on the DC magnetic field.

The experiments by McLeod et al. [78] show both a frequency dependence and a dependence on the electric field strength across the cell membrane. They exposed neonatal bovine fibroblast cells to electric fields in culture through a media bridge. The fibroblasts populated a collagen matrix that enabled the cells to be grown with a dominant orientation and exposed to a well-defined current. An estimate of newly synthesized protein was made by measuring the incorporation of (^{3}H) proline into macromolecules after a 12 h exposure to current densities ranging from 10^{-3} to 10 A/m^2 and frequencies from 0.1 Hz to 1 kHz. The results in Figure 5.8 show an approximately 30% reduction in the ^{3}H counts with current densities as low as 10^{-2} A/m^2. This reduction is interpreted as a reduction in the incorporation of newly synthesized protein into the extracellular matrix rather than as a change in the cell number. The frequency specificity for this threshold is

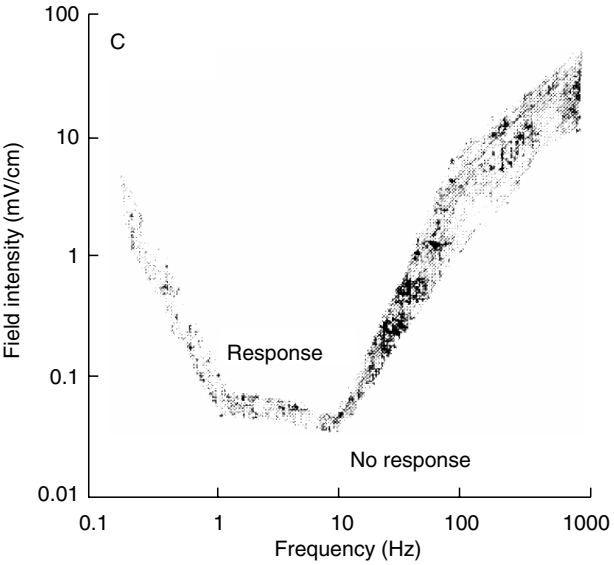

FIGURE 5.8
Minimum field intensity for a detectable response. Summary of results for all tested frequencies and current densities. Current densities were converted to peak field intensities by using the measured media resistivity of 65 Ω cm. The lower boundary of the gray region represents the highest field intensity at which no significant change in extracellular protein accumulation was detected; the upper boundary represents the lowest intensity evoking a statistically significant change ($n = 6$). (From McLeod, K.J., Lee, R.C., and Ehrlich, H.P., *Science*, 136, 1465–1469, 1987.)

shown in Figure 5.8; the peak sensitivity was recorded at $5 \times 10^{-3}\,A/m^2$ and 10 Hz. The corresponding peak electric field intensity was 4.5 mV/m. The fractional change in the (^{3}H) proline was nearly independent of the current density for increases in current density up to two orders of magnitude above $10^{-2}\,A/m^2$. The cell membranes have a resistance many times higher than the resistance of the matrix as a whole. The cells are also asymmetric, with a ratio of major to minor axes of about 7 to 10. Thus, the current through the cell membranes would be expected to be at a maximum when the long axes of the cells are parallel to the applied field. For randomly oriented cells, current densities of $3\,mA/m^2$ produced no significant effect on the rate of proline incorporation. However, when the cells were oriented parallel to the electric field that was estimated at 2 mV/m and 10 Hz, a little more than a 30% reduction was observed. The estimated transmembrane potential was 0.5 μV. With the cell oriented perpendicular to the field, no significant change in proline incorporation was measured at $5\,mA/m^2$.

In addition to the nonlinear conductances associated with Na^+ and K^+ currents, membranes also exhibit nonlinear (i.e., potential dependent) and frequency-dependent capacitances and inductances. It is sometimes useful to think of these effects in terms of a phasor diagram as shown in Figure 5.9, where the electric field vector $\vec{E}$ is rotating at a velocity ω, and ϕ is the phase angle between $\vec{E}$ and the current density $\vec{J}$. If there is, for example, a fixed time delay between the field activation of a current gate and the current flow, then, depending on the frequency, $\vec{J}$ may be in any of the four quadrants and appear capacitive or inductive or even present a negative resistance to an external driving source.

Nonlinear inductive effects seem to be associated with the time delay for the onset of the K^+ currents under excitation in a typical excitable membrane, and they have been studied in the giant squid axon [79]. The nonlinear capacitive effects are difficult to measure at frequencies below a few kilohertz. Extra care needs to be exercised to minimize the series resistance and the end effects of the wire being used to measure the capacitance or inductance. Additionally, corrections must be made in the calculations of the membrane capacitance to take into account the appropriate variations in the frequency response that these terms introduce. However, when this is done, it can be shown that the membrane capacitance has both frequency- and voltage-dependent terms. The capacitance of giant squid axons is shown in Figure 5.10 and Figure 5.11 as a function of frequency and membrane voltage.

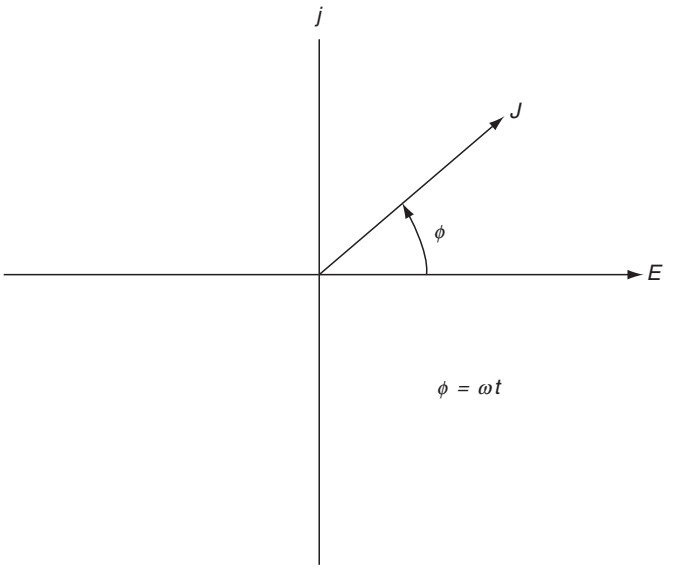

FIGURE 5.9
Steady-state vector characterization of electric fields $\vec{E}$ vs. current density $\vec{J}$ in polar form. ϕ is the phase angle between the sinusoidal electric field $\vec{E}$ and the resulting current density $\vec{J}$.

Variation of the capacitance of these membranes with frequency and amplitude differs from that of a simple bilipid membrane that has nearly constant capacitance. The variation appears to be associated with changes in the conformation of the proteins associated with the Na^+ conductance channels. Nonlinearity in conductance and capacitance can be induced into a bilipid membrane by the addition of Alamethicin. The nonlinear inductance or capacitance may also generate both sum and difference frequencies if two signals are applied. For the case of the single signal, a DC term is added to the current density that is proportional to membrane potential and the square of the applied AC signal [80]. The effects due to nonlinear membrane capacitance thus far observed are small. They

appear likely to be more important in providing an understanding of the possible gating mechanism in membranes than as a mechanism for introducing rectification.

Another form of nonlinearity in the electrical response of cells comes about in what is often described as adaptive processes. For example, we found that repetitive exposures of pacemaker cells (taken from the ganglion of an *Aplysia)* to microwave pulses resulted in a decreasing reduction in the firing rate by successive pulses. This kind of change has also been shown to occur in neurons that have been conditioned with repetitive stimulation. Studies of conditioning have shown decreases in potassium ion conductance through membranes, thus raising the internal potential and enhancing the excitability [81,82]. The decrease in resistance between adjacent cells can occur in two ways. First, the resistance of gap junctions may be reduced by repetitive electrical stimulation, which increases the electrical coupling between the cells by up to 62%. Second, repetitive electrical stimulation can modify the chemical excitatory postsynaptic potential by amounts ranging from 31% to 140% [83]. This change is associated with the movement of protein kinase C from the interior of the cell into the membrane. An accompanying change in Ca^{2+} concentrations and the movement of a second messenger, diacylglycerol, into the membrane reduce the potassium ion flow. This enhanced excitability reduces the voltage or the charge required to initiate an action potential. If charge is transferred efficiently between cells, either actively or passively, cell length is effectively multiplied in the linear model by the number of cells in the chain; this, in turn, reduces the external electric field required to generate a given voltage across a terminating membrane (see Chapter 11 in *BMA* by A. Pilla).

An interesting speculation that is raised by these adaptive processes is whether or not a neural network can be trained to identify a repetitive signal such as 60 Hz in the presence of larger electric fields generated by the surrounding biological material. To test this hypothesis, we programmed a computer to simulate a neural network as shown in Figure 5.12 [65]. Using a backpropagation algorithm to adjust the connecting weights between neurons, a sigmoidal summing junction to model the neurons, and a pseudorandom noise generator,

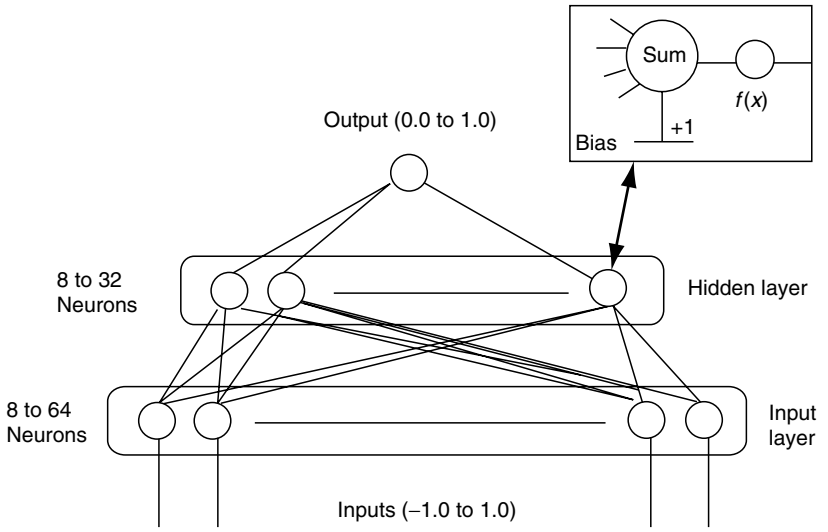

FIGURE 5.12
Backpropagation neural network. (From Barnes, F.S., *Bioelectromagn. Suppl.*, 1, 67–85, 1992. With permission.)

we measured the number of runs required to train the network to recognize a 60 Hz signal with 97% accuracy as a function of the input signal-to-noise ratio. The results in Figure 5.13 show that the training time increased from about 200 runs to about 1400 runs as the signal-to-noise ratio decreased from 1 to 0.001. The way the noise is presented to this network during the training makes a difference. For example, if you want the network to separate 59 Hz from 60 Hz, it helps to tell the network that 59 Hz is noise. This computer network model is clearly too simple to describe a biological nervous

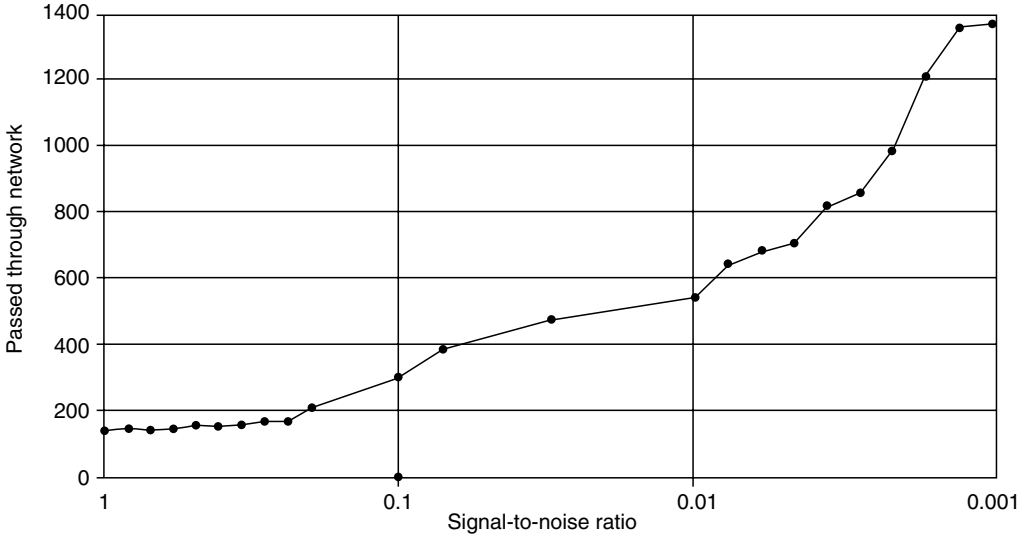

FIGURE 5.13
The learning response of a neural network with 64 input neurons, 8 neurons in the hidden layer, and 1 output neuron to a 60 Hz input signal and a pseudorandom noise signal with a decreasing signal-to-noise ratio. (From Barnes, F.S., *Bioelectromagn. Suppl.*, 1, 67–85, 1992. With permission.)

system, but it may provide a clue to one way in which a collection of cells may be able to respond to weak, externally applied electric fields, but a single cell would not.

5.7 Thermal Effects

One important effect of current flow due to electric fields is heating. The power input to a given volume of material can be expressed by $P' = I^2R$, where I is the total current and R is the resistance of the sample. For many calculations, a more useful expression is given by the power per unit volume or $P = \sigma E^2$, where σ is the conductivity, E is the electric field intensity. (For a more complete treatment of heating, see Chapter 10 and Chapter 12 of *BMA*.) The temperature rise resulting from this heat input is determined by the thermal capacity of the volume and the mechanisms for carrying the heat energy away. Typically, these thermal loss mechanisms include a combination of conduction and convection processes. For short current pulses, the heat dissipation is usually dominated by thermal conduction, and the basic equation for the rate of change of temperature is given by

$$\frac{\partial T}{\partial t} = \frac{P}{\rho' C_p} - \frac{T - T_0}{\tau_c} \tag{5.58}$$

where T is the temperature, T_0 is the initial temperature, t is time, and P is the power supplied per unit volume. ρ' is the density of the material (in kg/m^3), C_p is the specific heat under constant pressure, and τ_c is the thermal relaxation time.

If we consider a homogenous sphere of radius a immersed in an infinite fluid, the thermal conductive relaxation time is approximately given by

$$\tau_c = \frac{a^2}{4\overline{K}} \tag{5.59}$$

where $\overline{K}$ is the thermal diffusivity and is measured in meter square per second [84]. The thermal diffusivity is given by

$$\overline{K} = \frac{K'}{\rho' C_p} \tag{5.60}$$

where K' is the thermal conductivity (in cal/m sec °C), ρ' is the material density (in kg/m^3), and C_p is the thermal capacity (in cal/°C kg). If an applied current pulse is short compared to τ_c, the maximum temperature change is given by

$$\Delta T_{max} = \left(\frac{3}{2\pi e}\right)^{3/2} \frac{\overline{H}}{\rho' C_p a^3} \tag{5.61}$$

where $\overline{H}$ is the total input energy in calories and e is the base of natural logarithms [84]. For current inputs that are long compared to the thermal relaxation time τ_c, the peak temperature is determined by a balance between the input power and the dissipation process controlled by conduction and convection. It is interesting to note that if we assume the thermal properties of water as a first approximation to various kinds of tissue, then τ_c for a sphere with a equal to 1 μm is a little less than 2 μs. Since a sphere has the

smallest surface to volume ratio, Equation 5.60 gives an upper bound on τ_c, and Equation 5.61 gives an upper bound on the peak temperature excursion for small structures and pulses that are short compared to τ_c. Simply stated, it takes high power densities and large differential absorption coefficients to get significant differential temperature rises in small biological structures.

For situations where the volume involved is a cubic millimeter or larger, the thermal time constant is controlled by the amount of blood flowing through the volume. In these cases, temperatures may be more easily measured than calculated since a complicated thermal and electrical boundary value problem would have to be solved to calculate the temperature rise. This is particularly true since the viscosity η and other thermal and electrical parameters such as ρ, C_p, $\overline{K}$, etc. are functions of temperature. For example, C_p for an artificial bilipid membrane is shown in Figure 5.14 [85]. Another example of the importance of change in temperature is the conductivity of saline,

$$\sigma \approx C_1[10^{[(1/T)+\alpha](1/b)}] \times 10^{-4}\,\mathrm{S/m} \tag{5.62}$$

where C_1 is the concentration of NaCl in milligram equivalents per liter, T is the absolute temperature, $\alpha \simeq 6.23 \times 10^{-3}$ degrees^{-1}, and $b \simeq 1.4 \times 10^{-3}$ degrees^{-1} [86]. In the range around 37.5°C, this means that a 5°C change in temperature corresponds to a little less than 9% change in conductivity [86].

Changes in temperature are important, not only because they change transport properties such as viscosity, mobility, and the diffusion coefficient D, but also because they change chemical reaction rates. Typical biochemical reactions can be described by an equation of the form

$$\frac{dS}{dt} = -K'S \tag{5.63}$$

where S is the fraction of the material that has undergone the chemical reaction, t is the time, and K' is the reaction rate [87]. K' is often given by

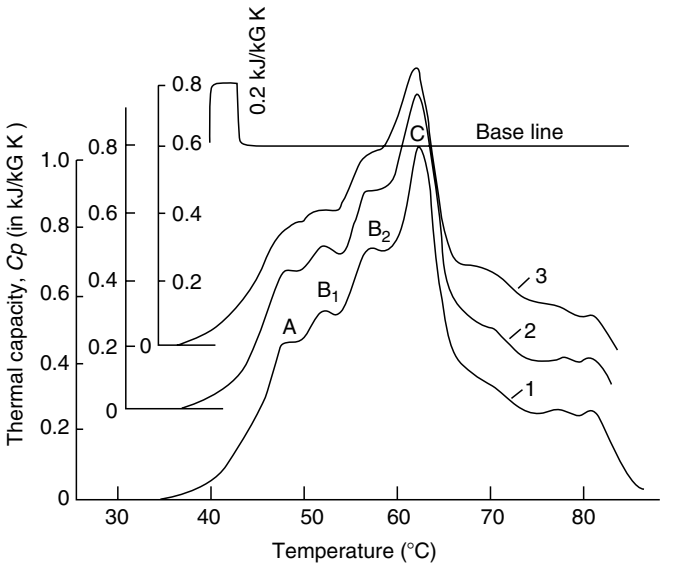

FIGURE 5.14
Differential changes in the heat capacity, C_p, of erythrocyte membranes as a function of temperature in 5 mmol/L sodium phosphate with pH 7.4 and a concentration of 5 mg protein per milliliter. The changes at A, B, B_2, and C correspond to changes in the structure of the membrane with temperature and are irreversible. Curve 1: intact membranes. Curve 2: irradiated at 330 mHz for 5 min (SAR 9 W/kg). Curve 3: irradiated at 300 mHz for 30 min (SAR W/kg). (From Shuyrou, V.L., Zhodan, G.G., and Akorv, I.G., Academy of Science, Institute of Biophysics, Pushchino, Moscow Region, Russia, personal communication, 1984. With permission.)

$$K' = \frac{kT}{h} \exp\left(\frac{+\Delta H' - T\Delta S'}{R'T}\right) \tag{5.64}$$

where k is the Boltzmann constant, T is the absolute temperature, H' is the free energy, S' is the entropy, h is Plank's constant, and R' is the gas constant. The significant feature is that the reaction rate K' varies exponentially with temperature, and $\Delta H'$ and $T\Delta S'$ are large numbers. Thus, very small changes in temperature can lead to big changes in chemical reaction rates.

In addition to chemical reaction rate changes, there may be changes in the binding of the proteins to cell membranes that lead to a shedding of proteins with a small increase in temperature. An exponential temperature dependence of the binding to membrane receptors is to be expected just as it is for chemical reactions [88].

A rule of thumb that the author uses to estimate whether or not significant biological changes are likely is to see if ΔT is $>10^{\circ}$C for 10^{-6} sec, 5°C for 1 sec, or 2°C for hours. If the ΔTs are larger, then they can be expected to lead to important changes in the biological system. Typical mammalian temperature regulatory systems will hold the internal body temperature constant to within $+/-0.5^{\circ}$C.

In addition to the magnitude of the temperature change, it can be shown that the rate of temperature rise, dT/dt, is important and can induce current to flow across membranes. Changes in the firing rate of pacemaker cells from the ganglion of *Aplysia* have been induced by total temperature changes of as little as $1/10^{\circ}$C when the rates of change are about 1°C/sec [89]. This change of the firing rate corresponds to the injection of approximately 1 nA into the cell. By taking the time derivative of the Nernst equation, which describes the passive equilibrium potential across a membrane for a single ion, it can be shown that a current proportional to the temperature derivative is to be expected, or

$$I = -qV_1'C_1\left(\frac{\phi}{\phi_T}\right)\left(\frac{\dot{\phi}}{\phi} - \frac{\dot{T}}{T}\right) \tag{5.65}$$

where q is the charge of the ion, V_1' is the volume of the cell, C_1 is the concentration of ions inside the cell, ϕ is the resting potential, ϕ is given by $\phi_T = \frac{kT}{q}$, $\dot{\phi}$ is the derivative of the membrane potential with respect to time, T is the temperature, and $\dot{T}$ is the temperature derivative with respect to time [90].

Bol'shakov and Alekseyev [91] have observed similar changes in the firing rate of pacemaker cells taken from the large parietal ganglion of the central nervous system of *Limnea stagnalis*. In their experiments they observed a slow increase in temperature (1°C/min or slower) to increase the firing rate of the pacemaker cell and a rapid increase in temperature (0.1°C/sec or faster) to decrease or stop the firing. They ascribe these changes to changes in the Na^+ pump as the rapid temperature effect was completely blocked by adding ouabain to the solution. In addition to the changes in the Na^+ currents, Ca^+ currents have been shown to be sensitive to rapid changes in temperature [92]. The rate of rise has also been shown to be significant in exciting a brain slice from a mouse with pulses of 10^{-3} sec and peak temperature rises of less than 0.5°C [93].

Temperature rises also lead to thermal expansion, and rapid temperature rises lead to the generation of acoustic waves [94]. These acoustic waves, in turn, can affect stretch receptors in nerve cells and other tissue and thus generate a biological response that may be at a considerable distance from the electrical heating [95].

To get an idea of the magnitudes of both heating (as described in Equation 5.58) and the effect of the rate of rise (as given by Equation 5.65), consider the case of liver tissue with $\sigma = 0.14$ S/m and a field strength in the tissue of 2×10^3 V/m. The rate of

temperature rise is approximately 13°C/sec assuming no conduction or convection heat losses and the thermal capacity of water. For this high field, a significant temperature rise occurs in about 1/2 sec. However, the rate of rise has been shown to be significant in exciting a brain slice from a mouse with pulses of 10^{-3} sec [96].

5.8 Natural Fields and Man-Made Fields

It is of interest to compare man-made with naturally occurring fields. First, we would like to know the approximate magnitudes of the fields that occur in nature outside man or the biological system of interest. Second, we would like to have values for the internal or physiological fields.

The natural electric fields at the surface of the earth have both DC and AC components [97]. One may think of the earth as a spherical capacitor where the surface is negatively charged with respect to an electrical conducting ionosphere that is about 50 km above the surface. This capacitor is being continuously charged by about 100 lightning strokes per second from thunderstorms worldwide. Since the atmosphere is a finite conductor, it also discharges with an *RC* time constant of about 18 sec. The result is an average electric field of about 130 V/m. This field is not uniform with height and typically falls off to 30 V/m at 1 km above the surface. The local values vary widely with temperature and humidity. In the Sahara during dust storms caused by winds in the dry season, a field of 1500 V/m has been measured with the polarity reversed from the normal. In thunderstorms, fields of up to 3000 V/m have been measured without lightning, and the polarity has been known to reverse in minutes. Storms as far as 50 km away have been shown to affect local fields. See Chapter 1 in this volume by Mild and Greenebaum for more details.

The atmosphere is a relatively poor conductor and as such will suspend a significant number of charged ions, dust particles, etc. This helps to contribute to local field variations of 20% to 50% over the course of the day and is a normal characteristic of our environment. The level of natural AC fields in the atmosphere falls very rapidly from a DC value of about 130 V/m [97]. The average value of the vertical component of the electric field above 1 Hz has a typical value of 10^{-4} V/m $\text{Hz}^{1/2}$. However, this value fluctuates widely with the time of day, the season of the year, and location. Additionally, the Schumann resonances impose multiple-cavity resonances on this spectrum with a periodicity of about 10 Hz. These resonances may be explained in terms of standing waves in a cavity formed by the earth and the atmosphere. These very low levels of the natural fields are one of the reasons why electronic communications in the ELF band are useful for ships at sea and submarines. However, because of the very low level of the natural atmospheric fields at frequencies above a few hertz, there is very little reason for biological organisms to develop natural protection against perturbations at these frequencies. It also means that biological systems could communicate internally at these frequencies using very low signal power levels and still maintain a good signal-to-noise ratio.

The signals generated within the body are the result of nerve firing and other cell activity. A typical nerve cell fires with an action potential of 50 to 100 mV and transmits a current pulse about 0.4 ms long [98]. The rise time for this current spike is approximately 0.1 ms, and the fall time is about 0.5 ms. Each pulse is followed by a refractory period that is typically on the order of 1 to 3 ms. The longitudinal fields along the exterior of a nerve cell membrane are estimated to have a maximum value of about 5×10^{-2} V/m during an action potential when the cell is surrounded by a relatively high conductivity fluid of 5 S/

m [98]. If we look at these signals closely, it will be noted that the interspike interval along any given nerve cell fluctuates in time. Additionally, variations in the beat-to-beat intervals for the ECG are random or chaotic, and the period can vary up to 30%. This is frequently seen, particularly at slow heart rates.

In looking at the natural fields in the body, we have two concerns. The first is how large an external signal takes to perturb the ongoing natural signal that is being used to communicate or control some biological process [99]. The second is how much of the signal field typically leaks away from active nerve fibers or bundles to form a background noise environment for surrounding tissue and processes. Regarding the first of these questions, it is interesting to look on the microscopic level at the electrical noise, i.e., the fluctuations that occur fundamentally as a result of the electrical process itself.

The first of several sources of noise that are always present is blackbody radiation, or Johnson noise, which is given by

$$P_{\mathrm{n}} = kTB \tag{5.66}$$

where P_{n} is the noise power, k is the Boltzmann constant, T is the absolute temperature, and B is the bandwidth [100–102]. The voltage equivalent of this noise power, which can be delivered to a matched load, or the mean squared voltage fluctuation $\overline{V}_{\mathrm{n}}{}^2$ across a resistance R, is given by [101,102]

$$\overline{V}_{\mathrm{n}}^2 = 4kTBR \tag{5.67}$$

or by the mean squared current fluctuations

$$\bar{i}_{\mathrm{n}}^2 = \frac{4kTB}{R} \tag{5.68}$$

Johnson noise applies to systems at thermodynamic equilibrium. Living systems are not at thermodynamic equilibrium. Thus, the foregoing expressions must be applied with caution to only those portions of biological systems where thermodynamic equilibrium is a good approximation. In the case of lasers, the spontaneous emission noise associated with the nonequilibrium population inversion of the energy levels can be obtained from Planck's radiation law by defining a negative temperature that assumes a Boltzmann distribution of atoms with N_2 atoms in the excited energy level E_2, which is greater than the N_1 atoms in the energy level E_1, such that

$$\frac{N_1}{N_2} = \exp\left[\frac{E_2 - E_1}{kT}\right] \tag{5.69}$$

In this case, the spontaneous emission noise $P_{\mathrm{n}} = h\upsilon B$, where h is Planck's constant and υ is the frequency of the radiation corresponding to a transition from E_2 to E_1 [100]. In those situations where the nonequilibrium characteristic may be described by an amplifier that can be modeled by a negative resistor or by energy storage in an inverted population distribution, the concept of a negative temperature may be a useful approach. Note that an equivalent temperature, T, is a convenient way to describe the energy distribution of a large number of particles. A much more complete description of nonequilibrium noise is given in Chapter 7 in this volume.

The second source of noise that is also present is the shot noise, which is given by

$$\bar{i}_{\mathrm{n}}^2 = 2q\bar{I}_{\mathrm{DC}}B \tag{5.70}$$

where $\bar{i}_n^2$ is the mean-squared current fluctuation. This noise comes about because of the discreteness of the electronic charge q and the assumption that the motion of each charge is independent. With negative feedback, this noise may be reduced, as has been shown for space charge-limited diodes. Shot noise results in an AC fluctuation, $\bar{i}_n^2$, which is proportional to the average value of the current, $\bar{I}_{DC}$. A third source of noise is $(1/f)$ noise. This noise may be generated by many processes, some of which are described in Chapter 7 in this volume. $1/f$ noise can be synthesized from Gaussian noise by filtering it with a circuit that requires about one low pass state variable per decade for the period of time over which the model is used to generate noise with a power density spectrum $S(f) = (C/f^{\alpha})$, where C is a constant and α is a constant between 1 and 2 [103]. We can expect to find this kind of noise for processes that evolve with time and, or have memory. $1/f$ noise describes the power spectral density of the fluctuations at low-frequencies in such diverse phenomena as transistors, quartz crystal oscillators, the closing Dow Jones Averages for the stock market, and the weather. It is also generated by the flow of ion currents through an orifice and thus is a fundamental part of the transport of current through channels in membranes [102]. Measurements of the noise voltage across a 10 μm hole in a 6 μm Mylar film showed that for a wide range of ionic concentrations the voltage noise spectral density $S(f)$ is given by

$$\frac{S_\phi(f)}{\phi^2} = \frac{a}{bnr^3 f} \tag{5.71}$$

where b is a numerical geometric factor, n is the density of ions in the solution, r is the radius of the hole, a is a constant, and ϕ is the applied voltage. The data showed that $2.5 < a < 40$ with a mean value of 10 for a wide range of solutions including HCl, KCl, and AgNO, with concentrations from 0.05 to 5 mol.

For natural membranes, this noise has been shown to take the form of

$$S_E(f) = \frac{C_E}{f^{\alpha}} \tag{5.72}$$

where $0.7 < \alpha < 1.2$ with a mean close to $\alpha = 1$. For the frog node of Ranvier, the noise is a function of the membrane voltage as shown in Figure 5.15 [104]. The dominant source of this noise appears to be the K^+ current, and it has a minimum when the membrane is biased, so that this K^+ current is biased to zero.

To get an estimate of the size of these noise sources, let us consider a pacemaker cell from the abdominal ganglion of *Aplysia*. This cell fires 20-ms pulses at about 1 Hz/sec. It has a resting voltage of about 50 mV and a resistance R measured with a microelectrode between the inside of the cell and the surrounding solution of approximately 10^6 Ω. If we assume a system bandwidth of 100 Hz and $T = 300$ K, the Johnson noise voltage would be $\overline{V}_n \approx 3 \times 10^{-6}$ V. This gives a resting potential-to-noise ($\overline{V}_n$) ratio of about 4×10^4. The peak current flow in these cells is estimated to be about 10^{-7} A, and thus the estimated shot noise current is $\bar{i}_n \approx 2 \times 10^{-12}$ A, and the ratio of the peak current to the noise current is about 2×10^4. We do not have the available value $S(f)$ for the *Aplysia*, $\bar{v}_\phi = \sqrt{S(f)B}$, where B is the bandwidth. If it is assumed that the maximum value of the noise is the same as that of the frog node of Ranvier, then for a bandwidth of 1 Hz we get $\bar{v}_\phi = 1.4 \times 10^{-5}$ V at a center frequency of 1 Hz from the curve for −50 mV in Figure 5.15. This is about a factor of 10^3 greater than the Johnson noise. It is likely that $(1/f)$ noise is the largest source of noise at the cell membranes for frequencies below 160 Hz [105,106].

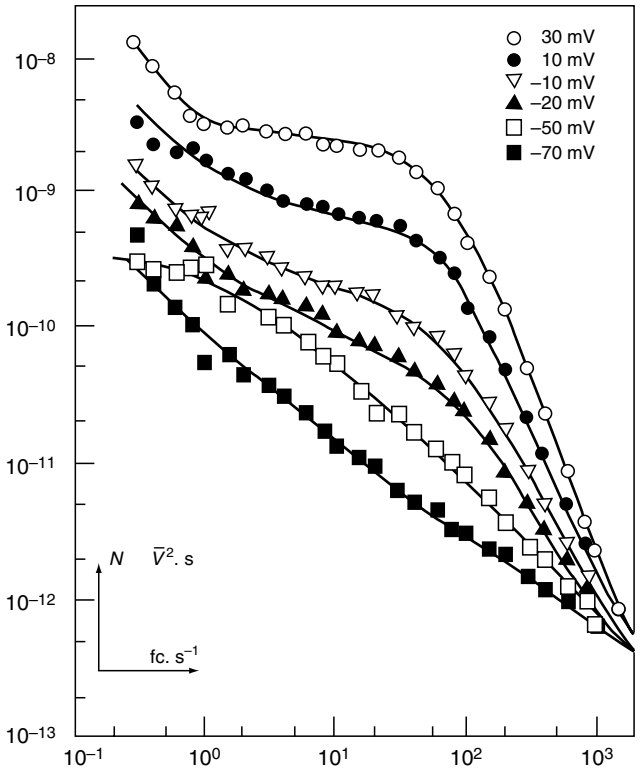

FIGURE 5.15
Voltage noise spectra of a frog node of Ranvier at different levels of membrane potential. (From Sichenga, E. and Verveen, A.A., in *Proceedings of the 1st European Biophysics Congress*, Vol. 5, Verlag Wiener Medizinischen Akademic, Vienna, Austria, 219, 1971. With permission.)

These fundamental sources of noise, which are generated by random fluctuations in the position of ions and their transport through channels, are spatially incoherent [73]. For many processes the important quantity in deciding whether or not an electrical signal is biologically important is the signal-to-noise ratio S/N where S is the power in the signal and N is the noise power. Typically, it is assumed that a signal-to-noise ratio of 1 is required for an externally applied signal to be detectable. In the foregoing discussion for both thermal and shot noise the movement of each charge was assumed to be statistically independent of each other. If for an externally applied signal the openings of the channels in a cell are excited in parallel and coherently and the noise is generated by incoherent random firing, then the signal-to-noise ratio increases with the square root of the number of channels. Similarly, the signal-to-noise ratio for a bundle of nerves would be expected to increase with the square root of the number of nerves for a signal applied externally to the whole bundle. Thus, a collection of cells can be expected to detect smaller signals than a single cell.

In addition to the electrical noise generated by currents and voltages that are part of the single-cell operation, electrical signals propagate through the body as a result of the incomplete confinement of electrical signals propagating in nerve cells. In a sense, these signals may be thought of as noise if they are not pertinent to the activity in that portion of the body through which they are propagating. If, on the other hand, they are used by tissue within the organism at some distance from the source, they must be thought of as signals. In the brain, the fraction of these signals that reach the scalp is called the electroencephalogram (EEG). The EEG is obtained by placing two or more conducting electrodes on the scalp and measuring the voltage between them. For electrodes placed 5 cm apart, the peak-to-peak voltages range up to 30 μV [107]. The author views this voltage as the integral of the vector sum of the leakage fields from the firing of the nerve

cells in the brain between the two electrodes. Since there are a very large number of cells firing, most of the 50 mV signals from an isolated nerve are canceled by summing over many like cells firing at different times and by the attenuation caused by propagation through the tissue. Estimates of surface potential gradients along a nerve fiber range from 3×10^{-4} to 5×10^{-2} V/m, and the corresponding current densities external to the nerve cells range from 5×10^{-2} to 4 A/m^2 [107,108]. The EEG voltage has a strong periodic component (particularly during sleep) near 10 Hz, which is known as the alpha (α) wave. A peak amplitude of this component may be as large as 50 μV when measured at the surface of the scalp. It is interesting to note that the EEG signal contains significant information on the brain's activity, and a few individuals have been trained to control these signals so as to control a computer in way that allows them write messages.

At the surface of the chest, a signal may be recorded between two electrodes known as the ECG or EKG (electrocardiogram). This signal results from the highly coordinated firing of the cells in the heart and has a definite wave shape that is closely related to the operation of the heart. The peaks of the so-called R wave in this signal may range up to 2.5 mV and are typically 0.5 to 1.5 mV, depending on the placement of the electrodes, the amount of body fat, etc. The pulse repetition rate is usually in the range of 1 to 2 Hz, and the ''QRS spike'' of the typical cardiogram is 40 ms long. Again, the signal measured at the surface of the skin is the result of leakage from electrically active cells located at a distance. The estimated current density near the firing heart cell ranges up to 1 A/m^2 [109]. In this case the shape of the signal reaching the skin is so closely related to the activity of the heart that it provides detailed information on heart function.

One result of electric discharges in the atmosphere, as well as natural ionizing radiation, is the creation of small positive and negative ions in the atmosphere. In clean country or mountain air, the typical ion density is about 10^{10}/m^3 with an average ion lifetime of a few minutes [110]. When a hot dry wind is blowing, positive ions created by the shearing forces can increase in concentration significantly. It has been shown that increases in the negative ion concentration reduce the amount of serotonin (5-HT) in mice and rabbits, possibly by accelerating the enzymatic oxidation process [111]. A similar result has been demonstrated in the oxidation of cytochrome *c*. Positive ions appear to block monoamine oxidase action, thus raising the concentration of free 5-HT [111]. Changes in 5-HT levels produce significant changes in the central nervous system, with high levels of positive ions raising the anxiety levels under stress. Other effects of increased positive ion concentration include a decrease in the survival rate of mice exposed to a measured dose of influenza virus, while an increase of negative ions reduced the mortality rate [111].

The significance of these results is that it is relatively easy to change the ion concentration in air using high-voltage DC systems where a leakage current of 1 μA from a burr or other sharp point would correspond to the generation of about 10^{12} ions per second.

Relatively few high-voltage DC transmission lines are in use today for distribution of power. Because the shocks resulting from a short contact across a high DC voltage are so painful and obviously dangerous, these systems are nearly always shielded. Thus, one is rarely exposed to DC electric fields $>10^3$ V/m. An additional feature of this exposure is that air is such a good insulator that the DC currents flowing through the body in a noncontacting situation are very small, as explained in the Introduction. For example, 1000 V across a 1-cm gap would yield a current density of approximately 10^{-7} A/m^2 flowing across the air gap. Thus, the principal hazards from DC fields occur when parts of the body make contact with a conductor.

5.9 Discussion and Summary

In this review some of the physical mechanisms by which DC and time-varying electric fields affect biological systems are presented. A few typical values of electric field strengths and current densities that are known to affect the biological system are compared with those of natural fields and other forces. Some values of electric fields and their gradients that are shown to modify the currents and shift energy levels are given. These in turn are shown to modify chemical reaction rates, which can lead to changes in the growth cells and other characteristics of biological systems. It is hoped that this information will help the readers to make their own estimates of when a given exposure to electric fields will be significant in modifying biological systems and provide a basis for understanding some of the biological results presented in other chapters of this handbook.

Acknowledgments

The author wishes to express appreciation to Mikhail Zhadin, Howard Wachtel, Maria Stuchly, Ross Adey, Mike Marron, Elliot Postow, Charles Polk, and many students for their many helpful comments and suggestions and to Adam Sadoff for help in the preparation of the text. He also wishes to express his appreciation to the Office of Naval Research under Contract N000l4-81-K-0387, the Mobile Manufactures Form, and the University of Colorado for financial support of his work in this area.

Magnetic Field Effects on Free Radical Reactions in Biology

Stefan Engström

CONTENTS

6.1 Introduction

The physical chemistry of spin-correlated free radical pairs offers several mechanisms explaining how magnetic fields may influence biochemical processes. The mechanisms are classified on the basis of the dominating contribution to spin interconversion, and they cover a wide range of field strengths. Of particular interest is what is called the low-field mechanism, which has been extensively developed over the last decade and is now capable of explaining biological effects induced by magnetic fields well below 1 mT.

The principal mechanism behind the free radical mechanism was discovered in the physical problem of magnetic field dependence on positronium decay (Deutsch and Brown, 1952; Halpern, 1954). However, the development of the radical pair mechanism in chemistry has its roots in the work of Kaptein and Oosterhoff (1969), Closs (1969), and Brocklehurst (1969).

An ambitious survey of the literature up to its date of publication is the review of Steiner and Ulrich (1989), which lists some 775 references, 58 of which are themselves reviews on magnetokinetic phenomena. Another, now classic, reference on the subject is the book by Salikhov et al. (1984). McLauchlan and Steiner (1991) published a review including the possible mechanisms at lower fields. The review by Grissom (1995) explored the higher-field mechanisms with particular attention to the context of biological systems. A didactic paper geared toward the issues in biological systems is that of Brocklehurst and McLauchlan (1996). There are also some recent reviews on the free radical mechanism in general (Woodward, 2002) and with particular attention to biological systems (Brocklehurst, 2002).

6.2 Theoretical Background

A radical is an atom or a molecule with an unpaired electron. It tends to be highly reactive, a property that defines their best known roles in biology. A spin-correlated (or geminate) radical pair is typically created by hemolytic cleavage of a covalent bond, that is, each molecule retains one of the electrons that formed the chemical bond that was broken. The electron spins may remain correlated for a significant time (microseconds) after the pair's creation. As the radicals separate, the electron interaction term becomes small, and the electron states of the pair will fluctuate between antiparallel (singlet, or ''S'') and parallel (triplet, or ''T'') because of coherent spin evolution by hyperfine interactions between the electron spin and the nuclei. There is a chance of reencounter between the spin-correlated radicals. Reforming the bond is only permitted by quantum spin selection rules if the electron spins are oriented in the singlet state.

Magnetic fields can affect the electron state in the time before the reencounter; and if singlet and triplet pairs have different chemical fates, we have a basis for magnetic field effects on free radical chemistry (Figure 6.1). In exemplifying the process, we will assume that the radical pair is formed in the singlet state, the normal case for biologically relevant reactions (Eveson et al., 2000).

Many physical transduction mechanisms proposed to explain magnetic field effects in biology are very vulnerable to the randomizing effects of thermal noise at normal temperatures of living systems (Binhi and Savin, 2003). The free radical mechanism is uniquely resistant to this obstacle since it is a nuclear effect and is not strongly coupled to the thermal bath (Adair, 1999).

A quantum mechanical formulation of the free radical mechanism contains many possible contributions to the hamiltonian; Steiner and Ulrich (1989) provide a good categorization of the main components. The stochastic Liouville equation (SLE) is a tool

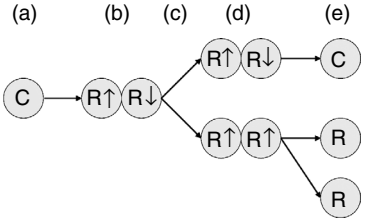

FIGURE 6.1
A molecule ''C'' (a) is split into two radicals (b). After diffusion and spin interconversion (c), the radicals may reencounter while still spin correlated (d). If the encounter occurs in the singlet state (e, top), the radicals may recombine. If the encounter occurs in the triplet state (e, bottom), recombination cannot occur, and the radicals will diffuse apart again and eventually lose their spin correlation. A magnetic field can influence this reaction by changing the rate of spin interconversion as long as the singlet and triplet products have different chemical fates.

for addressing the problem of simultaneous spin mixing and diffusion, but simplified models in which these two components are treated separately are often useful for the great reduction in problem complexity (Brocklehurst and McLauchlan, 1996). Recently, analytical results using a backward SLE have been presented (Pedersen and Christensen, 2004).

6.2.1 Hyperfine Interaction-Induced Singlet-to-Triplet Conversion

Hyperfine interactions between the spins of the electron and the nucleus cause the electron spins of the radicals to precess and induce singlet-to-triplet conversion. The triplet state has a net magnetic moment, and in the presence of an external magnetic field the energy levels of the triplet states that have a moment aligned with the magnetic field (T_+ and T_-) will be separated by Zeeman splitting. As the applied field strength is increased, the T_+ and T_- energy levels will be shifted away from the singlet state so much that they are decoupled from the spin interconversion process between singlet and triplet states, and only the remaining triplet state (T_0), which has a magnetic moment that is oriented perpendicular to the field, is capable of participating in the spin conversion process. In this way the magnetic field can reduce the number of triplet states that can be converted into singlet states and subsequently reform the original chemical bond. This is the ''normal'' magnetic field effect on free radical chemistry. It becomes relevant for external fields larger than the effective field driving the hyperfine interaction mixing, typically 1–10 mT.

A way in which singlet-to-triplet conversion can be facilitated is when an applied field causes the T_- energy level to cross the nonmagnetic singlet level, which occurs when the Zeeman differential matches the electron exchange interaction energy (cf. Figure 6.2). This effect has been observed for fields as low as 6.6 mT (Werner et al., 1993), but it can in principle be observed for much lower fields if the radical pairs are fixed with an appropriate separation.

6.2.2 High-Field Regime: Spin Rephrasing through the Δg Mechanism

The product of the magnetic field and the Landé g-factor determines the precession of the unpaired electron spin, independent of the hyperfine contribution. If the two radicals have slightly different g-factors, this provides an additional source of spin conversion. Differences are usually quite small, so this mechanism typically becomes significant only for quite large fields, $B > 0.1$–1 T.

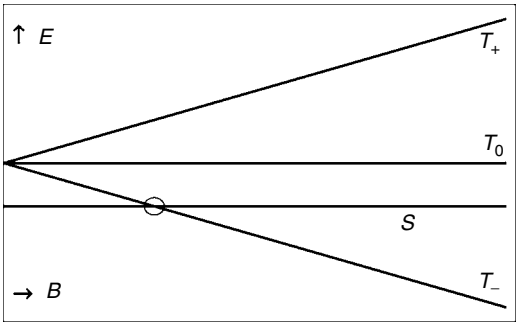

FIGURE 6.2
Energy level diagram for singlet and triplet states of a radical pair. At high fields, T_+ and T_- become completely disconnected from the singlet state, and only the T_0 state is left for singlet–triplet interconversion. At a specific B-field, the Zeeman split causes the T_- state to closely match the singlet state (circled), increasing the likelihood of transitions between the two states.

6.2.3 Low-Field Effect: $B < 1$ mT

At fields below the hyperfine interaction energy, it is still possible to see effects of external fields under certain circumstances. It was found by Brocklehurst (1976) that the selection rules of the hyperfine-induced spin mixing are more restrictive in zero field than when a field is applied (McLauchlan and Steiner, 1991). This becomes relevant, even for a very small field, as long as the coherence of the pair's state is maintained for long periods (100 ns to 1 μs). A helpful vector model to visualize this effect, along with some illustrative numerical examples, is given by Till et al. (1998).

The low-field effect (LFE) can theoretically produce a large (40%) drop in the singlet yield if the conditions are optimal (Timmel et al., 1998), but in practice only smaller effects attributed to this mechanism have been reported in the experimental literature.

Since long coherence times are required, it is necessary to understand spin relaxation effects and under what conditions they may be sufficiently long. Anisotropic hyperfine interactions provide noncoherent spin relaxation in solution, and it appears that the relaxation is slower in the low-field situation than has been generally thought (Fedin et al., 2001, 2003). It is becoming clear that understanding the local environment is crucial for evaluating LFEs (Eveson et al., 2000).

An important way to extend free radical magnetic field effects into the low-field region is to extend the lifetime of the spin-correlated pair. Integrating the magnetic field's influence over a longer time increases its ability to influence the spin evolution. Spin relaxation is not the primary problem here; rather, it is the reencounter probability that needs to be enhanced. There are several ways to achieve this:

1. Increased viscosity to restrict diffusion (Krissinel et al., 1999; Christensen and Pedersen, 2003; Kitahama et al., 2004)
2. Oppositely charged radicals that will oppose a tendency to diffuse apart (Adair, 1999)
3. Physically restricted mobility of the radicals through confining them to a surface or having the reaction taking place inside micelles, which are nanometer-scale compartments that form and reform on microsecond timescales and are able to confine the radical pairs and increase the reencounter probability (Eveson et al., 2000).

6.2.4 Free Radicals in Radio Frequency Fields

For higher-frequency fields ($f > 1$ MHz) the time modulation of the field starts to correspond to timescales present in the reaction dynamics, and a range of resonant interactions become available (Timmel and Hore, 1996). A detailed treatment of the coenzyme B_{12} system demonstrated resonant phenomena for relatively low-level radio frequency (RF) fields using a variety of mathematical techniques (Canfield et al., 1994, 1995).

6.3 General Characteristics of the Free Radical Mechanism

Free radical reactions are generally quite fast. There is evidence of picosecond reactions (Gilch et al., 1998; Musewald et al., 1999), but many known reactions occur over nanosecond timescales. If the free radical diffusion is constrained by micelles (Eveson et al.,

2000; Christensen and Pedersen, 2003) or by Coulomb attraction (Horiuchi et al., 2003), it may be possible to extend the radical pair lifetimes to hundreds of nanoseconds or even microseconds.

Since the free radical mechanism is practically instantaneous when compared to the timescale of time-varying magnetic fields in the extremely low-frequency regime (<300 Hz), one would expect that the observable output from a biological detection of the field should depend only on the time-averaged absolute field amplitude (Scaiano et al., 1995). However, if there is a downstream system that is able to decode the low-frequency signal, this statement is not necessarily true (Engstrom, 1997; Engstrom and Fitzsimmons, 1999).

6.3.1 Experimental Discrimination of Free Radical Models

The relative orientation of a static and a much smaller oscillating field will provide a discriminating test for a free radical-based model as long as the timescale of the applied field is long compared to the lifetime of the radical pair. In an isotropic system, such as a liquid suspension, described by this field situation, only the amplitude of the magnetic field is relevant. While the smaller parallel field adds linearly to the larger static field, the perpendicular component is effectively reduced by the calculation of vector length and will cause a much smaller variation in field amplitude (Engstrom, 1997).

For oriented systems in which the free radical chemistry steps have spatial preferences, it is possible to have angular dependence with respect to the angle of the applied field, $f(\theta)$. One can argue that some symmetry properties are very likely to be present in that kind of situation (Ritz et al., 2000). Polarity changes are not expected to be relevant, so $f(\theta + 180^\circ) = f(\theta)$. Furthermore, due to the isotropic distribution of nuclear spins in the initial state of the radical pair, one also expects that $f(180^\circ - \theta) = f(\theta)$.

If the free radical mechanism is active for low-frequency fields, one can also expect a response to RF fields in the same system, a property not expected by any other suggested physical transduction mechanisms for magnetic fields (Henbest et al., 2004). In a comparison between static fields in the range 0–2 mT, it was shown that a 300-μT, 5-MHz RF field applied perpendicularly or in parallel with the static field induced a response that was dependent on the magnitude of the static field (Henbest et al., 2004). This is qualitatively, if not quantitatively, similar to the observation that the magnetic sense of migratory birds can be disrupted by a 470-nT, 7-MHz field when the field is applied at an angle with the geomagnetic field (Ritz et al., 2004).

Magnetic isotope effects are another possible discriminating character of free radical effects, and it is possible to differentiate this signature from pure mass effects (Brocklehurst, 1997).

6.4 Free Radicals in Biology

6.4.1 Biological Transduction Mechanisms

Direct detection methods for free radicals have been developed in chemistry only relatively recently (Woodward, 2002). In biological systems, almost all experimental evidence for free radical involvement remains indirect. Generating hypotheses based on the signatures of free radical systems as outlined above are necessary to link free radical chemistry

to magnetic field effects, but there is circumstantial evidence that free radical chemistry underlies some effects reported in the bioelectromagnetics literature.

It has been suggested that complex dynamical systems may have special sensitivity to magnetic field influences (Grundler et al., 1992; Walleczek, 1995). This idea has been elaborated in a series of theoretical models of oscillatory systems (Eichwald and Walleczek, 1996a,b; Kaiser, 1996). These models show that enzyme dynamics involving free radical chemistry may be frequency specific, although only for timescales comparable to or slower than the chemical kinetics of the system (Eichwald and Walleczek, 1997). Field amplitude can influence enzyme dynamics in some instances and this can be used to exert some control over enzyme systems (Eichwald and Walleczek, 1998).

The peroxidase–oxidase system has interesting, well-documented dynamical properties (Scheeline et al., 1997). Detailed modeling of this system has shown how a magnetic field-induced perturbation can affect its dynamical behavior (Eichwald and Walleczek, 1998; Moller and Olsen, 1999). The point of interaction in this system is suspected to be electron-transfer enzyme intermediates (Moller and Olsen, 2000; Moller et al., 2000).

Downstream effects from changes in chemistry must be taken into account to evaluate biological significance (Brocklehurst and McLauchlan, 1996). This can both facilitate detection (Walleczek, 1995) as well as introduce interventions that could block the biological significance of a physical detection event.

It may be relevant that other enzyme systems have been studied in detail without the specific intention of addressing free radicals as a possible mechanism. Examples include electric and magnetic field effects in ATPase (Blank and Soo, 2001b). Direct interactions with DNA have been suggested; and electron transfer reactions are proposed interaction targets (Blank and Goodman, 2000; Blank and Soo, 2001a), although not by mechanisms addressed here. Myosin phosphorylation is another enzyme system that has shown sensitivity to time-varying (Markov et al., 1993) and static magnetic fields (Markov and Pilla, 1994), as well as gradient-specific effects (Engstrom et al., 2002).

6.4.2 Role of Freely Diffusing Radicals

Free radicals observed in biology are most commonly oxygen or nitrogen based with an unpaired electron, leading to the terms reactive oxygen species (ROS) and reactive nitrogen species (RNS). A dominant role for these radicals is to act in immunological defense. They are secreted by macrophages and neutrophils and during attempts to kill bacteria, viruses, and tumors (Nathan, 1992). The highly reactive nature of the radicals also means that damage to normal cells is possible, and various defense mechanisms against this have evolved as well (Yu, 1994). This immunological weapon with checks and balances already suggests that there is a signaling system built around free radicals, but it seems that the ROS and RNS also have roles in intracellular cell signaling (Lander, 1997) as well as intercellular communication (Thannickal and Fanburg, 2000).

Consider a biochemical reaction producing a spin-correlated free radical pair in the singlet state. Depending on the specific mechanism at work, the ratio of singlet-to-triplet product at reencounter will be modified. This will increase or decrease the fraction of pairs that tend to recombine because of a reencounter finding the spins in singlet versus the triplet states. For the LFE, the triplet state is favored, and we would see an excess of escape product. The situation is the opposite for the ''normal'' field effect, in which the T_- and T_+ states are decoupled from the interconversion process, increasing the proportion of singlet reencounters leading to a larger amount of cage product and leaving fewer freely diffusing radicals. The Δg mechanism brings the T_- and T_+ states back into play and therefore again boosts the triplet-reencounter escape products.

Given the wide involvement of free radicals in signaling and biological function, it is clear that there is the potential of both subtle and not-so-subtle effects on biological systems if we are able to alter the production of free radicals and thereby change the dynamics of already ongoing processes. The conventional wisdom regarding the deleterious effects of magnetic field effects on free radical recombination has been that more escape product means more radical-induced damage. This may be an oversimplification since the direct effects on cage or escape products are typically fairly small, certainly not larger than tens of percent, implying that drastic biological effects must involve downstream responses that amplify this relatively slight modulation. The answer may lie in the signaling properties of free radicals.

6.4.3 Animal Navigation Models Based on Free Radicals

The free radical mechanism was the first mechanism suggested as an explanation of avian use of magnetic fields for navigation (Schulten et al., 1978; Schulten, 1982). This model has since undergone several iterations of refinement (Ritz et al., 2000; Cintolesi et al., 2003). One interesting aspect of this work is a connection between photosensitivity and magnetoreception (Ritz et al., 2002). Dependence on light is a well-known feature of the avian magnetoreceptor (Deutschlander et al., 1999; Wiltschko et al., 2004a,b), but it has also appeared in other behavioral studies of animal magnetic field sensitivity (Prato et al., 1997, 1998).

The Ritz-Schulten model (Ritz et al., 2000) has an appealing geometrical application. Being integrated into the bird's retina, the suggested compass would appear as a modulation overlay on the bird's field of view. The mechanism operates through the so-called low field effect (LFE), based on a single nuclear spin, and operates near the limit of the theoretical sensitivity, despite omitting degrading effects such as the presence of multiple nuclear spins, dipolar effects, and various spin relaxation process that will start to become relevant for the long radical pair lifetimes (>100 ns) considered in the model.

Cryptochromes provide one possible source of free radicals in a spatially ordered system (Ritz et al., 2002). A recent theoretical model for avian magnetoreception develops that idea by investigating a flavin–tryptophan radical pair with a high degree of homology to the cryptochromes (Cintolesi et al., 2003). This multinucleus model is realistic in that it still manages to provide sensitivity to fields in the geomagnetic field range. Interestingly, it does not operate through the LFE described above (the multinucleus approach appears to remove most signs of that mechanism), but rather it depends on immobilized radicals and assumes that the free radical pair may have a lifetime up to 5 μs.

6.4.4 Coenzyme B_{12}-Dependent Reactions

Magnetic field effects in the coenzyme B_{12} are well explored experimentally with matching theoretical predictions (Harkins and Grissom, 1994; Grissom and Natarajan, 1997; Taoka et al., 1997). While most work on this model system has been concerned with intermediate and higher-field mechanisms, there are also detailed theoretical investigations suggesting that weak (<100 μT), relatively low-frequency (<100 kHz), might be able to affect this system (Canfield et al., 1994, 1995, 1996).

6.4.5 Other Experimental Observations

The addition of iron ions or exposure to a 7-mT static magnetic field (SMF) did not affect the survival of rat lymphocytes *in vitro* when performed in isolation, but combined

exposure led to a significant increase in cell death (Jajte et al., 2002). One possible explanation of this behavior is that the addition of iron ions enhanced levels of ROS and that the field exposure further promoted the creation of free radicals, leading to cell death by both apoptosis and necrosis. An experiment with a similar rationale used added $FeCl_2$ to stimulate ROS production, and a 930-MHz, 5-W/m^2 cell phone-generated field affected a biological marker for ROS production. It should be noted that the vacuum magnetic field associated with this exposure is quite low (approximately 0.14 μT) and the frequency is a relatively unexplored region for this mechanism.

Proliferation of chick fibroblasts was observed to be enhanced by a 100-Hz, 0.7-mT sinusoidal magnetic field (Katsir et al., 1998). In a follow-up study it was found that free radical scavengers (Katsir and Parola, 1998) suppressed this effect, suggesting that that free radicals may have a role in mediating the magnetic field effect on proliferation.

Genotoxic effects from intermediate static magnetic fields (250 mT) have been studied in *Escherichia coli* DNA, both *in vivo* and *in vitro* (Potenza et al., 2004). Free radical formation was stimulated, and the genetic damage was mapped as a function of exposure duration. *In vitro* experiments showed detectable genotoxic effects, but the *in vivo* assays did not, indicating that cellular protective responses may prevent damage in the intact system.

A reported effect on the oxidative burst in neutrophils by a 0.1-mT field was attributed to free radicals (Roy et al., 1995). In that study, the connection to free radicals lies in that the fluorescent probe used to study the neutrophil activity reacts specifically with free radical-derived oxidants that create the fluorescing compounds. Work in neutrophils in humans (Heine et al., 1999) using a much larger field (1.5 T) did not find any effects of magnetic fields on the respiratory burst of human neutrophils or on the production of radical species.

Phagocytosis was observed to be affected by 0.5–1.5-mT, 50-Hz sinusoidal magnetic fields (Simko et al., 2001). An attendant increase in superoxide production may be an indication that the field stimulated the system through a free radical process.

6.5 Conclusion

Free radical reactions are ubiquitous in biology, and recent developments of the low-field mechanisms (Timmel et al., 2001) and the consideration of detailed biochemical systems (Cintolesi et al., 2003) make this mechanism a contender for field effects down to geomagnetic field strengths. The physical transduction step is not vulnerable to thermal perturbations, a significant advantage over competing models.

This model does not produce large (factors >2) changes at the initial field detection step. Theoretical models and direct experimental observations in the low-field region typically operate around or below the 10% level, so we should expect the physical detection mechanism to need cooperation from downstream processes for biologically relevant detection of magnetic fields with free radicals as the starting point.

Signals, Noise, and Thresholds

James C. Weaver and Martin Bier

CONTENTS

7.1 Signals, Detection, and Measurement

Measurement is a quantitative observation and well known to be of great importance to science. However, measurements involving biological systems are complicated by the complexity of cells and tissues, particularly if fields are expected to interact weakly and field-induced changes are found to be small. Some key parameters, for example, temperature coefficient of a measured quantity, may be inadequately characterized, and related quantities may be determined incompletely (e.g., measurement or modeling of the time-dependent temperature throughout the volume of the biological system being studied). Detection is a special case of measurement, that is, the measurement is so coarse that an observer can only distinguish between ''signal'' and ''no signal.''

Generally speaking, the smaller the change in an observed quantity (e.g., cell biomass) due to a stimulus (e.g., an applied electromagnetic field), the more difficult the experimental interpretation. There may be multiple candidate causes if small changes in biomass are found, for example, any of many growth-altering biochemical changes, unnoticed and uncharacterized temperature variations, or even changes in ambient light or mechanical vibration. In physical science a model can often be made of the experiment. This allows estimates of the influence of various quantities and parameters on the expected experimental outcome (change in observed quantity in response to a stimulus) and is valuable in the interpretation of experiments. Similar approaches to bioelectromagnetics should also be valuable.

Consider an illustrative measurement on a biological system: a population of microorganisms contained within a glass toroid. Application of an alternating magnetic field to a primary coil wrapped around one part of the toroid induces an alternating current. The induced current can be measured with a coil wound around part of the toroid. The induced current is related to the electrical conductivity of the aqueous electrolyte. The electrical conductivity of the extracellular medium changes when small, charged metabolites are excreted, and measurement of microbial metabolic activity can thus be accomplished electrically. First observed in 1899 by a nulling technique [1], electrical impedance detection of microorganisms has received significant attention as a measurement method [2,3]. A toroidal device has actually been explored as the basis for determining microbial activity [4], with metabolic acid production causing a change in extracellular ion concentration (activity) and therefore creating a change in the electrical conductivity of the extracellular medium. But complications may arise. If cytotoxic chemicals leach from the glass, there can be a time-dependent poisoning of microbial activity. Ambient temperature changes couple through the glass to create internal temperature variations that alter the conductivity. In short, because electrical conductivity change has more than one candidate cause, this measurement system lacks specificity. This also illustrates a basic challenge to measurement of effects of electromagnetic fields on biological systems, namely, demonstrating both a statistically significant change and convincing evidence that it is the field interaction with the biological system, not an associated competing influence, that is responsible for the observation.

7.2 Specificity

Specificity is a hallmark of biological interactions involving biochemicals. A cell contains a large number of coexisting molecules whose interactions are not spontaneous but are instead highly regulated. Enzymes can be highly specific in the reactions they catalyze. Antibodies and receptor–ligand binding are also often specific. However, interactions of electromagnetic fields with a biological system are rather general. Magnetic fields interact indirectly by inducing electric fields and directly through magnetically sensitive reactions [5] and through interactions with magnetic material. Such magnetic materials may be contaminant ferromagnetic particles in the human body [6] or they may be biologically synthesized magnetite granules [7,8]. Electric fields interact nonspecifically with charge and polarizable material. Thus, unlike ligand–receptor biochemical interactions, there are no molecular receptors that are highly specific for electromagnetic fields. Instead, magnetic and electric sensory systems interact broadly and can be regarded as nonspecific. Evolved sensory systems are rather special. To date, it appears that biological, electric and magnetic field reception is indeed accomplished by organized systems.

Lack of electromagnetic field specificity has important implications for interpreting experiments. If an experiment quantifies a change in an observed parameter, the cause of the change is not automatically known. Continuing the example of cell growth determination based on biomass measurement, if an increase in biomass (or cell number) is associated with a field exposure, then additional analysis is needed to determine whether this change is due directly to the field or is instead due to interfering influences such as temperature change or biochemical concentration changes.

The challenge of specificity is not limited to weakly interacting fields. Consider the case of strong, electroporating fields *in vivo*, for which the motivation is local tumor treatment

or gene therapy. Strong fields can generate tissue movement by stimulating muscles and possibly also by bulk tissue polarization forces. Tissue motion can itself create membrane openings, and these can lead to biochemical transport [9–11]. Thus, observation of molecular uptake associated with electrical pulsing does not by itself show that electroporation is responsible. Specificity is an issue.

7.3 Signal-to-Noise Ratio

We adopt a recent discussion of the signal-to-noise ratio (S/N) for experiments with biological systems exposed to weakly interacting electromagnetic fields [12]. The observed quantity is x. For bioelectromagnetics experiments, examples of x include a local or spatially averaged transmembrane voltage change, temperature rise at a particular site, radioactivity of an incorporated unstable isotope, specific enzyme activity, intracellular calcium ion concentration, cell biomass, etc. Typically, experiments obtain data that can be characterized by their means and standard deviations, often presented as a bar chart. One bar of each bar pair represents the control result, and the other bar represents the exposed result. Each bar height represents the mean value, and the error bar is usually the standard deviation. (In some cases the error bars instead represent the standard error, that is, the uncertainty in the mean, rather than the standard deviation, but generally a report states which is being used.) Bar charts present a concise summary of an investigator's knowledge of the underlying natural distributions. The measured mean and standard deviation of the control distribution can be defined to be $\bar{x}_{\text{con}}$ and σ_{con}, respectively. Similarly, $\bar{x}_{\text{exp}}$ and σ_{exp} are the observed mean and standard deviation of the exposed distribution.

When repeating the same experiment and doing the same measurement many times over, one generally finds a Gaussian distribution of outcomes. This is because in a complex system there are many variables and sources of inaccuracy that are not under the control of the experimentalist. For the cumulative effect of all these imprecisions the central limit theorem becomes applicable. This theorem says that with many independent stochasticities involved, the outcome will be a Gaussian distribution [13]. As an example of this theorem in practice, do 100 coin tosses and record the number N of ''heads.'' Repeat this experiment many times. The result will converge to a Gaussian distribution of N that is centered around 50.

The threshold for a field exposure effect occurs under conditions of detection, that is, the minimum change of x that is discernable using generally accepted statistical criteria. This is equivalent to determining whether or not the control statistical distribution and the exposed distribution are distinguishable (significantly different by accepted criteria). This requires sufficiently precise knowledge of the statistical distribution parameters. Increasing the number of determinations of the natural distribution generates more precise knowledge of its parameters. For example, if an investigator carries out a number, m_{con}, of determinations of x_{con} and another number, m_{exp}, of determinations of x_{exp}, then the empirically determined values can be reported as

$$x_{\text{con}} = \bar{x}_{\text{con}} \pm \frac{\sigma_{\text{con}}}{\sqrt{m_{\text{con}}}} \quad \text{and} \quad x_{\text{exp}} = \bar{x}_{\text{exp}} \pm \frac{\sigma_{\text{exp}}}{\sqrt{m_{\text{exp}}}} \tag{7.1}$$

The ratio $\sigma/\sqrt{m}$ actually represents the aforementioned standard error. Increasing the number of determinations reduces the standard error and the ensuing uncertainty in the mean. However, it does not decrease the standard deviation, σ_{exp}, of the underlying distribution, which is assumed unperturbed by the measurement process.

As the means $\bar{x}_{con}$ and $\bar{x}_{exp}$ become better known through more determinations, the potential distinguishability of the two distributions increases. The p-value of the experiment is often reported as a measure of this distinguishability. The p-value is the probability that the two means would be found to be as different as observed (or even more different) purely because of random variability. For example, $p = 0.01$ indicates that there is only a 1% chance that the difference between the control mean and the exposed mean would be due to the (assumed) random variability of the measured quantity, namely, the standard deviation [14]. After an investigator completes an experiment and finds a reasonably small p-value (.01 and .05 are widely used values), it is a common practice for the investigator to report that an effect due to the field exposure has occurred. However this assumes specificity, namely, that the field exposure rather than an associated competing influence is responsible. Indeed, a small p-value supports an effect of some sort but not necessarily one due to the field during the exposure. Additional analysis that considers other competing influences such as temperature variations, vibrations, and chemical concentration variations [15,16] is required for that conclusion.

Bioelectromagnetics experiments with weakly interacting fields typically involve determination of changes with respect to background values of, for instance, transmembrane voltage, fluorescence intensity, enzyme activity, or cell number. Observed changes in ''exposed'' relative to ''control'' are generally small. At the other extreme, strongly interacting fields create large changes with respect to background, for example, molecular uptake by electroporation (see Chapter 9 on electroporation in Ref. [127]). For the ''weakly interacting'' situation the uncertainties (error bars) are about the same for exposed and control. However, there is another figure of merit, distinct from the p-value, namely, an empirically determined signal-to-noise ratio $(S/N)_{obs}$, which is associated with the observation and which is presumed due to the underlying statistical distributions for the control and exposed cases. Classical detection theory shows that the associated distributions are expected to be Gaussians [17].

In continuation of a recent discussion [12], we consider the observed signal (S_{obs}) to be the difference between the control and the exposed means, and the observed noise (N_{obs}) as the standard deviation of the control distribution [17]. This yields

$$S_{obs} = \bar{x}_{exp} - \bar{x}_{con} \quad \text{and} \quad N_{obs} = \sigma_{con} \tag{7.2}$$

so that the empirically determined signal-to-noise ratio is the magnitude of

$$(S/N)_{obs} = \frac{\bar{x}_{exp} - \bar{x}_{con}}{\sigma_{con}} \tag{7.3}$$

Like the p-value $(S/N)_{obs}$ is a measure of the distinguishability of the two distributions. However, unlike the p-value, the signal-to-noise ratio is an inherent characteristic of the biological system, its environment, and a particular field exposure and does not depend on the number of determinations. In this view, S_{obs} is the observed change and is assumed to be a measure of the strength of the perturbation to the biological system by the field exposure. N_{obs} is a measure of the natural variability in the system for the conditions of the experiment. In the absence of an exposure, N_{obs} provides the appropriate scale to gauge the strength of S_{obs}.

$(S/N)_{obs}$ is based only on experimental determinations of x. However, in many cases the field exposure is believed to *indirectly* alter x. According to this general hypothesis, the field exposure affects one or more molecular-level biochemical processes through physical interactions. In this sense, the exposure is creating a ''primary'' molecular change, which is then amplified through a biochemical cascade that creates a downstream change. It is this downstream change that is eventually measured. The signal-to-noise ratio cannot be increased by the amplification process. Later in this chapter, we will describe how amplification generally adds noise to a signal.

7.4 Detection Criteria

The criterion $(S/N) \leq 0.1$ is a very conservative basis for ruling out a particular class of biophysical mechanism for a given field exposure. Similarly, the criterion $(S/N) \geq 10$ is a conservative basis for ruling in a candidate biophysical mechanism for a given exposure, retaining that biophysical mechanism hypothesis for further evaluation. This approach provides a quantitative basis for rejecting or accepting hypothetical biophysical mechanisms as candidate explanations for an experimental measurement. The traditional choice $(S/N) \approx 1$ is a useful but somewhat arbitrary dividing line, which indicates conditions for which an effect might appear. $(S/N) \leq 0.1$ and $(S/N) \geq 10$ provide criteria for stronger conclusions, allowing rejection or provisional retention of a biophysical mechanism hypothesis.

We should recognize that thresholds are defined by generally accepted statistical criteria. The widely used p-values of .01 and .05 are examples of such generally accepted statistical values. In the case of signal-to-noise ratios, a commonly accepted value is $(S/N) \approx 1$, where the approximately equal symbol denotes the imprecision. Specifically, if (S/N) (empirical or theoretical) exceeds 1, then the threshold is viewed as being exceeded. Similary, if (S/N) is less than 1, the response is interpreted as subthreshold. Clearly, it makes little sense to take a strong position if (S/N) is close to 1. But, as noted above, if the signal-to-noise ratio is significantly greater or less than 1, then some confidence can be attached to the result. In short, a threshold is imprecise but nevertheless a useful guide.

7.5 Equilibrium Noise

In this section we will examine how Brownian noise, the simple random motion of molecules due to thermal agitation, interferes with the coupling of an electromagnetic field to a biochemical system. Some organisms have evolved an ability to sense and effectively ''measure'' electric and magnetic fields. We will see that the thermal noise that a signal has to compete against sets fundamental limits on detectability. We will also see how evolution has come up with structures to optimize the signal-to-noise ratio in sensory perception.

Fish generally carry a small dipolar field relative to the water that they swim in. Sharks, skates, and rays have developed special organs to detect such fields [18,19] and they use this ability to pinpoint the position of their prey when they get close and the water is too turbulent to rely on smell. To be effective, the shark should be able to sense its prey

instantaneously. So, for the signal not to be mistaken for Brownian noise and for Brownian noise not to be mistaken as a signal, a signal should carry an energy that is significantly larger than *kT*. *kT* constitutes the average energy in the thermal noise band [20]. This baseline criterion already works to explain some of the physiology of the electric sensing organs. The electric fields are picked up by the ampullae of Lorenzini. These ampullae terminate at pores in the skin around the fish's head. They are enclosed in a highly resistive material and are filled with a very conductive gel. The eventual setup is equivalent to an electrical wire with no voltage drop inside. These ampullae are, furthermore, well insulated against electrical noise that originates from the fish's own physiology. Two pores that are about 10 cm apart on the surface of the fish's head can, on the inside ends, be separated only by a few nanometers. A field of 500 nV/m can be detected. Two pores that are 10 cm apart on the surface could thus transfer 50 nV into a transmembrane potential.

By having a lot of ion channels that are sensitive to such small voltage variations, the thermal noise can be effectively averaged out. With N ion channels instead of just one, N times as much signal strength is picked up. The thermal noise at each channel is independent of that at any other channel. The noise is zero-average and the noise variances are added up for N channels. So the average noise amplitude will be only $\sqrt{N}$ times as large if N channels are involved instead of one. After detection, the fish has to amplify this signal to the millivolt range that the nervous system operates with. Amplifier noise constitutes a problem that builders of electric circuits have dealt with for decades. Amplifier noise is nonequilibrium noise, and we will discuss it in the next section. Over the past decade, researchers have built up a good and detailed understanding of the physiology [21] and physics [22,23] of the fishes' amplification system.

Many animal species have the ability to detect the geomagnetic field. Two mechanisms have been proposed for magnetosensitivity. The first mechanism involves chemical transitions that are sensitive to external magnetic fields. Upon excitation by light, many polyatomic molecules will start transiting between the singlet ground state, the singlet excited states, and the excited triplet state. The energy difference between a singlet ($\uparrow\downarrow$) state and a triplet ($\uparrow\uparrow$) state is affected by an external magnetic field. This energy difference is generally small for fields of the magnitude of the Earth's magnetic field. But the magnetism that living cells generate is even smaller. A magnetically sensitive reaction of this type is therefore not subject to significant thermal noise. However, a detection limit can be established by considering a model in which reacting product molecules can bind to receptors. There is an innate stochasticity in chemical reactions; rates represent an average behavior, and there is a Gaussian distribution around this average. This is called fundamental chemical noise, and we will come back to it later in this chapter. In this model, the average number of occupied receptors varies with the magnetic field, and the detection limits are set by this fundamental chemical noise [24]. The fact that many bird species actually need light for their magnetic compass to work is a strong indication that singlet–triplet transitions are involved in the navigation. Recently, additional evidence was found when it turned out that robins get disoriented when they are subjected to an RF magnetic field that oscillates at the singlet–triplet resonance frequency [5] (for more details, see Chapter 6 on free radical models).

The second mechanism that has been proposed to explain magnetosensitivity involves the small (<100 nm in diameter) granules of magnetite (Fe_3O_4). This material, also known as lodestone, is biochemically formed and has about 30% of the magnetic strength of pure Fe. In the 1970 s, it was discovered that certain microbes use single-domain magnetite granules, also called magnetosomes, as a kind of rudder to help them stay under water right at the interface between the water and the mud at the bottom. There is a force trying to align the magnetic granule(s) with the Earth's magnetic field,

and the microbe thus ''finds out'' what its own orientation is relative to the inclination of the Earth's magnetic field [25,26]. For a single-domain magnetite granule of about 100 nm in diameter, the product μB of the magnetic moment μ and the Earth's magnetic field B amounts to about $5kT$. This $5kT$ alignment is sufficient to exceed the kT thermal agitation in the granule's rotation. In higher animals it appears that the granules are commonly embedded in biopolymers and lined up to form a rigid linear rod. Such an alignment effectively increases the magnetic moment and thereby the sensitivity to small variations in the magnetic field [27]. Indications are that there can be up to a million magnetite-containing cells in the brain of almost any animal. Even humans, who exhibit no apparent magnetosensitivity, have magnetite in their brain tissue [7,8].

The intensity of the Earth's magnetic field varies from 25 to 65 μT, and the direction varies from parallel to perpendicular to the Earth's surface. The magnetic sensitivity of, for instance, homing pigeons has been shown to be such that field variations smaller than 10 nT can be detected. With such a sensitivity the pigeon can use the change of the magnetic field vector to furnish itself a kind of global positioning system (GPS) [29]. Recent data indicate that some birds incorporate both magnetite and singlet–triplet chemistry in their magnetosense [5].

It is tempting to hypothesize that extremely low-frequency (ELF) radiation or microwave radiation could have a physiological effect through the interactions with magnetosomes. Cells produce their own electricity and concurrent electric noise. But there is no significant endogenous magnetic field noise. So the magnetic part of ELF radiation or microwave radiation would not have to compete against such endogenous biological noise. The average 24-h personal 60-Hz magnetic field due to house wiring, distribution lines, electric motors, etc., for individuals in the U.S. population is about 10^{-7} T [30], that is, orders of magnitude smaller than the earth's stationary magnetic field. Starting from this premise, the magnetosome in the cytoplasm was modeled as a damped harmonic oscillator with an external 60-Hz modulation [31]. The restoring force is the force pushing to align the magnetosome's moment with the earth's magnetic field, and the damping is due to the viscosity of the cytoplasm. The associated equation is easily solved. Using reasonable values for the involved parameters, it is was found that even with exposure to a 60-Hz field with an amplitude of 5 μT, the alternating field transfers an amount of energy to the magnetosome that is orders of magnitude smaller than kT. In other words, the thermal agitations in the rotation far overwhelm any ''signal'' from an ambient 60-Hz field. But subsequently, the legitimacy of a simple linear approximation was questioned [32]. It was pointed out that there are intricacies that make the viscosity of the cytoplasm, which determines the damping coefficient in the model, hard to specify. Most importantly, the possibility of many individual magnetosomes in a cell acting in concert should be considered. With N magnetosomes in a cell instead of just one, the signal-to-noise ratio is $\sqrt{N}$ times larger. The explanation for this apparent amplification is the same as with the aforementioned N ion channels in the shark's electroreception. An alternative model that includes such cooperativity leads to a signal-to-noise ratio that is well over unity with a 2-μT amplitude 60-Hz magnetic field [32]. However, almost nothing is currently known about how forces on magnetosomes are transduced into physiological signals. More solid estimates of detection thresholds can probably be derived only after such biophysical mechanisms are revealed.

Electric fields are also of interest. Close to a power line, a human can be exposed to an electric field of about 10 kV/m. Two steps have to be taken to get to an assessment of the transmembrane voltage that such an exposure leads to. First of all, living tissue is much more conducting than air. So, charge in the tissue will move and follow the external field until it is compensated. Depending on the amount of movable dipoles, different materials

have different dielectric permittivities. The ratio between the internal field and the field in the air is [33,34]:

$$\frac{E_i}{E_0} \approx \varepsilon_0 \omega \rho_t \tag{7.4}$$

Here $\varepsilon_0 = 8.8 \times 10^{-12}\ \mathrm{C^2/(N\,m^2)}$ represents the dielectric permittivity of a vacuum, ω is the angular frequency ($2\pi f$), and ρ_t is the resistivity of the tissue. So for a frequency of about 100 Hz and with a typical tissue resistivity of about 1–2 Ω m, the attenuation factor for the field entering the body is found to be in a range of 10^{-8}–10^{-7}. Hence, most of the external field goes around the person in the way water in a river flows around a big rock. Once inside the tissue, an amplification at the cell membranes occurs again through the mechanism explained in the previous paragraph. For a spherical cell with a diameter of about $d = 10\,\mu\mathrm{m}$ in a field E, the voltage across the diameter will be $\Delta V = Ed$, and the eventual field in the membrane will be of the order of $E_{\mathrm{mem}} \approx E(d/h)$, where h is the thickness of the membrane. With $h \approx 5\,\mathrm{nm}$ we find an amplification factor of about a 1000. We thus find a net conversion factor of 10^{-5}–10^{-4} and an electric field of about 0.1–1.0 V/m across a membrane as a result of the 10-kV/m power line exposure. This leads to an ELF-induced potential difference of at most 10^{-8} V across the membrane. It should, however, be noted that muscle cells or nerve cells are cylindrically shaped and may have lengths in the millimeter or even centimeter range. When the imposed field is along the axis of the cylinder, there may be a conversion factor at the caps of the cylinder that is two to three orders of magnitude higher.

When a living cell is suddenly exposed to an external electric field, ions will start flowing in the conducting interior to compensate for this field. In a typical mammalian cell, it is generally within microseconds that ions have accumulated near the membrane to achieve a zero intracellular electric field. This means that stationary electric fields and ELF (<300 Hz) AC fields distribute over cell membranes. Power lines and high-voltage distribution stations have been the subject of a lot of public anxiety. The power grid operates at 60 Hz in the United States and at 50 Hz in most other countries, that is, well within the ELF regime.

The 10^{-8} V that we derived may appear small relative to, for instance, the transmembrane potential of about 0.1 V that is present in about every living cell. However, when we talk about detectability, this 10^{-8} V should first be compared to the transmembrane voltages due to Brownian motion. The thermal noise voltage across standard resistors was already detected in the 1920s [35]. A formula was subsequently derived by Nyquist [36]:

$$\langle dV^2 \rangle = 4kTRdf \tag{7.5}$$

This equation gives the average square voltage in a frequency window of width df. The noise is white, that is, it has the same intensity at all frequencies. Technically, this would lead to an absurdity. It would imply that the noise carries an infinite amount of energy. However, as Nyquist already pointed out, $\langle dV^2 \rangle$ starts vanishing when we get to high frequencies f where $hf \approx kT$. Here, h represents Planck's constant, $h = 6.6 \times 10^{-34}\,\mathrm{J\,sec}$. At these high frequencies, quantum physics takes over and makes $\langle dV^2 \rangle$ go to zero. Such high frequencies are not in our realm of interest.

What Nyquist had in mind for a resistor in his derivation was a Brownian gas of frequently colliding charge carriers. With a 5-nm cell membrane that consists of a lipid bilayer with embedded proteins, the charge carriers are small ions (Na^+, K^+, Cl^-, etc.).

The ions do not form a ''gas'' inside the membrane, and it is not *a priori* obvious that Nyquist's formalism would apply. The equilibrium noise current through a membrane that separates two ionic solutions is due to two-sided shot noise. Shot noise was first described by Schottky [37] in the context of vacuum amplifier tubes. It is due to the elementary charge being finite and the charge carriers making random ''jumps.'' It can be shown that two-sided shot noise ultimately leads back again to Nyquist's Equation 7.5 [38,39]. Ultimately, Equation 7.5 is a manifestation of something much more general than Nyquist may have had in mind. What underlies Equation 7.5 is Einstein's fluctuation–dissipation theorem. This theorem says that the same random collisions that cause diffusion, thermal noise, or shot noise also cause dissipation, friction, or resistance. The theorem, moreover, makes this connection quantitative:

$$\beta = \frac{kT}{D} \tag{7.6}$$

For the motion of a macromolecule in a liquid, D is the diffusion coefficient and β is the coefficient of friction, that is, the ratio $\beta = F/\upsilon$, where F represents the pulling force and υ represents the resulting average speed. But in the context of the current through a membrane, β represents the electrical resistance ($R = V/I$). For D we find $D = e^2 P_S c$ in the membrane electrical case. Here, P_S is the membrane permeability to the monovalent ion S that is responsible for the current, c represents the concentration of this ion on both sides of the membrane, and e is the elementary charge.

Electrically, a cell membrane can be modeled as in Figure 7.1a. A lipid bilayer membrane has a capacitance of about 1 $\mu F/cm^2$. The capacitance of an actual cell membrane is generally not much different. The resistance of a pure lipid bilayer depends on the ionic concentrations of the solutions on either side of the membrane. With these concentrations at biological levels the resistance of a lipid bilayer membrane can be as high as $10^9\ \Omega\,cm^2$. Because of the presence of ion channels, ion transporters, and ion pumps [40,41], an actual cell membrane has a resistance that is orders of magnitude smaller (typically about $10^3\ \Omega\ cm^2$). The resistance of a patch of membrane is inversely proportional to the area of that patch. So, in order to characterize a membrane, the approach is to measure the resistance through an actual patch and then multiply it with the surface area of that patch. That is why we give the resistance of a membrane in terms of $\Omega\ cm^2$.

The setup in Figure 7.1a is equivalent to the one in Figure 7.1b, that is, an ordinary RC circuit. When calculating the characteristic time, RC, of the circuit, the surface area cancels

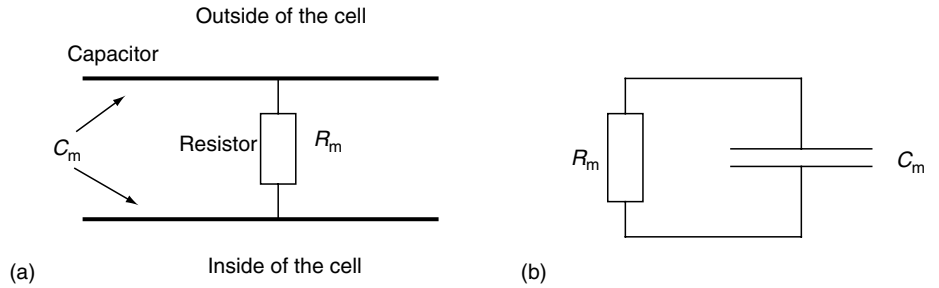

FIGURE 7.1
The electrical structure of the membrane is shown on the left. R_m and C_m are the resistance and capacitance between the inside and outside of the cell, respectively. The resistor also provides a thermal electromotive force. The equivalent circuit is shown on the right.

out. For a pure lipid bilayer the *RC* time constant can be of the order of minutes. But for a cell membrane it is of the order of milliseconds.

In our context, the resistor in Figure 7.1 is not just a resistor, but, following Nyquist (cf. Equation 7.5), also a white noise generator. At each frequency the resistor generates a harmonic oscillation. All these harmonic oscillations have the same amplitude. To evaluate the voltage across the capacitor, we thus have to analyze a simple *RC* circuit with an AC source. It has been argued that the high frequencies, that is, $f > (RC)^{-1}$, that are generated in the resistor do not have enough time to build up across the capacitor [42]. However, for low-frequencies, that is, $f < (RC)^{-1}$, changes are sufficiently slow for the capacitor to keep up and follow the voltage in the resistor. In this view the transmembrane voltage is the voltage across the capacitor, and the equilibrium noise is thus expected to occur mostly at low-frequencies. As mentioned before, the *RC* time of a cell membrane is of the order of milliseconds, and ELF fields thus operate in the $f < (RC)^{-1}$ regime where the noise is largest. A straightforward quantitative analysis shows that the low-frequency equilibrium noise far overwhelms any reasonable ambient power frequency field [42]. There would be no way to ever instantaneously detect such a field.

It was later put forward that everything that is happening in the cell membrane should, in the model of Figure 7.1, be imagined to happen inside the resistor [43]. Membrane proteins go through their catalytic cycle against a background of intramembrane noise. Inside the membrane means, in the context of Figure 7.1, inside the resistor. In this picture, the thermal noise voltage (cf. Equation 7.5) derives from a net electric field that results from inhomogeneities in the distribution of the charge carriers. Now at low-frequencies, the capacitor will be able to follow the imposed oscillation and effectively produce a field to counter the field generated inside the resistor (Figure 7.1a). This model thus leads to a vanishing net potential inside the membrane at low-frequency. At high frequency, the voltage changes in the resistor are too fast for the capacitor to keep up with. The capacitor will remain uncharged, and the thermal AC voltage will not be compensated for.

However, Figure 7.1 is no longer the appropriate model when we try to derive the intramembrane electric fields. For a cell of about 20 μm in diameter, the surface area amounts to about a billion square nanometers. The membrane is only about 5 nm thick, so the resistor resembles a very thin sheet. The lateral conductivity, that is, the conductivity from one place on the sheet to another, is very low. So at different spots on the sheet, different unrelated noise fields are generated. The more sensible model would therefore be one where the resistor in Figure 7.1 is cut up into millions of independent parallel resistors. Each of these resistors creates its own field. The capacitor plate corresponds to the conducting liquid on either side of the membrane, and it can be conceived of as having perfect lateral conductivity. So each resistor generates its own particular field, but they all experience the same field from the capacitor. With this model the noise gets very large. Not only there are more, say *N*, resistors producing noise. Each of these resistors has a resistance *NR* (*N* parallel resistors of resistance *NR* lead to a net resistance of *R*) and, according to Equation 7.5, thus produces more noise. Because the *N* parallel resistors that make up the resistance *R* are independent, they oscillate out of phase at each frequency *f*. As a result the parallel resistors end up pushing a lot of current in and out of each other. Most of the generated noise current thus remains intramembrane and never reaches the capacitor. The mathematics associated with this parallel setup is challenging, but an exact solution can be derived [39,44]. The capacitor, and therefore the *RC* time, plays no role in the intramembrane noise. The intramembrane noise is white and has an intensity that is many orders of magnitude larger than the noise that reaches the capacitor. What matters for biological function is actually the intramembrane noise. This, after all, is the noise that a membrane-embedded protein would ''feel.'' The protein's catalytic cycle takes place

against the background of such noise. The parallel setup model leads to a noise intensity that is much larger than that of the earlier models.

At first sight, all this extensive treatment of intramembrane noise may seem to have little to do with the two-sided shot noise that a membrane is subject to. However, when rigorously modeling the membrane as a thin sheet in an ionic solution, something similar to the overwhelming intramembrane noise is found. The ions that constitute the net charge on the membrane in Figure 7.1a move across the membrane–solution interface with an average speed of about 100 m/sec. This is just their thermal motion, and it is easily derived from $(1/2)mv^2 \approx kT$. This effectively causes laterally traveling electric pulses in the membrane. The noise intensity of these traveling electric pulses appears to be many orders of magnitude higher than the noise that is due to the shot noise-like membrane passages by the ions [39].

Current models of membrane noise thus lead to transmembrane voltage noise estimates that far exceed the strength of any reasonable magnitude ELF field-induced ''signal.'' What the previous paragraphs lead up to is the conclusion that an ELF signal cannot be detected instantaneously.

However, under certain conditions and given enough time, even the smallest signal can get out of the noise band. The following example is meant to illustrate this. Consider the system depicted in Figure 7.2. Let the the resistance R represent a membrane patch. For simplicity, imagine that on either side of the resistor there is an infinite reservoir (i.e., a capacitor with infinite capacitance), so no net voltage can develop across the resistor. The average square charge $\langle q^2(t)\rangle$ that accumulates on either side of the membrane can be easily derived from Equation 7.5 and amounts to

$$\langle q^2(t)\rangle = \frac{2kT}{R}t \tag{7.7}$$

Again, there is an obvious analogy between Equation 7.7 and the well-known diffusion formula $\langle x^2(t)\rangle = 2Dt$, which describes the average square displacement of a particle with a diffusion coefficient D during a time interval of length t. The above formula clearly shows how, in an electrical context, kT/R plays the role of the diffusion coefficient D.

From Equation 7.7 we infer that for the accumulated charge as a function of time we have $|q_{\mathrm{Br}}(t)| \approx \sqrt{\langle q^2(t)\rangle} \propto \sqrt{t}$. The thermal noise-driven accumulation of any charged or uncharged molecule on either side of the membrane carries this $\sqrt{t}$ proportionality. The coupling of ELF electromagnetic fields to biochemical activity occurs mostly through

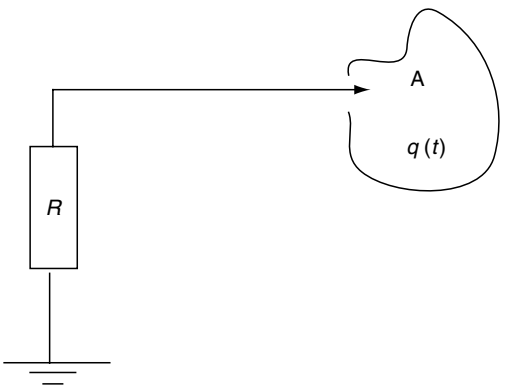

FIGURE 7.2
A resistor is connected to the ground and to an infinite reservoir A. The net voltage between the reservoirs remains zero. The situation is like the one in Figure 7.1 with the capacitor having infinite capacitance. Because of Brownian motion of electrons in the conduction band, there is a zero-average fluctuating current through the resistor. The net charge accumulating in the reservoir A is the result of these fluctuations in the same way that diffusive displacement is the result of random Brownian kicks. We have $\langle q^2(t)\rangle = 2(kT/R)t$ for the average square charge accumulation in time t.

membrane proteins. Membrane proteins whose conformational changes involve significant changes of the dipole moment are particularly sensitive. ELF fields can affect the catalytic rates of such proteins. So, for instance, electrogenic ion pumps [41], and also transporters or pumps that just carry a dipole, may have a slightly altered throughput in the presence of an ELF field. If there is no restoring force for a transported or pumped molecule, the accumulation will continue. The cumulative effect of the altered throughput will be a linear function of time. The excess charge that accumulates because of an ELF field thus follows $q_{\mathrm{ELF}} \propto t$.

Consequently, we see that on a small timescale the Brownian noise ($\propto \sqrt{t}$) will be stronger than the signal ($\propto t$). But there will always come a time $t = t_*$ when $|q_{\mathrm{B}r}(t_*)| = |q_{\mathrm{ELF}}(t_*)|$, and we then achieve S/N = 1. It depends on the values of the proportionality constants when t_* occurs. If molecular change is the measurement criterion, then it is only on timescales of the order of t_* that the effect becomes measurable. Estimates for t_* with realistic ELF exposure have been made [45] and have led to a timescale larger than the age of the universe.

7.6 Nonequilibrium Noise

In the previous section, we considered equilibrium noise. A living cell, however, constitutes a system that is far from equilibrium. Between the intracellular and extracellular solutions there is an electric potential difference of about 100 mV. For ions like Na^+, K^+, Cl^-, and Ca^{2+} there is a more than tenfold difference between intra- and extracellular concentration. The 100-mV transmembrane voltage over a width of about 5 nm implies a very strong field of tens of megavolts per meter.

The electrochemical potential across the cell membrane is an energy source for many processes [41]. The Na, Ca exchanger, for instance, is a membrane protein that picks up a sodium ion on the outside and then goes through a cycle in the course of which it drops the sodium ion off on the inside. The protein couples the energetically downhill movement of sodium to the uphill transport of calcium. In the course of the cycle a calcium ion is picked up on the inside and pumped, against the electrochemical potential, to the outside. The membrane potential is maintained by ATP-driven ion pumps. The most common of these is Na, K-ATPase. This is a membrane protein that, in the course of its catalytic cycle, hydrolyzes one ATP and uses the released energy to transport three sodium ions out of the cell and bring two potassium ions in.

Each working protein is like a small engine. A living cell contains millions of these engines: they are continuously converting energy from one form to another, and in the process, they are also generating heat, that is, dissipating energy. A living cell constitutes a far from equilibrium system, and the continuous transduction and dissipation of energy generates noise, which adds to the thermal, Brownian noise that was discussed in the previous section.

It would not be against the first law of thermodynamics (i.e., conservation of energy) if ion pumps were to extract heat from the environment and use it to power the maintenance of the transmembrane potential. This would, however, be in gross violation of the second law of thermodynamics. There are many equivalent formulations of the second law. The most common formulation is the proposition that every isolated system strives to increase and maximize its entropy. The teleological form of this formulation is somewhat bewildering. After all, most laws in science are formulated as conservation laws, for

example, conservation of energy, or as causal laws, for instance, Newton's $F = ma$. However, after properly defining entropy, entropy maximization is often the easiest form of the second law to work with when dealing with macroscopic systems.

When going to the molecular realm, the second law can pose some challenging paradoxes. Consider, for instance, an ion channel in a cell membrane. Many ion channels rectify, that is, they pass current more easily in one direction than in the other. So the I–V characteristic is not a straight line through the origin, but it also has a curvature. Any frequency from the white spectrum of equilibrium noise should, in principle, be rectified. It thus might look like a rectifying ion channel could use zero-average equilibrium Nyquist noise to charge a battery. It would not work, of course. As pointed out above, it would be in violation of the second law. Thinking in the context of rectifying p–n junctions, solid-state physicists ran into this paradox long before ion channels were discovered. In 1950, L. Brillouin wrote a paper ''Can the Rectifier Become a Thermodynamic Demon?'' [46]. In this paper, he presents a short derivation to show that in a circuit with all components at the same temperature, no diode can rectify. He is aware that his case represents a special case of the so-called principle of detailed balance: ''No system in thermal equilibrium in an environment at constant temperature spontaneously and of itself arrives in such a condition that any of the processes taking place in the system by which energy may be extracted, run in a preferred direction, without a compensating reverse process.'' The principle is a consequence of the second law [47,48] and, for our rectifier, basically states that there must, on average, be as much current in one direction as there is in the opposite direction.

In the *Feynman Lectures on Physics* [49] a ratchet and pawl system, originally thought up by Smoluchowski [50], is considered and eloquently discussed. The device operates as a mechanical rectifier (Figure 7.3) and essentially establishes the mechanical equivalent of Brillouin's paradox. The paradox is solved with the realization that the pawl must also be

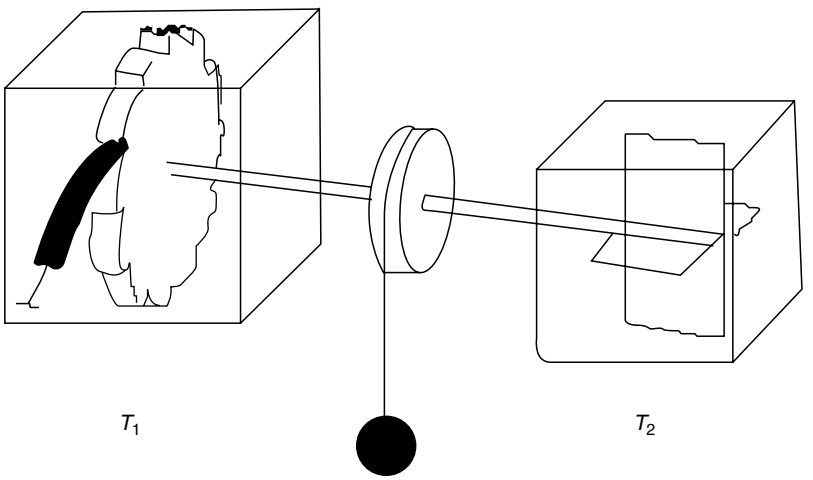

FIGURE 7.3
The mechanical thermal ratchet as it was originally conceived by Smoluchowski [50] and later discussed by Feynman et al. [49]. The device is small, and the paddle wheel in the right reservoir is moved by collisions of the molecules from the surrounding medium against the paddles. Because of the asymmetry of the teeth, the ratchet and pawl in the left reservoir allow motion in one direction and block it in the opposite direction. With the resulting net rotation it should be possible, in principle, to lift a weight. However, it would be in violation of the second law of thermodynamics to extract work from thermal fluctuations in the equilibrium situation, that is, $T_1 = T_2$. The solution of the paradox lies in the realization that the ratchet and pawl are also subject to thermal fluctuations if the system is small.

subject to thermal noise. The pawl involves a spring, and the spring will, at thermal equilibrium, exhibit a Boltzmann distribution over the accessible energy range. Even here the second law is involved, though on a deeper level. Given the macroscopic variables (e.g., temperature, concentration, pressure, etc.) there are still many possible molecular arrangements, that is, microstates, that correspond to that macrostate. For a fixed amount of energy the Boltzmann distribution is the energy distribution that has the most permutations [20]. It is therefore the most likely distribution. On the level of statistical mechanics, the second law can be formulated as the rule that given a macrostate, every microstate that corresponds to that macrostate has equal probability.

Second law issues can be subtle. The connection between statistics, entropy, information, and physical work still poses paradoxes that are hard to fathom. Books and articles still appear in which researchers are attempting to come to a fuller understanding and a better intuition [51,52]. At the scale of ion channels the simple invocation of detailed balance reveals little. An appropriate description is like the one Feynman gave for his mechanical ratchet and pawl: it involves Boltzmann distributions and Brownian motion. So it would simply be wrong to take any frequency from the white spectrum of equilibrium noise and model a rectifying ion channel as subject to this oscillation. The ion channel itself and its Brownian fluctuations have to be included in the description. At equilibrium, no part of a system can be ''subject'' to any other part. This is what detailed balance can be interpreted to mean.

However, when energy is dissipated, it is possible for one part of the system to impose its fluctuations on another part. When a rectifying ion channel is subject to nonequilibrium fluctuations, it will actually rectify the fluctuations and drive a net current. Consider, for instance, an electrogenic ion pump like Na,K-ATPase. As was mentioned before, this pump utilizes the energy of ATP hydrolysis to pump three sodium ions out and pump two potassium ions in. All this transport is against the electrochemical potential and requires about $15kT$ units of energy per stroke under physiological conditions. The power source is the hydrolysis of ATP, which under physiological conditions, releases about $20kT$ units of energy per cycle. It is the remaining $5kT$ that drives the process forward and that is ultimately released as heat. Na,K-ATPase is binding and releasing ions and thus generates fluctuating electric fields in its direct vicinity. For a nearby ion channel these fields can be conceived of as imposed because the $5kT$ that drives the Na,K-ATPase cycle is enough to overwhelm the small amount of energy ($<1kT$ [53]) necessary for the opening or closing of a channel. There is no feedback from the channel to the pump. The channel will rectify the fluctuations as a result, and a zero-average field can thus lead to net charge transport. In essence, the nonequilibrium fluctuations generated by the pump and imposed on the channel are part of the conversion of chemical energy, that is, the energy in ATP, to an electrochemical potential across the membrane.

So energy-dissipating, nonequilibrium oscillations and fluctuations are able to do work. ELF radiation from outside the organism can impose a varying field on an ion channel in much the same way that the nearby ion pump from the previous paragraph can impose a field on an ion channel. ELF radiation brings energy into the organism. Part of this energy will be dissipated to become heat, and part of it may be converted into chemical or electrical work. There is obviously no feedback from an ion channel back to the ELF source.

The selectivity of ion channels for the different kinds of ions is still hard to understand and model. But the rectification property is much easier to intuit (Figure 7.4). The channel is shaped like an asymmetric double cone, and charges in the lining of the channel are

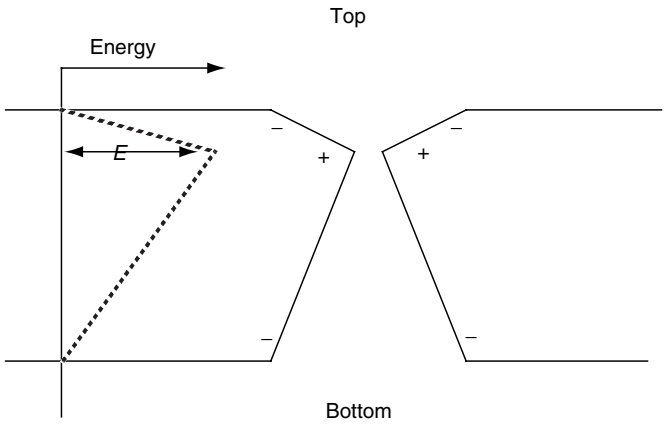

FIGURE 7.4
A simple continuum model of an ion channel imagined to be shaped like an asymmetric double cone. The energy profile on the left depicts the activation barrier that a positive ion going through the channel has to pass. The barrier has an obvious anisotropy.

indicated in the figure. A sodium or potassium ion that is going from the top to the bottom of the channel faces a rapid increase of the potential and then a slow decrease. A sodium or potassium ion that goes through in the opposite direction faces a slow increase and a fast subsequent decrease. A positive ion thus has a larger force to overcome when going from top to bottom than when going from bottom to top. Because of this, an imposed zero-average oscillation will lead to a net current [54]. As a matter of fact, any anisotropic potential shape along the length of the channel will rectify a zero-average harmonic field to lead to a net current [55]. Ion channels are proteins consisting of many amino acids, and anisotropy along the inside lining will be the rule rather than the exception.

The plethora of ratchet research in the late 1990s has made it clear that almost any zero-average oscillation or fluctuation imposed on a ratchet-like structure as in Figure 7.4 leads to a net current. Imagine, for instance, a temperature oscillation. With energy expressed in units of kT, a variation in temperature implies an oscillation of the barrier height E. Because of the difference in relaxation times on the slopes on either side of the barrier, a net current will result [55–58]. Recently, ever more examples have been found of nature exploiting ratchet effects for the purpose of regulation [59].

Researchers have meanwhile also succeeded in making artificial channels. Cone-shaped (and therefore anisotropic) channels form when a heavy ion is shot through an artificial membrane [60,61]. The I–V characteristic for the current of different types of ions has subsequently been recorded. It has even been experimentally shown that net charge transfer results when a zero-average field is imposed on such an artificial channel. The channel is thus made to behave like a kind of pump that converts an AC input into a DC output [62].

Imagine a number of identical anisotropic channels in a vesicle with an otherwise impermeable membrane. Next, put a large number of such vesicles in a beaker with an ionic solution. Any nonequilibrium fluctuation from the environment, or any ''signal'' for that matter, will now be picked up and converted into an electrochemical potential. The convection caused by a temperature gradient will heat up and cool down the vesicles and lead to their electrically charging up. The electric component of an ELF electromagnetic field will do the same thing. The beaker could thus be a battery that recharges by harnessing any incoming nonequilibrium fluctuation. This mechanism might, moreover, have played a role in the emergence of early prokaryotic life.

The Fourier spectrum of the noise that is associated with processes that dissipate energy is not white. Nonequilibrium noise appears to have higher amplitudes at lower frequencies; in other words, it exhibits an intensity that decreases with frequency. The so-called $1/f$ noise was first studied in the 1920s in the very nonequilibrium context of thermionic vacuum tube amplifiers [37]. In current scientific discourse the term ''$1/f$ noise'' actually applies to all noises that have spectral densities behaving like $1/f^{\alpha}$, where α ranges from about 0.5 to about 1.5. Especially in electrical devices, such noise is very commonly and easily observed. It is also known as ''excess noise'' or ''flicker noise.'' In a log–log plot the $1/f^{\alpha}$ behavior usually extends over several frequency decades.

In the 1930s, it was proposed that the flicker noise originated from a variable number of electrons present in the conduction band. Electrons would shuttle between a free state and a bound state as in a chemical reaction. Let the relaxation time of that reaction be $1/\lambda$. This leads to a simple exponential relaxation $N(t) = N_0 \exp[-\lambda t]$ after any kind of fluctuation that has a magnitude N_0. The Fourier transform of the exponential decay is easily found:

$$F(\omega) = N_0 \int_{t=0}^{\infty} \exp\left[-(\lambda + \mathrm{i}\omega)t\right] \mathrm{d}t = \frac{N_0}{\lambda + \mathrm{i}\omega} \tag{7.8}$$

For the power spectral density, $S(\omega) = \|F(\omega)\|^2$, we find:

$$S(\omega) \propto \frac{1}{\lambda^2 + \omega^2} \tag{7.9}$$

where the proportionality constant involves the magnitudes of the fluctuations as well as the rates at which fluctuations occur. The power spectral density is a useful quantity as it describes how the energy in the noise is distributed over the different frequencies. $S(\omega)\mathrm{d}\omega$ is proportional to the amount of power that the noise carries between the frequencies ω and $\omega + \mathrm{d}\omega$. Equation 7.8 describes a so-called Lorentzian power spectrum. With a log scale for the frequency, the resulting curve is a sigmoid. At high ω, $S(\omega)$ behaves like $1/\omega^2$. As better data became available, it was found that a better fit was obtained when a distribution of infinitely many relaxation times was assumed [63]. Take, for instance, a uniform distribution of relaxation times between λ_1 and λ_2. With Equation 7.9 this leads to:

$$S(\omega) \propto \frac{1}{\lambda_2 - \lambda_1} \int_{\lambda_1}^{\lambda_2} \frac{1}{\lambda^2 + \omega^2} \mathrm{d}\lambda = \frac{1}{\omega(\lambda_2 - \lambda_1)} \left\{ \arctan\frac{\lambda_2}{\omega} - \arctan\frac{\lambda_1}{\omega} \right\} \tag{7.10}$$

It is easy to check that on $\lambda_1 < \omega < \lambda_2$ this $S(\omega)$ is approximately proportional to $1/(\omega(\lambda_2 - \lambda_1))$. This $S(\omega)$ is, moreover, roughly constant for $\omega < \lambda_1$ and drops off like $1/\omega^2$ when $\omega > \lambda_2$.

If we let, between λ_1 and λ_2, the relaxation rates contribute proportional to $\lambda^{-\beta}$, we can actually get any $1/f^{\alpha}$ dependence that we want, since

$$S(\omega) \propto \int_{\lambda_1}^{\lambda_2} \frac{1}{\lambda^{\beta}(\lambda^2 + \omega^2)} \mathrm{d}\lambda \propto \frac{1}{\omega^{1+\beta}} \quad \text{for } \lambda_1 < \omega < \lambda_2 \tag{7.11}$$

At $\omega < \lambda_1$, this spectrum would again flatten out.

In experimental practice with electrical resistors and amplifiers the $1/f^{\alpha}$ behavior has been observed to extend over more than six frequency decades with no noticeable flattening at low-frequency [64].

$1/f^{\alpha}$ spectra have been observed in nature in a wide variety of systems: electrocardiac waves [65], the variation of sea levels [66], tardiness at work [67], etc. An essential feature of $1/f^{\alpha}$ noise is that it exhibits self similarity, that is, if one magnifies both time and space with the appropriate factor, the noise pattern is indistinguishable from the original one. So the noise does not have a characteristic timescale or length scale. $1/f$ noise is often seen as a signature of the fractal character of nature.

In 1987, Bak et al. [68] proposed a model for a universal mechanism behind $1/f$ noise. In their landmark paper they illustrated the concept of ''self-organized criticality'' with a sandpile model. When a sandpile has an inclination steeper than a critical angle θ, avalanches will occur that bring the pile back to the critical angle. When sand is added to the pile in a random fashion, these avalanches do not exhibit a characteristic size, nor do they appear after regular time intervals. Instead, there are bigger avalanches that are relatively rare and smaller avalanches that occur more frequently. The size distribution follows a power law in the frequency f. For instance, in one day there can be one avalanche involving more than 1000 grains, 10 involving more than 100 grains, 100 avalanches involving more than 10 grains, and so on. The picture that emerges is one of a system that is sitting on the critical edge between two phases and is ''organizing'' avalanches to stay there [69]. The most commonly cited real-life example of self-organized criticality is the Gutenberg–Richter power law for earthquakes. It appears that every year, on average, there is one earthquake larger than magnitude 8, 10 earthquakes larger than magnitude 7, and 100 earthquakes larger than magnitude 6. Self-organized criticality is an attractive theory. It proposes a simple mechanism and predicts power laws that can be easily verified or falsified. It has been utilized in a wide variety of contexts [69]. It has, for instance, been applied to evolutionary theory [70] and has been used to explain frequency-size distributions of forest fires [71].

How truly universally applicable self-organized criticality is and to what extent its claims may be unwarranted are matters that are still very much under debate. The $1/f$ proportionality for earthquakes applies only between magnitudes 5 and 8. Even for the archetypal sandpile, things turn out to be more involved upon close inspection than self-organized criticality suggests. Accurate measurements [72–74] on real sandpiles showed that in many cases there is no $1/f$ pattern in the avalanches. It turns out that system parameters, like the grain size and the rate of sand addition, determine to a large extent what kind of spectrum eventually emerges. The entire concept of self-organized criticality collapses, of course, if fine tuning by the experimentalist is crucial for the $1/f$ spectrum to materialize. All in all, $1/f$ noise is not as universal as first thought, and the dynamics behind nonequilibrium noise are usually best unraveled with *ad hoc* models.

The node of Ranvier is where the action potential for myelinated nerve cells is generated [75]. There is a high concentration of ion channels in the node of Ranvier, and in the days before patch clamp, it was a good place to record membrane electrical activity. In the mid-1960s, Verveen and Derksen measured 5–10 min of cell membrane voltage noise at a Ranvier node of an unstimulated nerve cell [76,77]. The resulting power spectrum showed two decades, between 10 Hz and 1000 Hz, of $1/f$ noise (see Figure 7.5). This $1/f$ noise, they found, was much larger in magnitude than what Nyquist's $4kTR$ formula (cf. Equation 7.5) would predict. Following the explanation for $1/f$ noise in ordinary resistors (cf. Equation 7.10 and Equation 7.11), Verveen and Derksen suggested that an ion channel could, from time to time, get ''clogged up.'' The wide distribution of waiting times (i.e., the λs in Equation 7.8 through Equation 7.11) before getting unclogged would then give rise to the $1/f$ spectrum [78].

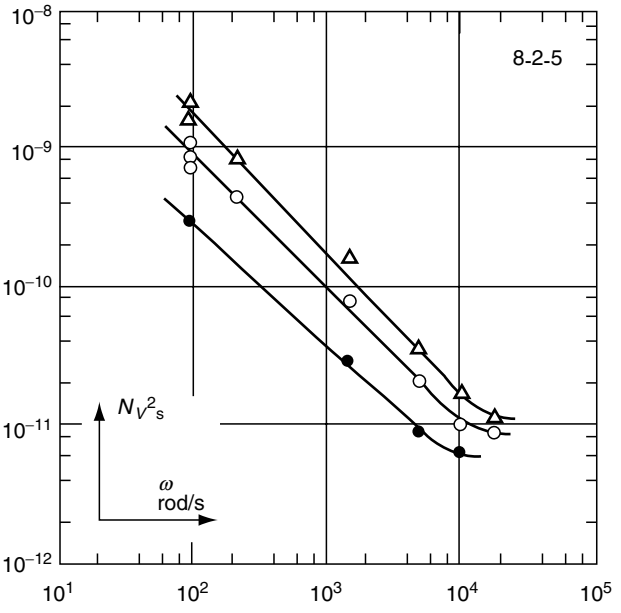

FIGURE 7.5
The voltage noise spectral densities from the frog node of Ranvier at room temperature at rest (open circles), at 10-mV depolarization (open triangles), and at 10-mV hyperpolarization (filled circles) [76,77]. (© Dutch Physiological Society. With permission.)

In the last two decades, single-channel recordings have shown how, even without stimulus, ion channels open and close repeatedly [40,75]. The kinetics behind the openings and closings is still very much a matter of debate. Modeling an ion channel as a two-state molecule with an open and a closed state and chemical steps with constant rates connecting these states appears not to account for the data in many cases. Electrophysiologists have commonly resorted to explaining the nonexponential distributions of open and closed times with a kinetic scheme that contains more than two states. With such an approach any distribution of open and closed times can always be fitted with a kinetic scheme [79–81]. It is just a matter of coming up with sufficiently many parameters (i.e., states and rates) to fit the data. In chemical kinetics the transitions are always assumed to be Markov transitions, that is, the probability of moving from a state 1 to a state 2 is constant and does not depend on the time that the molecule has been in state 1. A channel that is making such Markov transitions between a finite number of states always exhibits a power density spectrum that is a sum of Lorentzians. The number of characteristic times in the spectrum will always be one less than the number of states. If the characteristic times are sufficiently far apart, the power density spectrum will exhibit a number of identifiable plateaus when plotted on the customary logarithmic scale. The inflection points between the plateaus occur at the inverses of the characteristic times.

An alternative approach, foreshadowed by the aforementioned suggestion of Verveen and Derksen, has been to model the open to closed transition rates of an ion channel as time dependent, for instance $k(t) \propto t^{-\mu}$, where $0 < \mu < 1$ [82–85]. The exponent μ is taken to be smaller than unity to make $\int_{\tau}^{\infty} k(t)\, dt$ diverge for all $\tau > 0$ and thus guarantee the inevitability of an eventual transition. The proportionality $k(t) \propto t^{-\mu}$ leads to a decreasing transition probability, that is, the channel is ''stabilizing in its openess,'' as more time is spent in the open state. There is ample justification for the use of open–closed transition rates that vary in time. A protein has many degrees of freedom and is subject to many equilibrium and nonequilibrium fluctuations. If an intramolecular rearrangement, like a transition between an open and a closed state, can be modeled as the crossing of an

activation barrier, then that barrier will most likely not be fixed and stationary. A fluctuating barrier implies fluctuating open–closed transition rates. We could thus get the infinitely many relaxation rates that give rise to the $1/f$ power density spectra of Equation 7.10 and Equation 7.11. Under physiological conditions an ion channel is trafficking ions in an electric field of tens of megavolts per meter and comparable chemical gradients. This is a very nonequilibrium setup, and it has been conjectured that the channel operates as a self-organized critical structure. One authoritative textbook [65] states it as follows:

> A channel protein may be a self-organizing critical system. The channel protein consists of many pieces that interact with their neighbors. The energy added to the protein from the environment causes local strains that are spread throughout the structure. If these distortions spread faster than the time it takes for the structure to thermally relax, then the channel protein may be a self organizing critical system. If that is the case, then the fluctuations in the channel structure will be due to a global organization of the local interactions between many small interacting pieces of the channel protein. The fractal scaling would then be due to the fact the channel structure is poised at a phase transition between its open and closed conformational shapes.

Over the past few years increasing amounts of data have been gathered with ever more accurate technology. Recently, the $1/f$ power spectral density of a nerve cell that Verveen and Derksen discovered was more accurately rerecorded [86]. But through careful subsequent experimentation and computer simulations, these researchers were also able to show how the apparent $1/f$ result comes about as the sum of a number of Lorentzian contributions. Each type of channel has its own Lorentzian, and because of close characteristic times the sum of the individual sigmoids appears like a smoothly decreasing $1/f$ curve.

For a single channel, things often turn out to be much more intricate than simple $1/f$ versus Markov kinetics. In single-channel recordings of a bacterial ion channel it was found that actual channel openings and closings follow Markov kinetics and lead to Lorentzian contributions to the ultimate net power spectrum [87]. The $1/f$ noise that is present in the power spectrum originates from transitions between open states of a slightly different (about 1–5%) conductance. The rates of these miniconductance transitions appeared to be independent of the transmembrane voltage. The small transitions in conductance have been conjectured to be due to small clusters within the channel's structure moving in and out of the lining of the pore [87]. A cluster can cause a partial flow constriction when it sticks out into the pore. Following this idea, the apparent $1/f$ behavior can be attributed to many different clusters moving in and out with equally many different relaxation times. The voltage independence comes about because these clusters are either uncharged or the external electric field is somehow screened. Noise in synthetic channels has also been studied [88]. There it was found that potassium currents through a one-state, permanently open channel exhibit $1/f^2$ noise. An artificial channel that can open and close, on the other hand, was found to exhibit $1/f$ noise when the externally applied voltage is in the right regime. With this latter artificial channel there is good ground to attribute the open–closed transitions to the movement of ''dangling ends'' of polymers in the pore's lining. So the result supports the ''moving cluster'' for the mechanism behind $1/f$ noise in channels.

There appears to be no simple theory that can convincingly bring all manifestations of $1/f$ noise under one common denominator. All the indications are that an *ad hoc* approach to nonequilibrium noise phenomena is still the most fruitful one.

In ordinary resistors the amount of $1/f$ noise grows linearly with the dissipated power W. If we take $S(\omega)\,\mathrm{d}\omega$ to denote the power in energy per unit of time (watts) in an interval $\mathrm{d}\omega$, then we have for the power spectral density:

$$S(\omega) = \frac{gW}{f} \tag{7.12}$$

Here, g is a dimensionless constant the value of which depends on the type of resistor.

Nyquist noise is simple in that the net value of the resistance R fully determines the noise amplitude. With $1/f$ noise a more complex situation arises. Experimentally, the constant g (cf. Equation 7.12) turns out to be proportional to the volume-to-power ratio [89]. In Figure 7.6 the four resistors in design (b) are identical to the one resistor in design (a). It is obvious that (a) and (b) will have the same net resistance and therefore the same amount of Nyquist noise. Design (a), however, will exhibit four times as much $1/f$ noise as design (b). Design (b) is quieter because the energy dissipation is distributed over a larger volume. Generally, we have $g \propto 1/V$, where V denotes the resistor's volume. The gW in Equation 7.12 can be expressed as $g_\mathrm{e}w$, where g_e is the g-value for a single elementary charge carrier in the resistor and w is the energy dissipated in the volume of such a single, independent charge carrier.

Pumps and carriers move ions one by one. Imagine a single pump or carrier that moves ions across the membrane at a rate ν. During a small time interval $\mathrm{d}t$ there is a probability $p = \nu\,\mathrm{d}t$ that an ion is transported. We take $\mathrm{d}t$ to be sufficiently small so that the probability of more than one ion being transported during $\mathrm{d}t$ is negligible. We also take the duration of the catalytic cycle, that is, the ''processing'' time for an ion going through the membrane, to be negligible in comparison to the time between catalytic cycles. If we were not to make the latter assumption, we would simply have to multiply by the probability that an average channel is available for transport when we want to express the transport rate. For the average number of ions $\langle n\rangle_{\mathrm{d}t}$ transported by the channel in time $\mathrm{d}t$, we now have $\langle n\rangle_{\mathrm{d}t} = 1 \cdot p + 0 \cdot (1-p) = p$. For the variance we have $\sigma_{\mathrm{d}t} = \langle n^2\rangle - \langle n\rangle^2 = 1^2 \cdot p - (1 \cdot p)^2 = p(1-p)$. For M subsequent timesteps and $M\,\mathrm{d}t = T$, the variances add up, and we have $\langle n\rangle_T = Mp$ and $\sigma_T = Mp(1-p)$. So the standard deviation, $\sqrt{\sigma_T}$, works out to be proportional to $\sqrt{M}$. Over time the standard deviation becomes more and more negligible compared to the average. For sufficiently small $\mathrm{d}t$ we can take $1-p$ to be equal to 1, and we then have a variance that equals the average.

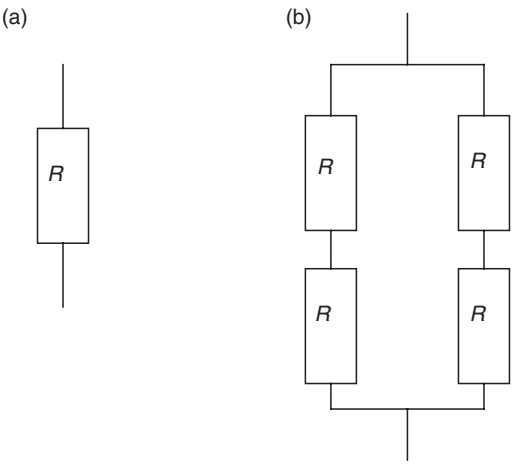

FIGURE 7.6
Design (a) and design (b) both have a net resistance R. They are different in that design (b) actually consists of two parallel resistors of $2R$. Designs (a) and (b) will exhibit the same amount of equilibrium noise, as it is only the net resistance (cf. Equation 7.5) that determines the equilibrium noise amplitude. It appears, however, that design (a) has four times as much power spectral density as design (b). The amount of nonequilibrium noise is proportional to the current density.

In the textbook by DeFelice [89] it is shown how the power spectral density of the process above amounts to $S(f) = 2\sigma_T/T = 2\nu$. The frequency-independent power spectrum can be intuited as follows. If the actual transport time through the membrane is small, then we can conceive of the transmembrane current as delta function-like pulses occurring at a rate ν. The Fourier transform of a Dirac delta function is a flat spectrum. In order to go from particle current to electrical current we must, to obtain the current power spectral density, multiply with the square of the charge of the involved ion. Taking this to be the elementary charge e, we find

$$S_i(f) = 2\nu e^2 = 2e\langle i\rangle \tag{7.13}$$

Here, $\langle i\rangle = e\nu$ denotes the average current through one pump.

Next, we let $\langle I\rangle$ denote the total transmembrane current due to pumps of a particular ion through the entire cell surface. We then have for the total current power spectral density:

$$S_I^{\mathrm{pu}}(f) = 2e\langle I\rangle \tag{7.14}$$

For a living cell in a steady state, for each kind of ion, there are just as many ions going in as there are going out, that is, there is just as much uphill transport through pumps as there is downhill flow through ion channels. So we have the same current $\langle I\rangle$ uphill as well as downhill. Below, we will first show that the downhill flow through the channels generates much more nonequilibrium noise than the uphill flow through the pumps. We will then show how the channel noise far exceeds the Johnson–Nyquist equilibrium noise.

Ion channels stay open for an average time of about $\tau_{\mathrm{op}} = 10^{-3}$ sec, and during that time there is a current of about 10^7 ions per sec (i.e., about 1 pA). So the equivalent of the elementary charge mentioned in the previous paragraph is now $N = 10^4$ ions.

However, before we blindly substitute Ne for e in Equation 7.14 to obtain the current power spectral density generated by the channel population of a cell, we have to take another source of variance into account. The channel-open time of about a millisecond is an average. If we view opening and closing of a channel as simple chemical steps between an open and a closed state, then the millisecond is the average of an exponential distribution of open times. For an exponential distribution the average open time equals the standard deviation in the open time. So the standard deviation ΔN equals N itself. The associated variance has to be added in. So we have $S_I^{\mathrm{ch}}(f) \approx 2\,\nu e^2\,(N^2 + (\Delta N)^2)$. The rate ν now represents the number of channel openings per unit of time. So we get for the current power spectral density produced by the channels:

$$S_I^{\mathrm{ch}} \approx 4Ne\langle I\rangle \tag{7.15}$$

So the channel contribution to the total nonequilibrium current noise is about 10^4 times as large as the contribution of the pumps. For the total current power spectral density, S_I^{noneq}, due to nonequilibrium currents, we thus neglect the pump contribution.

The above Equation 7.15 constitutes $S_I^{\mathrm{ch}}(0)$. At higher frequencies, when f approaches the average open time τ_{op} of the channel, $S_I^{\mathrm{ch}}(f)$ will decrease. The characteristic inverse time for a channel is $f_* = \tau_{\mathrm{op}}^{-1} + \tau_{\mathrm{cl}}^{-1}$, where τ_{cl} is the average closed time of the channel. With only one type of channel present in a cell, there will be a sigmoidally shaped, Lorentzian noise spectrum with an inflection point at $f = f_*$. With many types of channels for different kinds of ions present it is indeed possible to obtain a $1/f$ spectrum over several decades as the sum of Lorentzians [86].

To obtain the voltage power spectral density, we have to multiply $S_I^{\text{noneq}}(f)$ by R^2, where R represents the electrical resistance of the entire cell membrane. We let the cell surface area measure A. So we have $S_V^{\text{noneq}}(0) \approx 4\,Ne\,\langle I\rangle\,R^2$. The equilibrium Nyquist voltage noise across the same cell membrane is $S_V^{\text{eq}}(f) \approx 4kTR$. This is white noise and has the same strength at all frequencies. We thus obtain the following formula at $f = 0$ for the ratio $\theta(0)$ of the nonequilibrium noise and the equilibrium noise:

$$\theta(0) \approx \frac{Ne\langle I\rangle R}{kT} \tag{7.16}$$

The transmembrane current $\langle I\rangle$ is proportional to the cell surface A. The resistance R is inversely proportional to A. So eventually, the cell surface area and the cell geometry in general cancel out of the equation.

Data for the steady-state Na^+ flux through several types of cell membranes (e.g., rat soleus, sheep purkinje, squid axon, guinea pig auricles, and frog sartorius) are available [90]. That flux is about 50 pmol/(cm^2 sec). The vast majority of transmembrane ion transport is carried out by Na,K-ATPase, which transports two K^+ ions for every three Na^+ ions. We assume Na^+ and K^+ transport to therefore be about equal. After multiplying by Faraday's constant (the number of coulombs in a mole, i.e., about 10^5), we get a total current of about $\langle I\rangle \approx 10\ \mu A/cm^2$. The resistance of a cell membrane varies from 10^3 Ω cm^2 (squid axon) to 7×10^3 Ω cm^2 (mammalian cardiac cell). We thus find for $\theta(0)$ a value of about 5000.

Based on experimental data, it has been estimated that at 1 Hz the $1/f$ noise in the frog node of Ranvier is about a thousand times larger than thermal noise [91]. This is consistent with our estimate. Experimentally, it turns out that the power spectral density is constant from $f = 0$ up to about somewhere between 1 and 10 Hz [86,89]. At that point, the power spectral density starts to fall off as $1/f$. This means that we reach $\theta(f) = 1$, that is, the equilibrium and nonequilibrium noise being equal, somewhere near 10^4 Hz. Figure 7.5, in which the horizontal axis is in radians per second, indeed shows flattening between 10^3 and 10^4 Hz. At the 50- and 60-Hz power line frequencies, the nonequilibrium voltage noise is expected to exceed the equilibrium voltage noise by a factor of at least 10^2.

However, we should pause before taking the value of θ and employ it to incorporate nonequilibrium noise in the evaluation of a signal-to-noise ratio. As we saw earlier in this section, nonequilibrium noise may be a way to transduce energy from one stored form to another. So a signal can come in the form of a piece of nonequilibrium noise. With this gray area between signal and noise, it may no longer be straightforward to calculate a signal-to-noise ratio. There has been a natural selection toward high signal-to-noise ratios for signals whose detection has been important for the survival of the organism for many millennia. But what the signal-to-noise ratios and detection thresholds are for ELF and microwave radiation, which are relatively new phenomena in the environment, and how nonequilibrium noise figures in all of this is still open to conjecture and debate.

7.7 Chemical Noise

Chemical noise consists of both fundamental chemical noise (stochastic variations in net or accumulated amounts of a particular ion or molecule) and nonfundamental changes in chemical amount (molecular number) due to influences other than the applied field. We again adopt a recent discussion [12] in which an arbitrary biological system is considered.

In the discussion, attention focuses on weakly interacting fields that can create small chemical changes, but much of the approach is also relevant to strongly interacting fields, for example, those causing cell membrane electroporation (see Chapter 9 on electroporation in Ref. [127]). To begin, consider a small physical perturbation of the biological system due to the interaction of a local electromagnetic field, $\vec{F}_{\text{local}}(\vec{r}, t)$, that may vary from site to site within the volume of the biological system. In general, $\vec{F}_{\text{local}}$ may have a complicated dependence of its magnitude and direction on time and position, such that a formal prescription for calculating the field-induced molecular change due to an exposure is

$$\bar{n}_S = \int_{t=0}^{t=t_{\text{exp}}} \int_{\text{system volume}} J_0(t') f_{\text{bpm}}(\vec{F}_{\text{local}}(\vec{r},t')) \, dV \, dt' \tag{7.17}$$

We regard $\bar{n}_S$ as a molecular change signal. It is the primary consequence of the field exposure for the case where only one process, or one step in a cascade, is altered. Integration is carried out over the entire biological system volume and over the time comprising the exposure, t_{exp} (or control). This yields the accumulated, total chemical (molecular) change due to the applied field during the exposure. Other changes in the same ionic or molecular species may result from competing influences, for example, temperature variations, during t_{exp}.

The applied field interacts through one or more of a limited class of biophysical mechanisms. Here, *biophysical mechanism* means a class of interactions by which the field alters an ongoing biochemical rate (transport or reaction), with the rate arising from nonequilibrium processes dependent on metabolism. Examples of known biophysical mechanisms involving electric fields are heating (most biochemical processes have a nonzero temperature dependence), voltage-gated channels, electroconformational coupling of membrane enzymes, electroporation, and iontophoresis (mainly electrophoresis, but in some cases also electroosmosis). Examples involving magnetic fields are radical-pair reactions and twisting of magnetic material (magnetite or contaminant magnetic particles). As used here, a biophysical mechanism modulates an ongoing biochemical process, and both the coupling strength and the magnitude of the basal rate are important.

For a particular type of biophysical mechanism (bpm), the function f_{bpm} $(\vec{F}_{\text{local}}$ $(t))$ describes the instantaneous alteration of the basal rate, J_0, which itself can vary in time [92]. The local field can be computed numerically at the tissue level (millimeter scale; see Chapter 11 on dosimetry, this volume) [93–99] and at the cellular level [100,101]. The time and position dependence of $\vec{F}_{\text{local}}$ $(\vec{r},t)$ is often simple, namely, a constant magnitude (steady or DC) field, a constant amplitude periodic (AC) field, or at high frequencies a spatially decaying amplitude field due to power absorption. Environmental and occupational fields can be much more complicated, such that piecewise continuous representations may be needed.

If a weakly coupled physical perturbation alters the basal rate of a biochemical process (transport or reaction), the total chemical (molecular) change, expressed as the number of molecules, is

$$\bar{n} = \bar{n}_0 + \bar{n}_S \tag{7.18}$$

where $\bar{n}_0$ is the basal change during an exposure (sensing) time t_{exp}, and $\bar{n}_S$ is the (much smaller) molecular change due to the field exposure [22,45,92,102]. As noted above, $\bar{n}_S$ can be regarded as a molecular change signal. The basal process is far from equilibrium,

driven by free-energy differences associated with metabolism. The largest field-induced molecular change occurs for a steady (DC) field exposure [22,102]:

$$\bar{n}_S = K_{\text{bpm,dc}} F_0 \; J_0 \; t_{\text{exp}} \tag{7.19}$$

where $K_{\text{bpm,dc}}$ describes the alteration of the basal rate by the steady field, here of magnitude F_0. Equation 7.19 is the DC version of the case of a weakly coupled periodic perturbation, previously described for the case of an extracellular electric field [45,92], namely,

$$\bar{n}_S = K_{\text{bpm,ac}} F_0^2 \; J_0 \; t_{\text{exp}} \tag{7.20}$$

where $K_{\text{bpm,ac}}$ describes the coupling that leads to rectification of the ongoing rate [45]. For basal rates with more complicated time dependence, Equation 7.17 may need to be evaluated numerically, but the same basic ideas apply. Equation 7.20 is valid for long exposures, involving a large number of cycles of the periodic field. Basal rates that can be altered by weakly interacting electromagnetic fields by definition involve small interaction energies, so that thermal fluctuations and chemical free-energy differences result in nonzero basal rates. A zero basal rate with an extremely large activation or interaction energy cannot, therefore, be expected to be changed to a measurable nonzero rate by a weakly interacting field.

A generalized, molecular change-based signal-to-noise ratio can be constructed by estimating the ratio of primary molecular change to the combined competing changes for the same molecular (ionic) species. We consider the simplest case of the field altering the rate at one step in a single pathway but note that in principle the present analysis can be extended to include multiple steps involving more than one biochemical pathway. We further assume that this biochemical has its rate through the pathway altered slightly by a physical perturbation, here an electromagnetic field. But competing influences can also alter the rate. Such influences include temperature variations, normal physiological concentration variations, changes in hormones and other regulating biochemicals, and mechanical perturbations of cells and tissues. Competing molecular changes can also be created by a background electromagnetic field, for example, normal electrical activity within the human body or by movement in the earth's magnetic field, interacting through the same biophysical mechanism. Such competition goes beyond fundamental chemical noise (molecular shot noise). Nonionizing influences can only modulate ongoing processes, and therefore such influences cannot (essentially by definition) introduce foreign molecules. This has the important consequence that competing molecular changes may arise from several sources (Table 7.1).

TABLE 7.1

Quantities Employed in Generalized Chemical Noise

Symbol	Molecular Change	Source
S	$\bar{n}_S$	Field-induced molecular change signal
N	$\sqrt{\bar{n}} \approx \sqrt{\bar{n}_0}$	Molecular shot noise (fundamental)
V	$\bar{n}_V$	Molecular change due to temperature variations
C	$\bar{n}_C$	Molecular change due to concentration variations
I	$\bar{n}_M$	Molecular change due to mechanical interference
B	$\bar{n}_B$	Molecular change due to background fields

A generalized signal-to-noise ratio $(S/N)_{\text{gen}}$, can thus be considered. The field-induced molecular change signal, S, is thereby quantitatively compared to the several sources of competing molecular changes for the same biochemical (molecule or ion), yielding

$$(S/N)_{\text{gen}} = \frac{S}{f_{\text{com}}(N,V,C,I,B)} \tag{7.21}$$

The various competing molecular changes, which may or may not be independent, are combined to give the total competing molecular change, f_{com}. Important simplifications can be made if the various competing molecular changes can be approximated as independent and random around their mean values. In this case, f_{com} can be approximated as

$$f_{\text{com}}(N,V,C,I,B) \approx [N^2 + V^2 + C^2 + I^2 + B^2]^{1/2} \tag{7.22}$$

Alternatively, emphasizing the changes in terms of numbers of molecules,

$$f_{\text{com}}(N,V,C,I,B) \approx [\bar{n}_0 + (\Delta n_V)^2 + (\Delta n_C)^2 + (\Delta n_M)^2 + (\Delta n_B)^2]^{1/2} \tag{7.23}$$

All significant sources of competing molecular change are directly relevant.

Consistent with experimental treatment of errors as random, here we consider the special case that all the important competing molecular changes can be approximated as independent and random variations around their mean value, as this allows the competing changes to be added in quadrature (Equation 7.22). This leads to a general molecular change-based signal-to-noise ratio that involves Gaussian distributions, namely,

$$(S/N)_{\text{gen}} \approx \frac{S}{[N^2 + V^2 + C^2 + I^2 + B^2]^{1/2}} \tag{7.24}$$

Each of these competing molecular changes is discussed briefly below, with reference to Table 7.1.

As indicated in Table 7.1, $N = \sqrt{\bar{n}} \approx \sqrt{\bar{n}_0}$ is the competing molecular change due to fundamental stochastic variations in biochemical reaction and transport processes [15,45,92], which provides a fundamental, minimum molecular change noise. Fundamental chemical noise is increasingly recognized as important to understanding other aspects of biological systems, such as the circadian clock [103,104], control of genetic circuits [105,106], and bacterial chemotaxis [107].

Temperature variations within the volume of the biological system are generally expected to result in altered rates. When integrated over the system volume and over the exposure time, a contribution to the end-point molecular change is expected, because most biochemical processes have nonzero temperature dependence. Thus, $V = \bar{n}_v$ is the resulting, competing molecular change due to temperature variations [15]. Human core body temperature has daily variations of more than 1°C [108–113], and there are even larger variations in the extremities. Often *in vitro* electric and magnetic field experiments use feedback control, for instance, in temperature-regulated exposure chambers, but these typically have variations greater than about 0.01°C at one or a few temperature measurement sites. Temperature variations within the biological system itself are often inferred,

preferably by numerical models that can reasonably predict the temperature through the biological system by first predicting the specific absorption rate. During the exposure time, interfering temperature variation can be significant. To allow correction for temperature variations, the biological system should be characterized for its temperature sensitivity, and each particular apparatus should be characterized for its temperature variations for control and exposed conditions. As an example, an investigation first reporting athermal effects [114] was subsequently found to have temperature variation $\sim 0.1^{\circ}$C at temperature measurement sites [115]. Without thermal modeling of the exposure systems and the biological systems, however, larger temperature changes away from the measurement site cannot be ruled out. It is the temperature change and variation over the entire volume containing cells (or other specimens) that need to be quantitatively understood. Temperature measurement at one site, typically somewhere along the perimeter or boundary of a temperature-regulated apparatus, is generally insufficient. The measured biochemical quantity should also be characterized for its temperature sensitivity for the biological system studied, so that the expected V can be determined, to address the basic specificity question of whether an observed change is due to the field or to temperature changes [116].

Changes in concentration of biochemicals involved in a process are well known to alter the rate of a process. Relevant chemical species include substrates, products, inhibitors, etc. The competing molecular change due to one or more interfering concentration changes is $C = \bar{n}_{\mathrm{C}}$. In this case, a significant difference may exist for *in vitro* and *in vivo* experiments. Usually, only small, slow changes of chemical concentrations are expected *in vitro*, occurring, for example, through absorption or release of molecules (ions) from glass- and plasticware, spontaneous chemical decomposition, binding to cellular constituents, or evaporation. Uptake or release of interfering biochemicals from a biological preparation could be the predominant source, particularly if cells grow (taking up molecules) or die (releasing molecules). *In vivo* concentration variations are relatively large, because of normal physiologic variations. For example, Ca^{2+} concentration varies in humans by more than 1% over a day [117,118]. Unless buffered, these normal biochemical variations also compete with the field-induced molecular change.

Movement of tissue *in vivo* and vibration of an experimental apparatus containing a biological system can also create a mechanically induced molecular change, $I = \bar{n}_{\mathrm{M}}$, that competes with a molecular change signal. In this case, the competing molecular change is due to interference of mechanical stress and strain [119,120], often present at high levels in living humans [11,121,122] but at low levels for *in vitro* experiments. *In vitro* apparatus can have quite different mechanical properties and isolation from ambient vibrations. Indeed, it has been found in some experiments that mechanical vibrations create effects larger than the field exposure [123]. Tissues *in vivo* experience significant mechanical deformation, but there is the least strain expected within the bone marrow and the brain [120]. This may be relevant to the ''contact current hypothesis,'' which suggests that currents in the bone marrow may be important in exposures of children [124–126].

Background fields can, of course, also couple to biochemical processes through the same biophysical mechanisms as the applied field. Background field-induced molecular change competes, and is denoted by $B = \bar{n}_B$. Examples of background electromagnetic fields include the endogenous electrical fields generated within the body by cardiac, muscular, and neural activity and the sampling of different field values (local anomalies) in the ambient magnetic field as mobile humans move about in their environment. *In vitro* background fields will depend on the particular experimental environment, are usually small and constant, and are often measured.

7.8 Interpretation of Experiments

Specificity is fundamentally important to interpret experiments, as one wants to know what agent is responsible for the observed change(s). This is particularly relevant to experiments that find small changes in biological systems that are exposed to small electromagnetic fields. A basic challenge is to show that other influences are not responsible. Because it is well known that most biochemical processes have a significant temperature dependence, the approximate temperature sensitivity of the observed quantity should be determined or known, and some bound should be established for temperature drift or variations in the experiment. However, as already noted, even big changes can have more than one candidate cause. Both tissue electroporation and tissue movement can, for instance, underlie the changes in molecular uptake associated with large field pulses. For this reason, signal-to-noise ratio considerations should be preceeded by establishing field specificity, which can be much more difficult than observing a change associated with a field exposure. To establish specificity, a number of issues must be considered, many of which will be discussed next.

Many experiments determine quantities related to biochemical change. Exceptions are experiments that determine physical quantities such as voltages and currents, temperature changes, and magnetic particle rotation. However, electrical measurements are the most frequent physical measurement. These are incredibly important to systems of excitable cells, with experimental preparations ranging from isolated cells to electrophysiologic measurements on humans. Accumulation of charge might be measured, but probably as a voltage on a capacitance. Signal-to-noise ratio issues are still important, of course, but usually there is an important distinction: voltages and currents (rarely charge) are readily measured continuously.

A further distinction is that most experiments involving exposures to small fields use long exposure times (many seconds to hours or even days). Such experiments commonly determine biochemical quantities directly, for example, enzyme activity, or indirectly, for example, fluorescence emission from fluorescent indicators of intracellular calcium concentration. In this broad case, consideration of generalized chemical noise is relevant. Following the discussion in a recent paper [12], both the magnitude of the field perturbation and the nature and magnitude of chemical competition need to be understood. Such analysis should explicitly estimate the coupling to ongoing, far from equilibrium, metabolically driven biochemical processes and should quantitatively determine molecular changes due to competing influences. Only then can the analysis distinguish idealized conditions from *in vitro* conditions and *in vivo* conditions and then determine whether reported effects can be explained by known biophysical mechanisms.

In vivo there are several kinds of noise, and it is important to distinguish between them. Equilibrium noise comes about as a consequence of Brownian motion, that is, the random movement of molecules at finite temperature. At equilibrium, every degree of freedom takes on the same amount of energy, and equilibrium noise is therefore easy to evaluate. For a signal to exceed the equilibrium noise band, the quantitative criteria are often readily derived. Such baseline criteria can be useful when assessing the electroreception and magnetoreception that many organisms exhibit. But the nonequilibrium nature of life brings in nonequilibrium noise. When a primary molecular change is amplified through a biochemical cascade, ''amplifier noise'' is inevitable. Nonequilibrium noise appears whenever energy is dissipated, that is, when work is done. In many biological contexts the nonequilibrium noise is much more intense than the equilibrium noise. A serious complication is constituted by the fact that nonequilibrium noise, unlike equilibrium noise, is also able to perform work, that is, be a power source for an energetically uphill

process. Many biological processes may rely on the energy transduction that can be accomplished through nonequilibrium noise. The analysis of such situations poses challenges as the noise may be a signal and the signal may be noise. There is no easy general ''common denominator'' theory for nonequilibrium noise like there is for equilibrium *kT*-noise.

In a recent discussion [12], it is argued that experimental measurements can be plausibly related quantitatively to an underlying primary molecular change because of a field exposure operating through a biophysical mechanism. It is further argued that only the uncertainty in this change propagates through biochemical amplification and therefore dominates the measurement uncertainty. A more complete approach would involve traditional, independent determination of the instrumental or assay error (quantitative characterization of the experimental measurement system). After removal of the ''instrumental noise,'' the generalized signal-to-noise ratio $(S/N)_{\text{gen}}$, could be revised upward. This would allow interpretation (correction) of experimental error to estimate the uncertainty in the measured quantity itself. Assessment of combinations of biophysical mechanism models and particular exposure can then be carried out, using the most field-sensitive versions of theoretical models for the candidate biophysical mechanisms. The criterion $(S/N)_{\text{gen}} \leq 0.1$ is a very conservative basis for ruling out a particular class of biophysical mechanism for a given field exposure. Similarly, the criterion $(S/N)_{\text{gen}} \geq 10$ is a conservative basis for ruling in a candidate biophysical mechanism for a given exposure, retaining that biophysical mechanism hypothesis for further evaluation. This approach provides a quantitative basis for rejecting or accepting hypothetical biophysical mechanisms as candidate explanations for an experimental measurement.

The traditional choice $(S/N)_{\text{gen}} \approx 1$ is a useful but somewhat arbitrary dividing line, which indicates conditions for which an effect might appear. $(S/N)_{\text{gen}} \leq 0.1$ and $(S/N)_{\text{gen}} \geq 10$ provide criteria for stronger conclusions, allowing rejection or provisional retention of a biophysical mechanism hypothesis. This approach to interpreting experiments thus provides a general method for carrying out theoretical assessment of reported weak field exposure effects. This approach can distinguish relatively quiet *in vitro* conditions from *in vivo* conditions containing more and larger influences of competing molecular change. This in turn allows quantitative estimates of whether an *in vitro* result is relevant to *in vivo* conditions.

Biological Effects of Static Magnetic Fields

Shoogo Ueno and Tsukasa Shigemitsu

CONTENTS

8.1 Introduction

In ancient times, magnetism, especially permanent magnets, were a symbol of mystique because of the magnetic force that remains even after numerous attractions of iron. Although William Gilbert was called the pioneer of modern magnetics, he was surprised by the magnetism associated with living organisms. Magnetism, in contrast to transient static electricity, has been used as an explanation for various invisible effects and is expected to possess miraculous healing powers. Although people have been using magnetism for healing purposes without any scientific evidence, there have not been significant problems concerning the side effects of magnetism. As permanent magnets have improved in quality and achieved higher magnetic strength, magnetism has become more commonly used in modern medicine. For example, magnetism is commonly used in the correction of dentures.

In the society today there are many sources of electromagnetic fields. Humans are exposed daily to man-made and naturally originated fields. During the past decade, questions about whether the exposure to electromagnetic fields may be linked to adverse health effects have been raised. Although the interaction of electromagnetic fields with biological systems has been investigated, there are no biophysical mechanisms that can explain many of the observed biological effects of low-level of magnetic fields. Proposed mechanisms include effects on currents, direct forces on biomagnetic materials, effects on free radicals, ion cyclotron resonance, charge transfer processes, stochastic resonance, etc.

Recent developments in medical instrumentation such as magnetic resonance imaging (MRI) and transcranial magnetic stimulation (TMS) have raised questions as to whether or not strong (in the tesla range) magnetic fields influence human health. Medical applications of weak (1–200 mT) magnetic fields for the purpose of pain reduction and tissue healing have also been studied for many years. Therapeutic applications of permanent magnets and other magnetic devices have recently been expanded to various areas such as treatment of pain and diseases like rheumatoid arthritis and cancer.

The objective of this chapter is to describe some of the more recent information on biological effects and medical applications of static magnetic fields. This chapter consists of four sections. Each section has a comprehensive review of a recent topic of interest. A short summary of the mechanism of static magnetic field action on biological systems is described in the second section, which includes a brief review of well-known mechanisms that are discussed before mentioning the interactions of weak static magnetic fields with biological systems. The third section reviews and summarizes more recent *in vivo* and *in vitro* experimental results of the effects of static magnetic fields, including near-zero magnetic fields, geomagnetic fields, and MRI fields. The fourth section covers special topics including magnetic sensing, magnetite, and plant response to magnetic fields. In parallel with the comprehensive review of biological effects, the development and medical application of the static magnetic field phenomena are introduced in the fifth section and reviewed with emphasis on the applications that are currently under investigation.

8.2 Mechanisms of Biological Effects of Static Magnetic Fields

The biological effects of static magnetic fields are not well understood. Magnetic fields exert a force on moving charged particles at right angles to both the field and the velocity, $\vec{F} = q\vec{v} \times \vec{B}$, where $\vec{F}$ is the force, q is the charge, $\vec{v}$ is the velocity, and $\vec{B}$ is the magnetic flux density. In vacuum, the magnetic flux density is given by $\vec{B} = \mu_0 \vec{H}$, where $\vec{H}$ is the magnetic field strength and μ_0 is the magnetic permeability of a vacuum. (In this section

we will be careful to distinguish between $\vec{B}$ and $\vec{H}$, although in subsequent sections we will be less careful, using ''magnetic field'' as a general term that often is used to describe flux density.) Additionally, these fields exert a torque on particles with both fixed and induced magnetic dipole moments. This torque tends to align the dipoles along the magnetic flux density and is given by $\vec{T} = \vec{M} \times \vec{H}$ where $\vec{M}$ is the magnetic dipole moment. For paramagnetic and diamagnetic materials, $\vec{M}$ is proportional to the magnetic flux density. The magnetic susceptibility, χ, is given by the equation, $\vec{M} = \chi \vec{H}$, where $\vec{H}$ is the local value of the magnetic field strength and χ is dimensionless. All materials may be mainly divided into three categories based on their susceptibility values. Materials with negative susceptibility are called diamagnetic. Materials with positive values are referred to as paramagnetic. Materials with large susceptibility include both ferro- and ferrimagnetic materials. Recognition of the role of diamagnetic, paramagnetic, and ferro- or ferrimagnetic materials in the body helps in the understanding the underlying mechanisms of biomagnetic effects.

Table 8.1 shows three types of well-known mechanisms of the biological effects of magnetic fields including time-varying magnetic fields. As shown in Table 8.1, there are two basic mechanisms of static magnetic fields: first, the magnetic torques on objects and second, the mechanical force effects. A radical pair mechanism is also proposed.

When biological materials or systems are exposed to a spatially homogenous magnetic field, they tend to rotate to a stable direction, which is determined by the anisotropy of magnetic susceptibility of the materials and magnetic torque acting on the materials, as described by the following equation:

$$T = -\frac{1}{2\mu_0} B^2 \Delta\chi \sin 2\theta$$

where B is the magnetic flux density, $\Delta\chi$ is the anisotropy of magnetic susceptability of the materials, θ is the angle between the direction of the magnetic field and the long axis of the materials, and μ_0 is the magnetic permeability of a vacuum. The magnetic orientation of diamagnetic materials such as fibrin and collagen can be observed and explained by this principle (Torbet et al., 1981).

Next, when biological materials or systems are exposed to a spatially inhomogenous magnetic field, the materials or systems tend to move along the direction of the steepest

TABLE 8.1

Well-Known Mechanisms of the Biological Effects of Magnetic Fields

1. Time-varying magnetic field	
Eddy currents $J = -\sigma \frac{B}{t}$	Nerve stimulation
Heat SAR $= \sigma \frac{E^2}{\rho}$	Thermal effects
2. Static magnetic fields	
a. Homogenous magnetic field Magnetic torque $T = -\frac{1}{2\mu_0} B^2 \Delta \chi \sin 2\theta$	Magnetic orientation of biological cells
b. Inhomogenous magnetic field Magnetic force $F = \frac{\chi}{\mu_0} (\text{grad } B) B$	Parting of water by magnetic fields (Moses effect)
3. Multiplication of magnetic fields and other energy Photochemical reactions with radical pairs Singlet–triplet intersystem crossing	Yield effect of cage product and escape product

gradient of magnetic force. The magnetic force acting on the materials is proportional to the multiplication of the magnetic flux density B, the gradient of the magnetic flux density B (grad B), and the magnetic susceptability χ of the materials, as described by the following equation:

$$F = \frac{\chi}{\mu_0}(\text{grad}B)B$$

where μ_0 is the magnetic permeability in a vacuum.

Dramatic demonstrations of these forces can be seen when water is parted by magnetic fields using magnetic field exposures of 4–8 T with a gradient of 50 T/m (Ueno and Iwasaka, 1994a,b). Magnetic levitation of diamagnetic materials such as wood and other organic materials, is realized in magnetic fields of more than 20 T (Beaugnon and Tournier, 1991). This phenomenon can also be explained by the principles of magnetic force.

Oxygen is a paramagnetic molecule, and its behavior under magnetic field gradients has an important role both as a gas and when dissolved in solution. The blockage and disturbance of gas flow by magnetic fields have been observed (Ueno and Harada, 1987). This phenomenon, called a magnetic curtain, can be explained by the action of magnetic force on a paramagnetic molecule. The magnetic curtain in this example is a wall of oxygen or air. Experimentation with this principle has demonstrated the quenching of burning candle flames (Ueno, 1989), where the interception of oxygen by the magnetic curtain has a quenching effect on the flames. As a second example, when a human subject is positioned inside a space shielded by the magnetic curtain, one may expect the respiratory function, evaporation of water molecules, body temperature, blood circulation, and other physiological functions to be disturbed or modulated.

The effect of static magnetic fields on water vaporization rate was investigated (Nakagawa et al., 1999). This study demonstrated that the water vaporization rate was found to be significantly influenced when both air and oxygen were in the presence of magnetic fields, and the observed effect was dependent on the field–field gradient product rather than on the B field itself. It should be noted that this magneto-enhancement of vaporization might be the indirect cause of certain physiologic effects on living organisms.

For example, skin temperature decreases in rats exposed to magnetic fields have been observed (Ichioka et al., 2003). This observation can be explained in terms of the effects of the magnetic field on air convection. That is, high magnetic field gradients (135–140 T^2/m) push the diamagnetic water molecules toward the magnet bore. This increases the movement of water molecules in the air around the animal body and the vaporization rate. The heat of vaporization leads to a decrease in skin temperature. The decrease in the blood flow of the skin microcirculation is assumed to be a secondary change to the decrease in skin temperature.

Oxygen dissolved in water is also affected by magnetic fields. Changes in dissolved oxygen concentration were observed for magnetic field exposures on the order of 1 T (Ueno and Harada, 1982; Hirota et al., 2000; Kishioka et al., 2000). The changes in oxygen concentration are accelerated or regulated by gas transport of oxygen and water molecules inside and outside the water surface.

The magnetic field effects for large fields can be explained by these well-known mechanisms. With ever-increasing evidence indicating that weak static magnetic fields have profound effects on biological systems, a number of mechanisms for the action of these static magnetic fields, including geomagnetic fields, on biological systems have been proposed.

Possible biomagnetic and chemical effects can be expected when biological systems are exposed to both static magnetic fields and other forms of energy such as light and

radiation (Ueno and Harada, 1986). Photochemical reactions produced by a radical pair intermediate can be expected to show magnetic field effects that arise from an electron Zeeman interaction, electron-nuclear hyperfine interaction, or a hyperfine interaction mechanism including an electron-exchange interaction in a radical pair intermediate (Hata, 1976; Schulten et al., 1976; Tanimoto et al., 1976; Nagakura and Molin, 1992; Natarajan and Grissom, 1996; Hayashi, 2004).

The magnetic field effect observed with radical pair recombination is one of the well-known mechanisms by which magnetic fields interact with biological systems. Throughout the past decades there have been several experimental results describing the effects of magnetic fields on radical pair recombination. Mohtat et al. (1998) examined the behavior of radical pairs derived by hydrogen abstraction of triplet benzophenone and some of its derivatives from bovine serum albumin, human serum albumin, and calf thymus DNA. The magnetic field strength was as high as 150 mT with durations as long as 10 μs. This result indicated that radical pair behavior is sensitive to magnetic fields, and this effect can be interpreted by using the theory of free radical recombination. Using the triplet state of benzophenone as a convenient source of pairs, Eveson et al. (2000) examined the effects of weak (>1 mT) magnetic fields on radical recombination reactions in micells. They found that the concentration of free radicals escaping from the micelle was both affected and depended on the conditions surrounding the radical pair.

Timmel and Till discussed the weak magnetic field effects on free radical recombination reactions (Till et al., 1998; Timmel et al., 1998). Vink and Woodward (2004) described the effects of a weak magnetic field, 21 mT, on the recombination reaction of neutral free radicals in isotropic solution.

Ritz et al. (2002) reviewed the physiological basis of animal magnetoreception. They suggested that there was a link between photoreception and magnetoreception, from their findings in behavioral and theoretical studies. Migratory birds have the ability to sense the geomagnetic field and use it as a source of compass information. The candidates for a biophysical mechanism of this magnetoreception are magnetite and magnetically sensitive chemical reactions in animals. Ritz et al. (2000) postulated the possibility that magnetoreception involves radical pair processes as a biophysical mechanism.

8.3 Experimental Studies on Static Magnetic Field Effects

This section focuses on *in vivo* and *in vitro* studies of the effects of static magnetic fields. It covers the field effects observed on behavior, the cardiovascular system, reproductive system, cellular and tissue development, the neuroendocrine system, and the magneto-mechanical system, utilizing molecular, cellular, tissue, and cell-free systems.

8.3.1 *In Vivo* Studies

8.3.1.1 Animal Behavior: Recognition and Analgesia

Scientific interest in behavioral changes has led to the development of a psychology of learning that studies the effects of various external stimuli, and this research has further led to the development of behavioral pharmacology to observe the effects of drugs on the central nervous system. There have been several investigations for studying the effects of magnetic fields on behavior and the central nervous system using techniques developed

specifically in these research fields. Behavioral research directed toward the effects of magnetic exposure of living organisms mainly addresses two questions: whether magnetic fields are sensed and avoided and whether magnetic fields have any influence on the functions of leaning and memory. Magnetic field experiments designed to address both questions have been conducted using several indicators, such as open-field behavior, operant behavior, and spontaneous motor activity, as tools of observation and measurement. (See also Chapter 4 on behavioral effects by Johnston and D'Andrea.)

8.3.1.1.1 Animal Behavior and Recognition

Nikolskaya et al. (1996) investigated the influence of inhomogeneity of natural magnetic fields on rat cognition with regard to whether or not magnetic fields could serve as an informational factor for cognition. Under three natural magnetic field conditions, 37 $\pm$ 2 μT (condition 1; horizontal component (N–S) is 14 μT, and vertical 34 μT), 16–118 μT (condition 2), and 55–240 μT (condition 3), rats were subjected to a food-operant behavior study. All rats in conditions 2 and 3 were unable to form operant behavior, while rats in condition 1 demonstrated the behavior. Using the combination of an original behavioral model and a multiple alternative maze, an impact of Opilong, which is an analog of dermorphine and μ-receptor agonist, on rat sensitivity to 38 $\pm$ 2 μT, in the static magnetic field has been investigated by the same authors (Nikolskaya et al., 1999). They concluded that chemical modulation of the opioid system in rats induced both an increased magnetic field sensitivity and an allowed perception of magnetic field parameters. In the following study (Nikolskaya and Echenko, 2002), it was reported that cognitive activity in the natural magnetic field of 38 μT caused an increase of ethanol intake in 34.8% of rats.

During the 1980s, Liboff (1985) argued favorably for the combined effects of static (DC) with extremely low-frequency (ELF) magnetic fields (see also Chapter 9 resonance phenomena by Liboff on). A surprising effect was observed at the ELF magnetic field frequency close to the cyclotron frequency of a calcium ion. Thomas et al. (1986) reported the disruption of operant behavior in rats after exposure to low-intensity magnetic fields. The protocol developed by them in the report has been reexamined by Stern et al. (1996) in a two-part experiment. In the first part, the vertical component of the static field was reduced to 0.0261 μT. In the second part, both the horizontal and the vertical components were matched to those used by Thomas et al. The results obtained in these experiments were found to be inconsistent with the results reported by Thomas et al. Effects of the combination of static (DC) and AC magnetic fields at the cyclotron frequency on rat open-field behavior have been investigated (Zhadin et al., 1999). Levels of locomotor and exploratory activities were decreased after exposure to DC and AC magnetic fields at the calcium cyclotron frequency, whereas field exposure at the magnesium cyclotron frequency increased levels of these activities.

Studies have been conducted to determine whether rats could acquire a two-choice discrimination based on a specified discrimination stimulus (Creim et al., 2002). The specified discriminative stimulus used in this study was tested both in ambient illumination as well as in a combination of an oscillatory field of 50 μT at 60 Hz and a static field of 26 μT. The results demonstrated that rats were able to discriminate between two-choice tasks easily during the period of changing illumination and that the presence or absence of the static and oscillatory fields had no observed effect on these findings.

Tsuji et al. (1996) evaluated physiological consummatory behavior by observing intakes of food and water and changes in the body weight using BALB/c mice exposed to magnetic field levels of 5 T for a period of 24 and 48 h. Exposure to a 5-T magnetic field for 48 h suppressed eating and drinking behavior. The decreased body weight, the increased blood urea nitrogen (BUN) level, and the slightly increased BUN–Cr ratio

observed in this experiment might be attributed to the loss of body fluid secondary to decreased food and water intake.

For the purpose of observing changes caused by magnetic field exposure, MRI systems and application of their high-strength static magnetic fields have been useful and widely used to obtain intact images. There have been three reports describing the behavioral effects observed as a result of high-strength static magnetic field exposure of rats and mice. Using a conditioned taste aversion technique, it was shown that rats developed a conditioned taste aversion after exposure to a high magnetic field of 9.4 T for 30 min (Nolte et al., 1998). Following this report, similar experiments were carried out. Restrained rats and both unrestrained and restrained mice were exposed to magnetic fields of 7 and 14 T generated by superconducting magnets (Houpt et al., 2003). In the report, it was found that exposure of rats to high magnetic fields suppressed rearing and locomotor circling and induced conditioned taste aversion and expression of c-Fos in vestibular neclei. The rat's orientation in magnetic fields is a key factor for the direction of circling. Similar results were obtained with mice (Lockwood et al., 2003). All tested mice showed development of conditioned taste aversion, and a significant number showed tight circling and rearing suppression. Effects were observed more significantly in unrestrained mice than in restrained mice. Snyder et al. (2000) have identified brain stem regions that were activated by exposure to static magnetic field levels of 9.4 T for 30 min, of restrained rats, by using a c-Fos immunohistochemisty detection assay. Increased expression of c-Fos and neural activation in visceral and vestibular nuclei by magnetic field exposure have been reported. It has been suggested that the neural activation response might be a factor in promoting conditioned taste aversion learning.

Superconducting high magnetic field exposures of 7 T have been reported to have reduced the trehalase enzyme activity in honey bees (Kefuss et al., 1999). There were no changes found in the level of fatty acids, triacyglycerols, and steroids in this study.

8.3.1.1.2 Analgesia

Effects of a hypogeomagnetic environment with a flux density of 4 μT inside a Mu-metal box on stress-induced analgesia in C57 male mice have been investigated (Del Seppia et al., 2000). This study consisted of three consecutive parts: (1) maintaining the mice under various magnetic exposure conditions: hypogeomagnetic, altered magnetic field, and Earth's geomagnetic field of 46 μT for 90 min; (2) immobilizing the animals in a tube for 30 min under each exposure condition; and (3) recording nociceptive responses of the restraint-stressed mice as the latency of front-paw lifting to hot-plate stimulus. Stress-induced analgesia was significantly reduced in the animal group exposed to the hypogeomagnetic field, and this result was comparable with that in the mice exposed to altered magnetic fields or treated with prototypic opiate antagonist naloxone. It has been suggested that the exposure period in a hypogeomagnetic environment might be responsible for the inhibition of stress-induced analgesia. They also demonstrated that exposure to altered magnetic fields induce more rapid habituation to a novel environment (open field) (Del Seppia et al., 2003). The experiment was carried out to investigate effects of irregularly varying (<1 Hz), 20–70-μT or regular 37-Hz, 80-$\mu T_{p\text{-}p}$ magnetic fields with a 2-h exposure of mice. The nociceptive response was measured by a hot-plate test and showed that the nociceptive sensitivity was significantly greater in magnetically treated mice than in controls.

Various sensing-transduction mechanisms have been proposed to explain the biological effects of magnetic fields. Prato et al. (1996a). showed inhibitory effects of 60-Hz magnetic fields at levels of 299 $\pm$ 1 $\mu T_{p\text{-}p}$ and static magnetic fields at levels of 78 $\pm$ 1 μT on opioid-mediated analgesia in the land snail, *Cepaea nemoralis*. It has been reported that

the effects were dependent on the relative direction of both the weak static and the 60-Hz magnetic field, as well as on the presence of light. In a following study, indirect and direct mechanisms of ELF magnetic fields on an endogenous opioid peptide-mediated analgesic response have been proposed. It was shown that the energy transduction mechanism did not involve induced electric currents or magnetite (Prato et al., 1996b), and the results indicated that a direct magnetic field detection mechanism was consistent with the parametric resonance model. In a later study to reexamine the results obtained and further clarify the role of light, it was found that reduction of the opioid-induced analgesia by magnetic field exposure was enhanced by the presence of light. It was reported that the reduction rate of analgesia was not dependent on ELF frequency; however, the effect of the ELF magnetic field was in fact mediated by direct magnetic field detection.

In order to detect static magnetic field-induced functional changes in brain tissue, Veliks et al. (2004) carried out an investigation to identify the effects of static magnetic fields on rat brain structures using heart rate and heart rhythm as physiologic indicators. Rats put under ketamine–xylazine anesthesia were exposed to magnetic field levels of 100 mT for 15 min. Before and after the exposure, an electrocardiogram was recorded for analysis of heart rate and heart rhythm. Static magnetic fields were found to evoke changes in both heart rate and heart rhythm in 80% of the subject animals.

McLean et al. (2003b) examined the effects of inhomogenous static magnetic fields, alone or in combination with the chemical agent phenytoin (PHT), on audiogenic seizures (AGS) in DBA/2 mice. In experimental studies where the static magnetic fields ranged from 0.26 to 10.5 mT, with a field gradient ranging between 0.012 and 0.48 T/m, seizure severity decreased as the magnetic flux density and exposure duration period increased. It was found that the magnetic field pretreatment enhanced the effect of PHT, and it was also found that a static magnetic field alone had some anticonvulsant effects as well. Further investigation is required to clarify the anticonvulsant effects of magnetic fields in AGS.

8.3.1.2 Reproduction and Development

The effects of static magnetic fields, including MRI fields (static, gradient, and RF), on fertility, the developing embryo, and the fetus have been investigated. There have been a series of reports describing the effects of 10- and 35-day exposures to a magnetic field level of 0.7 T on mice, in terms of sperm motility, maturation, and production and morphological and developmental changes (Tablado et al., 1996, 1998, 2000). In the first report, mice were exposed to a magnetic field level of 0.7 T for time periods between 1 and 24 h/d, over 35 d. It was found that sperm motility, maturation, and production were not affected. Two years later, it was reported that the size of sperm heads was still intact; however, the animals that had undergone continuous exposure demonstrated increased sperm head abnormality. In a study by Tablado et al. of magnetic effects during developmental changes, experiments were carried out to investigate the *in utero* exposure effects from magnetic field levels of 0.5 to 0.7 T on testis and epididymis development in mice. After mating, female mice were exposed from day 7 of gestation until the day of birth. Results showed that there were no significant differences between exposed and sham-exposed animals in terms of body weight gain of dam, litter size, body weight of male pups, and testis–epididymus weight gain of pups up to 35 d of age. In addition, there were no detectable changes found during a histopathological evaluation of the testis and epididymis of pups.

Narra et al. (1996) reported the biological effects of a static magnetic field on spermatogenesis and embryogenesis in Swiss Webster mice. Male and pregnant female mice were exposed to a magnetic field level of 1.5 T for 30 min. There was no increase in sperm head shape abnormality and no reduction in testicular sperm numbers; however, a decreased survival rate of preimplantation embryos was indicated.

It has been reported that there were no harmful effects detected in a static magnetic field of 4.7 T on ICR mice (Okazaki et al., 2001). Pregnant ICR mice were exposed to the field from days 7.5–9.5 of gestation and sacrificed on day 18.5 of gestation. There were no significant differences in the incidence of prenatal death or malformations between the exposed and control groups. The investigation has been conducted for potential adverse effects of a 10-week exposure to a 9.4-T magnetic field on the development of male and female rats as well as their offspring (High et al., 2000). All rats were exposed to 9.4 T for 3 h twice a week with an intermittent duration of 5 week on, 2 week off, and 5 week on. The results demonstrate hematological, biochemical, pathological, and behavioral changes in both adults and their offspring; however, there were no adverse effects observed in either male or female adult rats, as well as in their offspring.

Effects of long duration and high magnetic field exposure on fetal growth and postnatal development in mice have been investigated (Magin et al., 2000). One group of mice was exposed for 9 h on day 9 or on day 12 postcoitus (or both) to MRI conditions (static magnetic field of 4 T with 5-T/s gradient and whole-body SAR of 0.2 W/kg at 170 MHz). A second group was exposed to a combination of ultrasound and MRI fields. There were no significant changes in fetal growth in animals exposed to MRI or ultrasound fields individually. The average fetal weight of animals exposed to combined fields was lower than that of the other group. Carnes et al. (1996) investigated the effects of static magnetic field levels of 4.7 T, which is equivalent to the level used in MRI, on fetus, adult growth, and testicular development in mice.The 8-h exposure was carried out on day 9 or day 12 of gestation (or both). Effects of the combined application of 1 MHz ultrasound on day 9 and MRI on day 12 was also investigated. The average fetal weight of the exposed groups was found to be less than that of the control groups. It was found that the postpartum death rate was higher after the MRI exposure, and sperm production was reduced; however, no changes were detected in embryonic death rate, sex ratio, body weight at day 50, spleen weight, and seminal vesicle weight.

Jove et al. (1999) studied the effects of static magnetic field levels of 18 and 36 mT on the development of chick embryo, including the pineal gland. They found that static magnetic fields affected the development and growth of embryos, and this effect was dependent not only on the intensity but also on the length of exposure time. Ruggiero et al. (2004) reported the effects of a 3-h exposure to a magnetic field level of 0.2 T generated by a clinically used MRI system on the angiogenesis of chick embryo. Angiogenesis was evaluated using a chick embryo chorioallantoic membrane assay. Results indicated that static magnetic field exposure inhibited angiogenesis in chick embryo. Effects of a uniform static magnetic field of 29 mT on cell migration and differentiation in the cerebellum of chick embryo have been studied (Espinar et al., 1997). The cerebella of chick embryos was exposed to the magnetic field on 6 d of incubation and sacrificed at day 13 of incubation. Results showed that static magnetic field exposure could induce irreversible developmental effects on cell migration and differentiation. Clear signs of cell degenerations and delay in the process of neuronal differentiation were indicated.

There have been a series of reports describing the effects of static magnetic field on fish embryos (Formicki and Winnicki, 1996, 1998; Winnicki et al., 1996; Formicki et al. 1997; Formicki and Perkowski, 1998). First, it was reported that during a prolonged transportation of fertilized salmonid eggs and trout (*Salmo trutta* L. and *Oncorhynchus mykiss*), a magnetic field of 4 mT lowered the mortality rate and enhanced the conservation condition (Winnicki et al., 1996). Effects of static magnetic fields ranging from 50 to 70 mT on the cardiac muscle activity of carp (*Cyprinus carpio* L.) embryos and larvae have been investigated (Formicki and Winnicki, 1996). An increase in heart rate was observed after exposure to these fields. Effects from both the strength and the direction of the geomagnetic field and static magnetic fields of 0.5 and 1 mT on the orientation of trout embryo

(*S. trutta*) and rainbow trout (*O. mykiss*) have also been investigated. Results have shown that the embryos were sensitive to the static magnetic fields, with a preference for a certain field direction. Further investigation has been conducted to clarify the response of fish embryos and larvae from the same type of trout to a static magnetic field (Formicki and Winnicki, 1998). Eggs were placed in magnetic fields during the period from fertilization to hatching. The exposure of eggs resulted in slower embryonic development; thus, eggs were incubated for a prolonged period of time. Embryos of rainbow trout (*O. mykiss*) and trout (*S. trutta*) exhibited orientation both in the natural magnetic field and in artificial magnetic fields of 0.5 and 1 mT. In a supplementary paper, Formicki and Perkowski (1998) showed the effects of static magnetic fields of 5 and 10 mT on the gas exchange in rainbow trout (*O. mykiss*) embryos. An increase of oxygen uptake was observed. It was determined that the impact of magnetic field exposure on the respiratory system was significant in the periods of advanced morphogenesis.

It has been reported that the exposure to static magnetic fields of 10–100 mT could alter the early embryonic development in two species of sea urchin embryo, *Lytechinus pictus* and *Strongylocebtrotus purpuratus* (Levin and Ernst, 1997). Results suggested that static magnetic fields delayed the onset of mitosis in both species. A static magnetic field of 30 mT caused an eightfold increase in the incidence of exogastrulation in one species. Static magnetic field effects of 4 and 8 mT and effects of exposure to 60-Hz AC magnetic fields of 6 and 8 mT on the first division of two sea urchin embryos, *Sphaerechinus granularis* and *Paracentrotus lividus*, have been studied (Pagnac et al., 1998). No differences were found in the time of the first cleavage in both exposures.

In a static magnetic field of 35 mT, the fruit fly (*Drosophila melanogaster*) was reared through several generations to investigate the width and length variability of both wings (Stamenkovic-Radak et al., 2001). In the second-generation exposure, there was a significant difference between sexes in the context of directional change of wing size variability. In the sixth generation, the differences in wing size between the magnetic field exposure group and control groups showed the same directional pattern in both sexes. Pan and Liu (2004) reported the effects of high static magnetic fields of 9.4 and 14.1 T on the hatching behavior of fresh mosquito eggs. Hatching was delayed, and the delay time depended on the intensity of the magnetic field.

Effects of exposure to high static magnetic field with levels up to 16.7 T on the first three cleavages of *Xenopus laevis* embryos have been investigated (Denegre et al., 1998). Results have indicated that cleavage furrows aligned parallel to the magnetic field. The most significant effects on the second and third cleavages have been observed in homogenous fields, not in the gradient fields. It has been suggested that this phenomenon was caused by interactions between the magnetic fields and the diamagnetic materials in the *Xenopus* embryo. Further studies have shown that after exposure to static magnetic fields of 17–22 T during either or both of the first two cell cycles, the third cell cycle mitotic apparatus at metaphase could be induced, and the third cleavage furrows aligned perpendicular to their nominal orientations (Valles, 2002; Valles et al., 2002). Valles et al. (1997) investigated the magnetic field gradient levitation (MFGL) as a technique for simulating low gravity for biological systems.They levitated living biological specimens, embryos of the frog *X. laevis*, using a large inhomogenous magnetic field. MFGL of embryos reduced the body forces and gravity-induced stress on them.

8.3.1.3 Circulatory System Effects

Recently, effects of static magnetic field applications on the circulatory system have been reviewed in experimental animals (Tenforde, 2005) and in humans (Chakeres and de Vocht, 2005; Crozier and Liu, 2005; van Rongen, 2005). Most of the studies have been

related to MRI systems, and it has been reported that in MRI-related studies using strengths of up to 8 T, there were little or no significant changes in cardiovascular and circulatory parameters. In contrast, it was found that moderate-intensity static magnetic fields ranging from 1 to 350 mT can have significant circulatory system effects, most notably on cutaneous microcirculation and arterial blood pressure.

8.3.1.3.1 Microcirculation

Ohkubo and Xu (1997) studied the acute effects of 1–10-mT static magnetic fields applied for 10 min on the microcirculatory changes in conscious rabbits using a rabbit ear chamber (REC) and microphotoelectric plethysmography (MPPG). The static magnetic fields induced biphasic changes in vasomotion in a non-dose-dependent manner. Static magnetic fields suppressed vasomotion when the vascular tone was high, while the same level fields enhanced vasomotion when the tone was low. To clarify these effects, the same group, Okano et al. (1999), investigated the effect of a 1-mT static magnetic field for 10 min on microcirculation in conscious rabbits using pharmacological manipulation together with REC and MPPG. The results showed that the static magnetic field enhanced vasodilatation and increased vasomotion under norepinephrine, which induced high vascular tone and, in contrast, induced vasoconstriction and decreased vasomotion under acetylcholine, which induced low vascular tone.

These studies are strongly supported by another independent study that examined the effect of a moderate-intensity static magnetic field on microcirculation, suggesting that the static magnetic field could modulate the biphasic responses of relatively smaller-diameter blood vessels (arterioles). Morris and Skalak (2005) studied the acute effect of a 70-mT static magnetic field for 15 min on the diameter of microvessels in rat skeletal muscle placed under pentobarbital anesthesia, using intravital microscopy. This study suggested that the static magnetic field could modulate microvascular tone in a restorative fashion, thereby acting to normalize the tone.

Gmitrov and colleagues reported the acute effects of 250–350 mT static magnetic field exposures for a time period of up to 80 min on microcirculation within cutaneous tissue of the rabbit ear lobe placed under pentobarbital anesthesia using REC and MPPG (Gmitrov and Ohkubo, 1999a,b; Gmitrov et al., 2002). They demonstrated that application of static magnetic fields to the carotid sinus baroreceptor region for a period of 65–80 min increased microcirculation. The static magnetic fields suppressed or recovered a Ca^{2+} channel blocker, verapamil, which reduced microcirculation.

Xu et al. (1998) observed the subchronic effects of a 180-mT static magnetic field, with length of exposure times for up to 4 weeks, on cutaneous microcirculation in conscious rabbits, using REC and MPPG. The static magnetic field significantly increased the long-lasting vasodilatation and enhanced the vasomotion. The same authors found that exposure to static magnetic fields at 1 mT or higher for 10 min enhanced microcirculation and increased peak blood velocity (Xu et al., 2000).

Mayrovitz et al. (2001, 2005) investigated the effects of static magnetic fields with strengths as high as 100 mT and exposure periods of up to 36 min on skin blood flow in humans, using a laser-Doppler flowmeter. They showed that the static magnetic fields have no significant effect on the normal, unstressed circulation or vasoconstrictive response in conjunction with skin temperature. Steyn et al. (2000) also indicated that there are no effects observed on blood flow in horses after exposure to static magnetic fields.

In a series of studies that observed the effects of ultrastrong (>5 T) static magnetic field exposure, Ichioka et al. (1998, 2000) investigated the acute effect of an 8-T static magnetic field exposure for a period of 5 min on blood flow in rat by using a laser-Doppler flowmeter and thermistor-derived measurements.They demonstrated that blood flow

and skin temperature decreased during the field exposure, through the movement of water vapor over the animal and the decreased humidity in the air.

8.3.1.3.2 Blood Pressure

Gmitrov and colleagues studied the influence of both a 350-mT static magnetic field and geomagnetic field activity on mean arterial blood pressure (MAP) in pentobarbital-anesthetized rabbits (Gmitrov and Ohkubo, 2002; Gmitrov et al., 2002). Application of the static magnetic field to the baroreceptor region for 65–80 min decreased MAP. In testing geomagnetic field applications, they found that there was a positive correlation of this field's activity with MAP, and this result implied that magnetic storms could increase the incidence of severe cardiovascular events.

Okano and Ohkubo (2001) examined the acute effect of a 1-mT static magnetic field applied for 30 min on pharmacologically altered blood pressure in conscious rabbits. It was found that (1) the static magnetic field reduced the vasodilatation effect from enhanced vasomotion and antagonized the reduction of blood pressure under a Ca^{2+} channel blocker, nicardipine, which induced low vascular tone, and (2) the static magnetic field attenuated vasoconstriction and suppressed the elevation of blood pressure while under the influence of a nitric oxide (NO) synthase inhibitor, L-NAME, which induced high vascular tone. However, two of their experiments, which were carried out under normal conditions without pharmacological drugs, showed that static magnetic fields did not induce any significant effects on hemodynamics and blood pressure (Okano and Ohkubo, 2001, 2003a). With regard to these undetectable effects, Muehsam and Pilla (1996) speculated that physiologically significant bioresponses to therapeutic signals appear to occur only when the physiologic state of the target system is far from homeostasis.

In contrast to the experiments done without pharmacological manipulation, Okano and Ohkubo (2003a) found that exposure to a 5.5-mT static magnetic field for 30 min caused the suppression of norepinephrine- or L-NAME-induced vasoconstriction and hypertension in rabbits. Furthermore, they tested exposures of 5–10-mT static magnetic fields for a period of several weeks on the development of hypertension in spontaneously hypertensive rats (Okano and Ohkubo, 2003b; Okano et al., 2005a). Experimental results indicated that the static magnetic fields suppressed and retarded the development of hypertension because of the reduction in plasma levels of both angiotesin II and aldosterone together with lower levels of NO metabolites (NO_x).

In addition, the antihypotensive effects of static magnetic fields on reserpine-induced hypotensive rats were investigated (Okano et al., 2005b). The result suggested that exposure to a 25-mT static magnetic field for several weeks suppressed the reserpine-induced hypotension and bradykinesia through the inhibition of norepinephrine depletion.

Saunders (2005) commented that most of these studies were undertaken in the context of the potential therapeutic effects of static magnetic field on various disorders. Further studies with some independent replications are required even if the effects of static magnetic field on both blood flow and blood pressure indicate possible medical applications.

8.3.1.4 Neuroendocrine, Visual, and Neurophysiological Systems

Effects of static magnetic field exposures of 0.05 μT to 80 mT, and 7 T on the level of melatonin in rat have been examined (Kroeker et al., 1996). The first experimental exposure using field strengths of up to 80 mT for 12 h/d and 8 d showed no significant changes in night-time pineal and serum melatonin levels, as did the second experimental exposure using 7 T for 45 min. The visual system of the fruit fly (*D. melanogaster*) was

investigated after an exposure to a zero magnetic field (Creanga et al., 2002). Adults from pupae maintained in a zero magnetic field for 20 h were used for the electroretinogram. A significant increase in sensitivity of neural cells from the first optic ganglion was indicated.

Osuga and Tatsuoka (1999) tested the effects of a 1.5-T static magnetic field by using an MRI system application on neuroconduction in a partially active nerve in the bullfrog (*Rana catesbeiana*). The action potential and nerve impedance measurements indicated that a field strength of 1.5 T had no effect on neuroconduction; therefore, it was determined that neuroconduction in damaged nerves was not affected by the exposure.

8.3.1.5 Magneto-Mechanical Systems

Testorf et al. (2002) studied the influence of homogenous static magnetic fields of 8 and 14 T on melanophore aggregation in black tetra (*Gymnocorymbus ternetzi*). The result showed no significant field effects on the aggregation after exposure to magnetic fields.

Effects of a 0.2-T static magnetic field on a normal human neuronal cell culture, FNC-B4, has been investigated with MCF-7 and WEHI-3 cells as controls (Pacini et al., 1999b). FNC-B4 cells changed their morphology after the exposure. Cells became elongated and formed vortexes, while controls did not show any alteration. The morphological changes in MRC-5 fibroblasts were evaluated as well (Pate et al., 2003). The cells were screened for cell mobility, cell distribution, and cellular morphology (size, shape, lysis, and background). These cells were exposed to both a static magnetic field and a pulsating magnetic field for a period of 0, 24, 48, and 72 h. Although the static magnetic field-exposed cells showed cell membrane damage and morphological change, as well as other interesting findings that were included in the report, this report may not be useful because it did not provide essential dosimetric data, such as strength of the field.

Danielyan et al. (1999) examined the effects of a 0.2-T static magnetic field on binding of ouabain-H^3, which is a specific inhibitor of Na^+-K^+-ATP-ase, in normal glandular breast tissue and in cancerous breast tissue. The static magnetic field-induced decrease of binding was considered as evidence for the dehydration effect of the field. This study has indicated that the static magnetic field tested could influence the cancer cell's metabolism through cell hydration changes. They investigated the effects of a 0.2-T static magnetic field on the hydration of rat tissues (Danielyan and Ayrapetyan, 1999). They assumed that the target for magnetic field action was the structured water of the cell. Decreases in hydration and adaptation of brain, liver, and spleen and an increase in the case of kidney were observed.

8.3.1.6 Musculoskeletal System

Yan et al. (1998) investigated the effects of static magnetic fields on bone formation of rat femurs. They implanted magnetized samarium cobalt rods with a field strength of 180 mT into rat femurs. The bone mineral density (BMD) and bone calcium content were measured 12 weeks after implantation. Results indicated that the femurs adjacent to the magnetized specimens had significantly higher BMD and calcium content. However, BMD and calcium content levels were found to be normal in both magnetized and unmagnetized specimen groups. The same research group further studied the effects of a 180-mT static magnetic field on bone formation, using an ischemic rat femur model (Xu et al., 2001). It was reported that the enhancement of the femoral bone formation was due to the improved blood circulation in the femur.

Satow et al. (2001) observed the effect of a 0.65-T static magnetic field on muscle tension in the neuromuscular preparation of the sartorius muscle of bullfrog (*R. catesbeiana*). The

tension development was obtained by stimulation of the sciatic nerve or of the sartorius muscle itself for a duration of 30 min. A decrease in muscle tension was observed. The results indicated that application of the static magnetic field was responsible for tension development.

8.3.2 Tissue, Molecular, and Cellular Studies

8.3.2.1 DNA and Chromatin

The exposure of isolated rat lymphocytes to a static magnetic field of 7 mT for 3 h did not increase the number of damaged cells (Zmyslony et al, 2000). Although incubation with 10 μg/ml $FeCl_2$ did not cause DNA damage, the number of damaged cells increased when the $FeCl_2$-incubated lymphocytes were simultaneously exposed to the field. A hypothesis for these observations was that the number of reactive oxygen species generated by iron ions in cells might increase after the exposure to the magnetic field (Jajte et al., 2002).

Binhi et al. (2001) have reported the effect of a weak static magnetic field on *Escherichia coli* K12 AB1157 cells, by using anomalous viscosity time dependence (AVTD) assay methods. The AVTD changes were found when the cells were exposed to static magnetic field levels up to 110 μT. These results were consistent with the calculations of individual rotations of the ion–protein complexes Ca^{2+}, Mg^{2+}, and Zn^{2+}, provided that all complexes rotated at the same speed. They suggested that the rotation for all ion–protein complexes is on the same carrier, such as DNA.

The effect of a zero magnetic field on the conformation of chromatin in human VH-10 fibroblasts and lymphocytes was investigated by the AVTD method (Belyaev et al., 1997). A decrease in the AVTD peaks was observed within 40–80 min of exposure to fibroblasts, and this decrease was transient, disappearing 120 min after the beginning of exposure. A similar effect of zero field was observed when cells were exposed for 20 min and kept at an ambient field. They concluded that both zero field and γ-rays caused hypercondensation and decondensation of chromatin. Zero field effects were more significant in the beginning of the G_1-phase than in the G_0-phase in human lymphocytes.

Okuda et al. (1998) evaluated the effects of a 6.34-T static magnetic field on the instability of microsatellite repetitive sequences in DNA mismatch repair (MMR)-proficient and MMR-deficient cell lines, HeLa S3, and HCT116, respectively. After exposure to the field, both cell lines exhibited no significant microsatellite sequence changes. This result suggested that the static magnetic field might not induce the genetic changes in microsatellite sequences.

8.3.2.2 Cell Growth, Cell Proliferation, and Cell Cycle

Potenza et al. (2004b) showed that *E. coli* cell growth and gene expression were affected by a static magnetic field exposure level of 300 mT. Cell proliferation at the stationary phase was increased by exposure to those cells growing in a modified medium culture containing glutamic acid; however, cell proliferation was not affected in those cells growing in traditional Luria–Bertani (LB) medium. Gene expression differences were estimated by differential display assays using arbitrary primers, and four genes were found to be responsive to the static magnetic field. One clone, expressed only in the exposed cells, corresponded to a putative transposase. Potenza et al. suggested that the static magnetic field exposure might stimulate transposition activity.

Stansell et al. (2001) reported that antibiotic (piperacillin) resistance of the clinically isolated *E. coli* was increased by the heterogenous static magnetic field exposure level of

8–60 mT for 45 min. They suggested the observation may be unique to the particular strain of *E. coli* or the specific antibiotic used. They did not suggest any mechanistic implication for this observation.

Poiata et al. (2003) reported zero magnetic field effect on the antibiotic resistance of *E. coli* strains isolated from human subjects. They used 26 *E. coli* strains and 5 different antibiotics, ampicillin, ceftazidine, tetracycline, ofloxacin, and kanamycin. Approximately one third of the tested strains was sensitive to the zero field treatment. Minimum inhibitory concentrations (MICs) of each antibiotic for some strains were decreased by zero magnetic field exposure, while the MICs for other strains were increased by the exposure. Their mechanistic hypothesis, based on magnetic particles, did not support these observations.

Ruiz-Gomez et al. (2004) showed that growth of the haploid yeast strain *Saccharomyces cerevisiae*, a eukaryotic cell, was not affected by exposure to static magnetic field levels of 0.35 and 2.45 mT.

Effects of a 0.2-T static magnetic field, generated by MRI alone or in combination with vitamin D treatment, on cell damage and proliferation in the human breast cancer cell MCF-7, human neuronal cell FNC-B4, and murine leukemia cell WEHI-3 have been investigated (Pacini et al., 1999a). Three-hour exposures to the 0.2 T field had no effect on the cell colony formation number in all three cell lines. Results demonstrated that [^{3}H] thymidine incorporation level decreased in MCF-7 and FNC-B4 cells, while no changes were observed in WEHI-3. It was also demonstrated that the treatment of cells using vitamin D had a permanent antiproliferative effect.

Long-term effects on proliferation of human fetal lung fibroblast (HFLF) cells of repetitive exposure to a 1.5-T static magnetic field with exposure periods of 1 h/d for 3 weeks have been investigated (Wiskirchen et al., 1999). Results showed no changes in clonogenic activity, DNA synthesis, cell cycle, and proliferation kinetics. In a following paper, effects of static magnetic field levels of 0.2, 1.0, or 1.5 T on the cell cycle in both synchronized and nonsynchronized HFLF cells were evaluated (Wiskirchen et al., 2000). The exposure condition was 1 h/d for 5 consecutive days. Results showed no significant differences in cell cycle events between synchronized and nonsynchronized cells.

A series of research studies on growth enhancement by strong inhomogenous static magnetic fields have been reported. Tsuchiya et al. (1996) showed that the growth of *E. coli* was affected by both a strong homogenous static magnetic field strength of 7 T and inhomogenous field strengths of 5.2–6.1 or 3.2–6.7 T. In the stationary phase, the cell number under a high magnetic field was about two to three times higher than that of a control. The effect of the inhomogenous field was much stronger than that of the homogenous field. They also showed that the transcription activity of *E. coli* was enhanced by the strong inhomogenous static magnetic field levels of 5.2–6.1 T (Tsuchiya et al., 1999). The transcription levels of the *rpoS*, gene which encodes sigma factor of RNA polymerase, was increased in the stationary phase by the static magnetic field exposure. This transcription factor is specifically activated during the stationary phase and plays an important role in the transcription control of other genes in the stationary phase.

Horiuchi et al. (2001) showed that *E. coli* cell death in the stationary phase was suppressed by strong inhomogenous static magnetic field levels of 5.2–6.1 T with a gradient of 24 T/m and that the suppression was dependent on the addition of amino acids to the LB medium. The addition of glutamic acid enhanced cell death as pH increased in the stationary phase, and cell death was dramatically suppressed by the field exposure. At the same time, *rpoS* gene expression was increased 20% by the field exposure. They suggested that the increase of *rpoS* gene expression in the stationary phase by the field exposure might be related to the base resistance because the *rpoS*-disrupted strain showed a lower base resistance than the wild-type strain (Ishizaki et al., 2001). It has

been shown that the medium supernatant, when used after the static magnetic field exposure, could enhance the suppression of cell death (Horiuchi et al., 2002). The pH of the medium after the static magnetic field exposure was only slightly different from that of the control (by a factor of 0.07 pH), and pH-adjusted medium from both exposed and control supernatants still had the suppression effect characteristics from the exposure to static magnetic fields. It has been suggested that other factors also were involved in the full suppression effect of cell death by the field exposure.

The growth advantage in stationary phase (GASP) phenomenon is described as follows. When *E. coli* cells grown for 10 d (aged culture) and *E. coli* cells grown only for 1 d (young culture) were mixed, the cell number of the young culture decreased, and the population of the young culture was taken over by the aged culture, and eventually only aged cells predominantly survived in the system. It has been found that the GASP phenomenon disappeared with the exposure to strong inhomogenous static magnetic field levels of 5.2–6.1 T (Okuno et al., 2001). They suggested that the disruption of the GASP phenomenon might be related to an effect on the *rpoS* gene by the static magnetic field exposure.

Gray et al. (2000) evaluated static electric and magnetic field effects on the action enhancement of the chemotherapeutic agent adriamycin in transplanted mammary adenocarcinoma in female B6C3F1 mice. Treatment consisted of using 10 mg/kg of adriamycin in combination with a 4-h exposure to a 110-mT field. Tumor regression in the groups exposed to a static magnetic field was greater than in the group treated with adriamycin only.

Tanioka et al. (1996) evaluated the effects of a 6.34-T static magnetic field on proliferation and metastatic activity in the B16 melanoma and EL-4 T-lymphoma cell lines. Cell cultures were incubated in the presence of magnetic fields for 12, 24, 36, or 48 h at 37°C. It was found that the proliferative and the metastatic activities of both cell lines were promoted under certain conditions.

Tofani et al. (2003) exposed immunocompetent mice bearing either the murine Lewis lung carcinoma or the B16 melanotic melanomas to static field levels of 3 and 4 mT and treated them with two commonly used anticancer drugs, cisplatin and cyclophosphamide, respectively. The survival time of mice treated with cisplatin and exposure to the magnetic fields was significantly longer than that of mice treated only with cisplatin or only exposed to the magnetic fields, surpassing that of mice treated with 10 mg/kg i.p. of the drug and showing that the magnetic field acts synergically with the pharmacological treatment. When mice treated with cyclophosphamide were exposed to the magnetic field, no synergic effects were observed. No clinical signs or toxicity were seen in any of the mice exposed to the magnetic field alone or along with cisplatin or cyclophosphamide treatment.

Raylman et al. (1996) studied the effects of exposure to a static magnetic field of 7 T for 64 h on cell viability in three malignant human cell lines, melanoma (HTB 63), ovarian carcinoma (HTB 77IP3), and lymphoma (Raji; CCL86). It has been reported that the static field exposure reduced the viable cell count and appeared to inhibit cell growth.

Using two types of mammalian cells, mouse leukemia cells P388 and Chinese hamster fibroblast cells V79, Sakurai et al. (1999) tested the effects on cell growth patterns of exposure to a 7-T static magnetic field for up to 5 d. No significant magnetic field effects on cells were found.

In a series of papers (Kula, 1996; Kula and Drozbz, 1996a,b), the magnetic field effects on cultured fibroblasts isolated from the BALB/c mouse have been investigated. The fibroblast cultures were exposed to a static magnetic field of 0.49 T and a 50-Hz AC magnetic field of 0.02 T for a time period of 2–64 min/d over four consecutive days. The following parameters were studied: the dynamics of culture growth; protein content;

thymidine incorporation; Zn, Fe, and Cu ion content; the activity of superoxide dismutase (SOD) and catalase (CT); and glycosaminoglycan metabolism. The static magnetic field exposure had no effect on both the vital functions and glycosaminoglycan metabolism and did not show any changes in the free-radical process in fibroblasts. Kula et al. (2000) further evaluated the activities of SOD, CT, glutathione peroxidase, and malondialdehyde (MDA) in the livers and kidneys of rats exposed to a static magnetic field of 0.49 T and a 50-Hz AC field of 0.018 T. While the 50-Hz magnetic field was found to influence free-radical processes in both liver and kidney tissue, the static magnetic field showed no effects. Magnetic field effects on the lipid peroxidation product, MDA, in mouse subcellular fibroblast have been evaluated by the same protocol in a previous report (Kula et al., 2002). It was found that exposure to a static magnetic field caused no changes in peroxidation of membrane structures.

Effects with a combination of static and alternating magnetic fields on cell attachment and induction of apoptosis in rat tendon fibroblast and rat bone marrow (RBM) osteoprogenitor cells have been reported (Blumenthal et al., 1997). Experiments utilized 60-and 1000-Hz AC magnetic fields of up to 0.25 mT_{p-p} and static magnetic fields of up to 0.25 mT. It was found that AC fields and static magnetic fields tested with various combinations of field strengths and frequencies resulted in extensive detachment of preattached cells and prevented the normal attachment of cells not previously attached to substrates. Results suggested significant alterations in cell metabolism and cytoskeleton structure after the exposure.

Blanchard and Blackman (1994) proposed the ion parametric resonance (IPR) model for the prediction of the interaction between magnetic fields and biological systems (see also Chapter 9 on resonance phenomena by Liboff). According to the IPR model, the relationships among the strength of a static magnetic field, the AC magnetic field frequency, and the charge-to-mass ratio of ions of biological relevance were important key factors. Blackman et al. (1996) tested the influence of magnetic fields on neurite outgrowth in PC-12 cells and showed that the PC-12 cell response to perpendicular AC and static magnetic fields was distinct and predictably different from that found for parallel AC and static magnetic fields. It has been reported that the response to perpendicular fields was dominant in an intensity-dependent nonlinear manner.

The effects of the combination of AC and static magnetic fields on the behavior of Friend erythroleukemia cells have been studied (Eremenko et al., 1996). The combined fields were a geomagnetic field of 45 μT, together with a 70-μT field at 50 Hz which was produced in a solenoid coil, and 20-nT DC and 2.5-pT AC fields in a magnetically shielded room. It was found that the culture growth cycle of cells was slightly accelerated inside the solenoid, and the degree of acceleration appeared to depend on sensitivity of the cell cycle to the magnetic field. On the other hand, it was found that the culture growth cycle of cells inside the magnetically shielded room was slightly decreased.

Effects of a static magnetic field exposure of 10 T for up to 4 d on the rate of cell growth or cell cycle distribution in Chinese hamster ovary (CHO-K1) cells have been investigated (Nakahara et al., 2002). The exposure to the static magnetic field alone did not affect micronucleus formation. In x-ray irradiated cells, exposure to the 10-T static magnetic field resulted in a significant increase in micronucleus formation. Buemi et al. (2001) examined the effects of a 0.5-mT static magnetic field on the cell proliferation and cell death balance in monkey renal cells (VERO) and in rat cortical astrocyte cells. After 6 d of exposure to the magnetic field, they observed the effects on cell proliferation and cell death balance and suggested that the effects might vary depending on the cell type. Magnetic fields may also have a nephropathogenic effect.

Tofani et al. (2001) investigated the role of magnetic field characteristics on the growth of WiDr human colon adenocarcinoma, MCF-7 human breast adenocarcinoma,

and MRC-5 embryonal lung fibroblast. Cell death induction was observed with a magnetic field exposure of greater than 1 mT when the combined static magnetic field and 50-Hz magnetic field was applied. The report showed that significant tumor growth inhibition appeared when the total field strength was greater than 3.59 mT.

Schiffer et al. (2003) studied the effects of four different types of magnetic field applications on the cell cycle progression in two different tumor cell lines, the human acute myeloid leukemia cell HL-60 and the mouse lymphoma cell EA2. The four types of magnetic field applications used were (1) the static magnetic field of 1.5 and 7.05 T, (2) the magnetic gradient field with ± 10 and ± 100 mT/m at 100 Hz; (3) the pulsed high frequency magnetic field (5.8 μT at 63.6 MHz); and (4) the combination of (1)–(3). The exposure duration ranged from 1 to 24 h. Cell cycle fractions at G_0/G_1, S, and G_2/M phases were analyzed by flow cytometry. Cell cycle analysis did not show differences between the exposed and control cells. In conclusion, during MRI, no influence of magnetic field on cell cycle progression was observed in these cell lines.

8.3.2.3 Cell Membrane and Cell Metabolic Activity

Chignell et al. (1998) studied the effects of static magnetic fields of 25–150 mT on the photohemolysis of human erythrocytes by ketoprofen. An application of a static magnetic field during UV (>300 nm) irradiation of ketoprofen and erythrocytes significantly decreased the time required for photohemolysis. It has been suggested that the magnetic field increases the concentration and lifetime of free radicals that escape from the radical pair.

Chionna et al. (2005) investigated the effects of a 6-mT static magnetic field, applied for 24 h, on cell shape, cell surface sugar residue, cytoskeleton, and apoptosis in the hepatic transformed cell line Hep G2. Significant modifications of cell shape and surface by the field exposure have been observed. The exposed cells were found to be elongated, with many irregular microvilli randomly distributed on the cell surface. The shape of the cells was found to be less flat at the end of the exposure, although the morphology of the organelles remained unmodified throughout the exposure period. It has been reported that cell proliferation was partially affected. Results suggested that the static magnetic field caused a time-dependent biological effect on Hep G2 cells.

Sonnier et al. (2000) found that there were no effects from the exposure of static magnetic field levels of 0.1, 0.5, 5, or 7.5 mT, applied for 5 sec, on resting potential in cultured neuroblastoma cells. They also used the patch-clamp technique to measure transmembrane Na^+, K^+ currents in neuroblastoma cells SH-Sy5Y exposed to static magnetic fields of up to 7.5 mT (Sonnier et al., 2003). The magnetic field exposure did not result in detectable changes in any of the action potential parameters.

Trabulsi et al. (1996) measured the excitatory postsynaptic potential (EPSP) after the exposure of a mouse hippocampal slice to static magnetic field levels of 2–3 mT and 8–10 mT for a period of 20 min. They observed biphasic effects at 2–3 mT and depression of EPSP at 8–10 mT. It has been suggested that changes in intracellular Ca^{2+} concentration were responsible for these effects. Isolated *Helix aspersa* neurons were exposed to static magnetic field levels of 0.07–0.7 T, and their action potential was measured (Azanza and del Moral, 1996). A decrease in the spike depolarization voltage has been observed, and it has been attributed to desensitization of the membrane Na^+-K^+-ATP-ase pumps through an anisotropic diamagnetism reorientation.

Wieraszko (2000) studied the effect of 2–3-mT static magnetic fields applied for 20 min on the evoked potential response in B57/J56 mice hippocampal slices. Results, which were based on measurements of hippocampal function, showed both an alteration of the evoked potential and an effect on the influence of dantrolene, an inhibitor of intracellular Ca^{2+} channels.

The voltage-activated calcium channel function in cultured GH3 cells has been investigated (Rosen, 1996). A static magnetic field of 120 mT was applied for 150 sec. Reversible changes in calcium channel function were observed and were found to be temperature dependent. Results indicated that these changes were a result of alterations in the membrane proper because of the magnetically induced deformation.

Using the whole-cell patch-clamp technique, voltage-activated Na^+ channels in GH3 cells were examined (Rosen, 2003). The effects of exposure to a static magnetic field of 125 mT for 150 sec on voltage-gated Na^+ channel kinetics included a slight shift in the current–voltage relationship, a 5% reduction in peak current, and an increase in the activation time constant, τ_m, during and at least 100 sec after the exposure to the field. Significant changes were only observed at 35°C and 37°C. It was suggested that the temperature dependence factor that affected this process was probably due to the greater ease with which the liquid crystal membrane was deformed. Results suggested that the changes might be due to the reorientation of diamagnetic anisotropic molecules in the membrane. Hinch et al. (2005) showed the effects of static magnetic fields on action potential propagation and excitation recovery in nerve. At a field level of 125 mT, which was the same condition previously used by Rosen, they did not observe major changes in the electrical functioning of neurons.

Aldinucci et al. (2003a,b) investigated the effects of a 4.75-T static magnetic field exposure applied for 1 h, and also a 1-h exposure using combined fields of 4.75 T with a pulsed field of 0.7 mT, on proinflammatory cytokines, in human peripheral blood mononuclear cells (PBMCs) and Jurkat cells. They measured Ca^{2+}, proliferation, and the eventual production of proinflammatory cytokines. The static magnetic field exposure alone did not show any effects on the physiologic behavior of normal lymphocytes; however, the combined static and alternating magnetic field exposure contributed synergistically to the increase of $[Ca^{2+}]_i$. The exposure of PBMCs was carried out in a static magnetic field of 10 T (Onodera et al., 2003). It was reported that the magnetic field exposure reduced the viability of phytohemagglutinin (PHA)-activated T cells in both CD4+ and CD8+ subclasses. Sabo et al. (2002) observed a decrease in the metabolic activity of human promyelocytic leukemic cells HL-60 when exposed to a field of 1 T for 72 h. The decrease was also observed in the presence of antineoplastic drugs, which included 5-fluorouracil, cisplatin, doxorubicin, and vincristine.

Miyamoto et al. (1996) studied the effects of strong 6-T homogenous magnetic fields on both active and passive Rb^+ influx into HeLa cells. Using field exposures of 1.6 T and lower, and of 2.0 T, at various temperatures did not cause any changes in active or passive Rb^+ influxes.

Mouse islet of Langerhans cells have a very regular oscillation of calcium concentration. Madec et al. (2003) showed no effects of combined AC and static magnetic fields on these calcium oscillations in mouse islet of Langerhans.

8.3.2.4 Gene Expression and Signal Transduction

Fanelli et al. (1999) found a decrease of apoptosis in the human cell lines U937 and CEM, following exposure to a static magnetic field of 600 μT. It was suggested that the protective antiapoptotic effect was due to cellular modifications from the static field exposure, which affected the ability of the cell to enhance Ca^{2+} influx from the extracellular medium. Cohly et al. (2003) examined the effects of a 0.618-mT static magnetic field on a human osteoblast cell line (MG-63) culture, in terms of proliferation, proline uptake, and gene expression. Results showed that the exposure might be detrimental to bone formation.

Mnaimneh et al. (1996) investigated the effects of static magnetic field levels from 1 to 100 mT and also an AC field of 1.6 mT delivered at 1 Hz on NO production by murine

BCG-activated macrophages. No significant differences were observed in NO levels after a 14-h exposure.

Brief exposure effects from a static magnetic field of 100 mT for 15 min on protein expression in cultured rat primary hippocampal cells have been reported (Hirai et al., 2002). Expression of DNA binding activator protein-1 (AP-1), neural marker protein (MAP2), and neural differentiation marker protein (GAP-43, c-Fos, Fos-B, Fra-2, c-Jun, Jun-B, and Jun-D) were examined. Cytoplasmic Ca^{2+} and lactate dehydrogenase activities were also analyzed. It was found that exposure to the static field increased AP-1 DNA binding through expression of Fra-2, c-Jun, and Jun-D in immature cultured hippocampal neurons.

Flipo et al. (1998) examined *in vitro* effects of the static magnetic field levels of 2.5–150 mT applied for 24 h on the mitogen response to concanavalin A, phagocytosis, apoptosis, and Ca^{2+} influx in C57Bl/6 murine macrophages, spleen lymphocytes, and thymic cells. The exposure resulted in a decrease of phagocytosis, an inhibition of mitogenic response in lymphocytes, and a marked increase of apoptosis in thymic cells.

Salerno et al. (1999) measured *in vitro* expressions of activation markers and interleukin release in human PBMCs after exposure to a static magnetic field of 0.5 T for 24 h. They observed that the expression of CD69 at 0.5 T was reduced after PHA stimulation. Increases in interferon-γ and interleukin 4L (IL-4L) releases were observed; however, no changes in tumor necrosis factor α (TNF-α), IL-6, and IL-10 releases were observed.

Effects of a static magnetic field of 1.5 T applied for 240 min on human L-132 cells have been investigated (Guisasola et al., 2002). Heat shock proteins hsp70, hsp27, and their corresponding messenger RNAs (mRNAs), along with cyclic AMP and Ca^{2+} ions were analyzed. No field exposure effects were observed.

Effects of the exposure of HL-60 cells to a 6-T spatially inhomogenous magnetic field with a strong gradient of 41.7 T/m and to a spatially homogenous magnetic field of 10 T have been studied (Hirose et al., 2003b). The expression of c-Jun protein increased in HL-60 cells after exposure to the 6-T static magnetic field for 24, 36, 48, and 72 h.

Using budding yeast (*S. cerevisiae*) as a model for an *in vitro* biological test system, Ikehata et al. (2003) examined the genome-wide gene expression profile of yeast cells after exposure to 5- and 10-T fields for periods of 2 and 24 h. Exposure to static magnetic fields did not affect gene expression. Slight changes in the expression of several genes were observed after exposure to 14 T for 24 h.

8.3.2.5 Genotoxicity

Previous studies have shown that static magnetic fields alone did not have a lethal effect on cell growth and survival under normal culture conditions, regardless of the strength of the magnetic field applied. Effects of 5-h exposures of HL-60 cells to 6-mT static magnetic fields, with or without camptothecin, which is a DNA topoisomerase I inhibitor, have been investigated (Teodori et al., 2002). Results indicated that the field exposure did not cause apoptogenic or necrogenic effects. It was reported that exposure to the static magnetic field alone or with camptothecin did not affect cell viability.

Potenza et al. (2004a) showed that the conformation of plasmid DNA was altered by exposure to static magnetic fields of 250 mT. Various DNA point mutations were found, while no DNA degradation was observed. It was shown that the DNA degradation from H_2O_2 was accelerated by simultaneous field exposure; however, the plasmid DNA in *E. coli* cells exposed to the same static magnetic field did not show any alteration. They suggested that the magnetic field could change DNA stability directly or by activating the reactivity of oxidant radicals. It has also been suggested that the genotoxic effect could be minimized in living organisms by the presence of protective cellular responses, such as the DNA repair system and the buffering action of heat shock proteins.

In order to reveal the genetic effects of a 0.6-T static magnetic field, mutagen-sensitive mutants of the fruit fly (*D. melanogaster*) were used for the somatic cell test (Koana et al., 1995). It was shown that the exposure resulted in damaging effects in larval cellular DNA, and somatic cells without normal DNA repair functions failed to continue cell division, which resulted in developmental lethality of mutant larvae. The genotoxic activity of the field exposure was estimated to be the same as that of UV irradiation with 0.14 mJ/m^2/sec. Further study has been conducted with *D. melanogaster* using a wing spot test to estimate possible mutagenic or carcinogenic activity of the static magnetic field (Koana et al., 1997). A DNA repair defective mutation *mei-41*^{D5} was introduced into the conventional *mwh/flr* test system to enhance mutant spot frequency. Third-instar larvae were exposed to a field of 5 T for 24 h. It was shown that the exposure significantly enhanced the somatic recombination, and the recombination was found to be suppressed by supplementation of vitamin E. Results indicated that the magnetic field enhanced the genotoxic effects of spontaneously produced free radicals (Takashima et al., 2004).

In a report describing the investigations of whether static magnetic fields have cytogenetic effects in BALB/c AnNCrj male mouse bone marrow cells, Suzuki et al. (2001) indicated that the frequency of micronuclei was significantly increased by exposure to a 3-T field for 48 and 72 or a 4.7-T field for 24, 48, and 72 h. The increase in micronucleus frequency was shown to be dose dependent.

Micronuclei in cells have been used as an indicator of DNA damage. A study for *in vitro* assessment of the effects of a 4.7-T static magnetic field on the frequency of micronucleated cells in the Chinese hamster CHL/IU cell line with preexisting damage induced by exposure to mitomycin C (MMC) has been carried out (Okonogi et al., 1996). Results indicated a decrease in the frequency of micronuclei formation after 6 h of exposure and also the influence of the static magnetic field on the DNA damage stage produced by MMC.

An *E. coli* mutation assay has been carried out to assess the mutagenic effects of strong static magnetic fields (Zhang et al., 2003). Results obtained with a wild-type *E. coli* strain GC4468 and several derivatives, which were defective in DNA repair enzymes or redox-regulating enzymes, showed no effects of the exposure in terms of the survival rate of cells. On the other hand, the mutation frequency was significantly increased by exposure to the 9-T static magnetic field for 24 h in *soxR* and *sodAsodB* mutants, which were defective in their defense mechanism against oxidative stress. Results indicated that static magnetic fields induced mutations by increasing the production of intracellular superoxide radicals.

Ikehata et al. (1999) reported that 2- and 5-T static magnetic fields did not have mutagenic potential in a bacterial mutation test using *Salmonella typhimurium* (TA98, TA100, TA1535, and TA1537) and *E. coli* (WP2 *uvrA*) strains. They also reported that the exposure resulted in an increased mutation rate of the WP2 *uvrA* strain when induced by the agents *N*-ethyl-*N*′- nitro-*N*-nitrosoguanidine (ENNG), *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG), ethylmethanesulfonate (EMS), 4-nitroquinoline-*N*-oxide (4NQO), 2-amino-3-methyl-3*H*-imidazo-[4,5-*f*]-quinoline (IQ), and 2-(2-furyl)-3-(5-nitro-2-fulyl) acrylamide (AF-2). The mutagenicities of 2-aminoanthracene (2-AA), 9-aminoacridine (9-AA), *N*-4-aminocytidine, and 2-acetoamidofluorene (2-AAF) were not affected by the exposure. The bacterial growth did not change after the exposure. They suggested that the mechanism of these effects might be related to *in vitro* interactions between the chemicals and DNA and to repair systems in the test strains.

8.3.2.6 Cell-Free System, Free Radical, Enzyme Activity

Markov and Pilla (1994, 1997) studied the Ca^{2+}/calmodulin-dependent myosin phosphorylation and observed magnetic field effects of 44-μT, ambient, and 200-μT vertical fields for 5 min on the Ca^{2+} binding property. Phosphorylation increased up to at 200 μT

depending on the [Ca^{2+}] concentration. The magnetic field effect disappeared as [Ca^{2+}] approached saturation for calmodulin. They emphasized that very small alterations in ambient level static magnetic fields are sufficient to have a profound effect on a cell-free enzyme system. In an attempt to replicate the results of Markov and Pilla, Coulton et al. (2000) saw no effects on myosin phosphoration in a cell-free system in vertical static magnetic fields up to 400 μT. As a result, in this experiment, no effects of static magnetic fields on the calcium/calmodulin binding property were observed. Engstrom et al. (2002) investigated the effects of nonuniform static magnetic fields of 0.7–87 mT with a gradient of 0.4–20 T/m for a period of 5 min on myosin phosphorylation and reported that the magnetic field exerted an influence on the rate of myosin phosphorylation. Increased phosphorylation was observed. It can be seen that the magnetic field gradients played a specific role in this experiment. Liboff et al. (2003) investigated the effect of a 30-min exposure to a static magnetic field of 20 μT on calmodulin-dependent cyclic nucleotide phosphodiesterase activity in cell-free systems and reported that the activity was altered in comparison to zero magnetic field exposures.

After studying the theoretical background of a cell-free system—Ca^{2+}/calmodulin-dependent myosin light chain phosphorylation reaction—Markov (2004a,b) designed experiments to test the effects of a pulsed radio frequency (RF) field, pulsating magnetic fields, gradient magnetic fields, and homogenous static magnetic fields on this cell-free system. He suggested that the magnetic fields affect the cell-free enzyme system by modulating ion–protein interactions.

Watanabe et al. (1997) measured and evaluated lipid peroxidation in the liver, kidneys, heart, lung, and brain of 8-week-old male BALB/c mice. The mice were exposed to 3.0- and 4.7-T fields for 3–48 h. The lipid peroxidation level in the liver was increased after exposure to the 4.7-T field. In kidney, heart, lung, and brain, no changes in the level of lipid peroxidation were observed compared to the control. The exposure to the 3.0-T field showed no alteration of the lipid peroxide level in all the tissues. The combination of CCl_4 administration and 4.7-T field exposure increased the lipid peroxidation level in the liver. It was concluded that the exposure to high static magnetic fields could induce the increase of lipid peroxidation levels in the liver of mice and could enhance the hepatotoxicity caused by CCl_4 injection.

Using fireflies, *Hotaria parvula* and *Luciola cruciata*, as bioluminescence systems, Iwasaka and Ueno (1998a) studied the effects of 8- and 14-T static magnetic fields on the emission of light. They showed that changes in the emission intensities under a magnetic field were related to the change in certain biochemical systems of the firefly, systems such as the enzymatic process of luciferase and the excited singlet state responsible for subsequent light emission.

Zhadin et al. (1998) have undertaken experiments that investigated the combined action of static and AC magnetic fields on ionic current in aqueous glutamic acid solution. Results showed that the combined parallel static and AC magnetic field causes a rapid change in the ionic current flow when the AC frequency is equal to the cyclotron frequency.

During the last few years, Brocklehurst and McLauchlan (1996) discussed the free radical mechanism involved in the observed effects of environmental electromagnetic fields on biological systems. Grissom and Natarajan (1997) summarized the theory of magnetic field effects on chemical and enzymatic reactions. Magnetic field effects have been used as a powerful technique to study enzymatic and chemical reactions with radical pair intermediates. They suggested that the coenzyme B_{12}-dependent enzymes with radical pair intermediates are well suited for the study of this effect. Taoka et al. (1997) tested the magnetic field effects on coenzyme B_{12}-dependent enzymes. The end point was that ethanolamine ammonia lyase and human enzyme

methylmalonyl–coenzyme A mutase catalyze coenzyme B_{12}-dependent rearrangement reactions. While the end point was affected, the authors speculate that the change would have little physiological significance.

Eichwald and Walleczek (1996) showed a model for magnetic field effects on radical pair recombination in enzyme kinetics. The magnetic field effects in radical pair chemistry have been reviewed (Grissom, 1995; Brocklehurst, 2002; see also Chapter 6 on free radicals by Engström).

8.4 Miscellaneous

8.4.1 Biological Sensing and Magnetite

Many studies have suggested that the magnetic field is an important marker for animal navigation and spatial discrimination (Wiltschko and Wiltschko, 1995). The blind mole-rat (*Spalax ehrenbergi*) was used as a model to examine the possibility of the perception and use of magnetic fields in their orientation in space (Kimchi and Terkel, 2001). Experiments were performed in an eight-arm maze under Earth's natural and artificial magnetic fields. Results showed that the blind mole-rat was able to perceive and use Earth's magnetic field to orient in space. Kimchi and Terkel showed that blind mole-rats spontaneously preferred to place their nests toward the south of the magnetic North. Deutchlander et al. (2003) showed that Siberian hamsters (*Phodopus sungorus*) used directional information from the magnetic field to set a position for their nests. In contrast to blind mole-rats, the directional preference for nest position demonstrated by Siberian hamsters appeared to be a learned response.

Since the neural substrate subserving magnetic orientation is not known, the combination of two techniques, a behavioral test for magnetic compass orientation and an immunocytochemical visualization of the transcription factor c-Fos as a neuronal activity marker, has been used to investigate magnetoreception in the mole rat (*Crytomys anselli*) (Nemec et al., 2001). Nemec et al. found that the superior colliculus of the hypothalamus contained neurons that would respond to magnetic stimuli, and thus determined the involvement of a specific mammalian brain structure in magnetoreception.

Edmond (1996) showed that a very sensitive magnetic compass is formed by the incorporation of a small quantity of ferromagnetic, single-domain crystals, such as magnetite, within a nematic liquid crystal. Winklhofer et al. (2001) localized high concentrations of Fe^{3+} in the upper-beak skin of homing pigeons (*Columba livia*), and identified the materials of magnetite nanocrystals as the core of a magnetic field receptor.

Lohman et al. (2001) found that hatchling loggerhead sea turtles (*Caretta caretta*), when they were exposed to magnetic fields found in three widely separated oceanic regions, swam in the direction that would help to keep them within the currents of the North Atlantic gyre and facilitate their migratory pathway. It was found that young loggerheads used a guidance system of magnetic fields to assist in their navigation.

Although the mechanism of magnetoreception has not been clearly identified, geomagnetic orientation has been well recognized. A biophysical model has shown that changes in the wavelength of light can influence magnetic field orientation through the interaction between the geomagnetic field and photoreceptors. Deutschlander et al. (1999a) found that light-dependent orientation in the newt (*Notophthalmus viridescens*), was mediated by extraocular photoreceptors located in the pineal complex or deeper in the brain. Using newts, Phillips et al. (2001, 2002b) showed the role of photoreceptors in magnetic compass

orientation and the magnetic inclination for deriving map information. They investigated the possibility that the fixed-axis response of the newts was mediated by a magnetoreception mechanism involving single-domain particles of magnetite (Phillips et al., 2002a).

There are several explanations for the magnetic sensitivity in fish. The aquatic animal might perceive an electric voltage induced by the water current or by its own movement in the geomagnetic fields. Elasmobranch fish such as sharks, skates, and rays are known to possess a sensitivity to the induced electric field through the sensory organs called the ampullae of Lorenzini.

Yano et al. (1997) studied the migrating behavior of the chum salmon (*Oncorhynchus keta*) fitted with a magnet to investigate the role of magnetic compass orientation in the North Pacific off the coast of Kushiro, Hokkaido. The magnetic field strength was about 0.6 mT around the head area, with polarity changes every 11.25 min. There were no effects observed on the movement of salmon.

Effects of electric and magnetic fields have been observed in the behavior of marine animals and freshwater and terrestrial species. In addition, there are a growing number of questions concerning the effect on aquatic ecosystems of the growing spread of artificial techniques such as underwater sea DC cables. There are many underwater DC cables under various seas all over the world, which carry electrical currents (see also Chapter 1 on fields in the environment by Mild and Greenebaum). These electric currents induce static magnetic fields with intensities up to 3.5 mT around cables on the sea bottom, where there are many invertebrate and vertebrate species. Research has been carried out to examine whether the exposure to magnetic fields of 3.7 mT for several weeks could influence the survival rate and fitness of common benthic animals of the Baltic Sea (Bochert and Zettler, 2004). The investigation was carried out on the crustacean (*Crangon crangon*, *Rhithropanopeus harrisii*, and *Saduria entomon*); the mussel (*Mytilus edulis*); and the flounder (*Planthichthys flesus*). Results showed no differences between experimental and control animals. Since this is the first study for investigating the effects of static magnetic fields generated by sea-positioned DC cables, on aquatic organisms and marine benthic animals, further studies are required.

In a study to confirm the magnetite-based detection mechanism in rainbow trout (*O. mykiss*), magnetic crystals in the area of olfactory lamellae were found, and the arrangement of several magnetic crystals in a chain of about 1 μm has been confirmed (Diebel et al., 2000).

It was shown that magnetizable material abolishes the behavior of bobolink (*Dolichonyx oryzivorus*) by blocking the ophthalmic branch of the trigeminal nerve (Beason and Semm, 1996). The result was consistent with the hypothesis that magnetite is a constituent of the magnetoreceptors associated with the ophthalmic nerve.

It is suggested that migratory birds, amphibians, and reptiles may have the ability to sense the geomagnetic field and use it as a source of compass information. Phillips (1996) presented a graphical model that predicts qualitatively the changes in the direction of homing orientation. Munro et al. (1997) investigated the effect of pulse remagnetization on the orientation of inexperienced, juvenile migrant birds, such as the Australian silvereye (*Zosterops l. lateralis*). The ability of juvenile birds to maintain their normal magnetic orientation after pulse application indicated that the pulse does not impair the magnetic compass. On the other hand, the deflection observed in adult birds after pulse treatment appeared to reflect ''false'' map information, which leads to a change in course. This is consistent with evidence that the magnetic compass involves light-dependent magnetoreception mechanisms.

Wiltschko and Wiltschko (2001) studied the behavior of European robins (*Erithacus rubecula*), under monochromatic light of various wavelengths and intensities to investigate magnetoreception. At a quantal flux of 7×10^{15} quanta/sec/m^2, the birds were well

oriented in their migratory direction under 424 nm blue, 510 nm turquoise, and 565 nm green, whereas they were disoriented under 590 nm yellow. Changes in behavior depended on increasing the light intensity. This finding suggested that light-dependent magnetoreception may involve receptors and a neuronal pathway of its own.

Ritz et al. (2000) postulated the possibility that magnetoreception involves radical pair processes as a biophysical mechanism. They first considered a system of radical pairs as a model for the magnetic sensory organ and evaluated the influence of the geomagnetic field on radical pair systems. European robins (*E. rubecula*), were used in this study, and the results showed the disruption of magnetic orientation behavior of robins when exposed to a vertically aligned broadband field of 0.1–10 MHz and 0.085 μT or the single frequency of 7 MHz and 0.47 μT, together with the geomagnetic field (Ritz et al., 2004). The disorientation observed was found to depend on the angle between the 7-MHz oscillating field and the geomagnetic field. The robins oriented in the migratory direction when the oscillating field was parallel to the geomagnetic field. The author suggested a magnetic compass based on a radical pair mechanism, due to the resonance effect on singlet–triplet transitions in the oscillating fields.

Fuller suggested the significance of the time constants of magnetic field sensitivity in animals (Fuller and Dobson, 2005). Conditioning experiments have had great success in the analysis of animal sensory physiology. Wiltschko and Wiltschko (1996) commented that the conditioning technique did not appear to be suitable for testing magnetic sensitivity.

Some insects are able to respond to magnetic fields, especially the geomagnetic field. Mosquitoes were tested for the presence of remanent ferromagnetic material and their behavioral response to magnetic fields. Most mosquitoes, when placed in a uniform static magnetic field of 0.1 mT, moved around until they were oriented parallel to the field. It was reported that a significant remanence found on the surface of both living and dead mosquitoes might be due to attraction of ferromagnetic dust onto the body (Strickman et al., 2000). It is well-known that magnetic fields influence honey bee behavior, moth navigation, beetle larvae, the behavior of hatchling loggerhead sea turtles, migration of birds, etc. Slowik et al. (1997b) speculated that the red imported fire ant (*Solenopsis invicta*) might use magnetic field information in their nesting activities and in orientation, since their first observation suggested that fire ant workers moved as a colony toward the magnetic field. In a second paper, Slowik et al. (1997a) suggested the presence of small amounts of ferromagnetic material in fire ants.

Many review papers have been published during the last few years. Deuschlander et al. (1999b) and Wiltschko and Wiltschko (2002) reviewed the light-dependent magnetoreception in animals. Lohmann and Johnsen (2000) described the difference between a magnetic directional sense and a magnetic map sense and reviewed the three hypotheses of vertebrate magnetoreception.

8.4.2 Plant Growth, Response, and Magnetotropism

The enhancement of plant growth using various magnetic field applications has been reported by many researchers (Phirke et al., 1996). Effects of magnetic fields on seed germination, crop growth, physiological response, sporulation, water uptake, and rate of seed have been studied; however, there has been no consistency in results among the various reports.

Studies directed toward investigating the effects of magnetic field treatment on seeds and water in terms of the rate and percentage of germination of rice (*Oryza sativa* L.) and on the length and weight of germinating barley (*Hordeum vulgare* L.) and wheat (*Triticum aestivum* L.) have been carried out (Carbonell et al., 2000; Martinez et al., 2000, 2002). The

field strength ranged from 125 to 250 mT depending on the research strategies. Results by Carbonell et al. showed that the rate and percentage of germination increased after chronic exposure to 150-mT fields. Magnetically treated water was found to improve the germination of rice seeds. Martinez et al. (2000) showed that the magnetic field increased the length and weight of barley seed, and the degree of this effect depended on the duration of exposure. Effects of magnetic biostimulation on the initial growth stages of wheat, with an exposure duration of 0, 1, 10, 20 min, 1 h, 24 h, and chronic exposure were investigated (Martinez et al., 2002). In the report, they defined the magnetic doses in terms of magnetic field energy density (J/m^3). An increase in plant height had been observed as the magnetic dose increased; thus, it was suggested that the stimulatory effects might be related to the amount of magnetic field energy. Florez et al. (2004) investigated the effects of 125- and 250-mT static magnetic fields on the germination and the initial growth stages of rice seeds (*O. sativa* L.). The seeds were exposed to the magnetic fields for various time durations, and the germination time was found to be shortened when the seeds were exposed to these fields. The seeds' maximum length and weight were obtained for the chronic exposure. It was shown that magnetic treatments, when applied under specific conditions, affected germination and the first stage of growth.

Piatti et al. (2002) investigated the effects of inhomogenous static magnetic fields ranging between 6 and 10 mT on the growth and viability of the plant-growing bacteria *Serratia marcescens*, barley callus cells (*Hordeum vulgare*), and blackberry (*Rubus fructiosus*). While there was no field effect observed on blackberry cells, it was found that the exposure reduced the number of bacterial cells and lowered both the number and the viability of barley cells. Diamagnetic susceptibility and root growth response to magnetic field exposure on three plant species, *Lens culinaris*, *Glycine soja*, and *T. aestivum* were investigated (Penuelas et al., 2004). Magnetic fields of 17.6 mT reduced root growth in all three plants. The field strength of 2.1 mT had no significant effect on reduction in the cereal *T. aestivum*.

Among the many studies that examined gradient magnetic field effects on various engineering, biological, and physicochemical phenomena, a study of effects of gradient magnetic fields of up to 10 T on the germination and growing process of cucumber (*Cucumis sativus* L.) was carried out (Hirota et al., 1999). It was found that the shoot germinated toward the field center, whereas the root grew in the opposite direction of the shoot. This observation seemed to be a result of the magnetic force influencing the geotaxis of the cucumber.

After calculating the magnetic field dependence of the ionic current density across the cellular membrane, Reina and colleagues examined the effects of 0–10 mT static magnetic fields on the amount and rate of water absorption in the lettuce seed cell membrane (*Lactuca sativa*) in order to compare the calculated and experimental results (Reina and Pascual, 2001; Reina et al., 2001). Theoretical calculations showed that the static magnetic field induced changes in the ionic concentration and in the osmotic pressure, which regulates the entrance of water into the seeds. The magnetic field exposure was 10 min in a Helmholtz coil, and this was carried out immediately before placing the seeds in water inside a climatized room. The investigators demonstrated a close correlation between their theoretical calculations and the actual experimental results. It was shown that exposure to the static magnetic fields altered the water absorption in seeds, which may possibly explain the change of germination rate. Adair (2002) discussed and questioned these results. Amyan and Ayrapetyan (2004) investigated changes in the wet and dry weight of barley seed after treatment by static magnetic field levels of 1.25, 2.50, and 3.75 mT. Seed treatment was carried out in cold (4°C) and warm (20°C) distilled water. After pretreatment by the fields, the seeds were incubated for 72 h. Results suggested that effects depend on not only the field strength but also the incubation time period.

Growth and sporulation of phytopathogenic microscopic fungi have been investigated under exposure to a static magnetic field that ranged from 0.1 to 1 mT (Nagy, 2004). It was

shown that the growth was decreased by the magnetic field exposures. Increases in the number of developed conidia of *Alternaria alternata* and *Curvularia inaequalis* and a decrease in the number of *Fusarium oxysporum* conidia have been observed as well.

Effects of combined AC and DC magnetic fields on the germination of hornwort seed (*Cryptotaenia japonica* Hassk) have been reported by Kobayashi et al. (2004). They tested three directions of the AC magnetic field, which were vertical, parallel, and perpendicular to the direction of total geomagnetic field (DC). The frequency and strength of the AC magnetic fields ranged between 3.5 and 14 Hz and 500 and 750 μT. The total geomagnetic field was 50 μT. The seeds were exposed to the fields for 16 d at 24 h/d. The vertical AC magnetic field applied simultaneously with the DC field was found to promote the germination of seeds. Field level applications of 7 Hz, 750 μT and 14 Hz, 500 μT showed the maximum effects.

Effects of static magnetic fields ranging from 0 to 350 μT on gravitropic bending in the apical stem segments of flax seedlings (*Linum bienne*) have been investigated (Belova and Lednev, 2001). In comparison with the control group kept in a geomagnetic field of 46.5 μT, stimulation of the gravitropic bending was observed at $0 \leq B_{DC} \leq 2\,\mu T$ and $200 \leq B_{DC} \leq 350\,\mu T$, and inhibition was observed at $100 \leq B_{DC} \leq 170\,\mu T$.

Investigations of static magnetic field effects on the curvature of primary roots of radish seedling (*Raphanus sativus* L.) have been carried out (Yano et al., 2001). When radish roots were exposed to an inhomogenous static magnetic field, they responded to the south pole of the magnet. Trophic response was found at a field level of 13–68 mT with a gradient of 1.8–14.7 T/m. A small response to the north pole of the magnet was found as well.

Jovanic and Sarvan (2004) studied the effects of static magnetic fields on fluorescence spectra and leaf temperature in intact plant bean (*Phaseolus vulgaris* L.) The field strengths were as high as 160 mT, and the plant was grown for 3 weeks. It was reported that significant changes in fluorescence spectra and leaf temperature were induced after the field exposure. An increase of fluorescence intensity ratio and changes in leaf temperature ΔT were observed in parallel with increase in field intensity.

8.4.3 Magnetotaxis

There have been many studies reporting that magnetic fields affect the swimming behavior of *Paramecium*. A decrease in swimming velocity and an increase in the frequency of directional changes were observed after exposure to a magnetic field of 0.126 T during a motility study of *Paramecium* (Rosen and Rosen, 1990). Nakaoka et al. (2002) found that a typical ciliated protozoan, *Paramecium*, swam perpendicular to a static magnetic field of 0.68 T. It was suggested that the diamagnetic anisotropy of cellular components cilia and trichocysts was important for the magnetic orientation of their swimming.

Effects of horizontal magnetic fields on the movement of *Euglena gracilis* (ca. 50 μm in length) have been reported (Tanimoto et al., 2001). When the horizontal magnetic field with a gradient of ca. 400 T^2/m was applied, living *E. gracilis* moved to the higher field (positive magnetotaxis), whereas dead *E. gracilis* moved to the opposite, lower field. *E. gracilis* was found to be oriented perpendicularly to the magnetic field regardless of whether they were alive or dead. Thus, magnetotaxis of living *E. gracilis* may be explained by taking into account both the environmental inhomogenous magnetic forces and the magnetic orientation of *E. gracilis*. In contrast, magnetotaxis was not observed in a uniform magnetic field of 8 T. Effects of strong magnetic field gradient (max. 8 T, ca. 400 T^2/m) on the movement of *E. coli* have been investigated (Tanimoto et al., 2005). *E. coli* cells were placed in a 5 mm (diameter) × 150 mm (length) glass tube containing viscous media that flowed in the tube. The speed at zero field was 0.65 cm/h. The observed velocities of the movement from a high field (8 T) to a low field (1.5 T) and the movement in the opposite direction around

were 1.35 and 0.49 cm/h, respectively. Diamagnetic *E. coli* experienced a repulsive behavior to magnetic forces of increased magnetic gradient. Therefore, it has been speculated that the velocity of *E. coli* would be accelerated toward the direction of the lower-strength field, while it would be decelerated in the direction of the stronger fields. Results suggested the magnetic force specifically, could be an important mechanism of magnetic field effects when a low-frequency high magnetic field was applied, since the microorganism might respond to mechanical stress due to alternating magnetic forces.

8.4.4 Others

As an initial study for investigating the relationship between magnetic fields and amoebae, Berk et al. (1997) examined the inhibitory effects of static magnetic fields on the population growth of amoebae. They tested three species, *Acanthamoeba hatcheii*, *Acanthamoeba castellanii*, and *Acanthamoeba polyphaga*. Amoebae were exposed to magnetic field strengths of 71 and 106.5 mT with an exposure duration up to 72 h. Results showed that magnetic fields decreased the growth of all three potentially pathogenic ameba populations significantly within 72 h. It was reported that the inhibitory effect did not depend on the field strength, and it was shown that this research would be important and advantageous in the development of disinfection strategies for surface material, such as the surface of contact lenses.

Rai et al. (1997) investigated the effects of a 0.1-T static magnetic field on the electrical parameters of goat eye lens. Under magnetic field application, the complex impedance between real and imaginary parts was obtained in the form of a Cole–Cole plot. It was reported that the static magnetic field altered the current flow in the tissue.

Iwasaka and Ueno (1998b) investigated the effects of a static magnetic field of up to 14 T on the near-infrared spectrum of water molecules and glucose solutions. They demonstrated the possibility that the static magnetic field affected the formation of hydrogen bonds of water molecules and the hydration of glucose molecules.

Morariu et al. (2000) exposed human blood samples to zero magnetic fields for 72 h in order to observe the aging process of erythrocytes. The control samples were kept in a normal geomagnetic field. In a zero magnetic field, increases in the rate of Na^+ and Ca^{2+} influx, in the rate of K^+ outflow, and in homolysis were observed. Reduction in Na^+-K^+-ATPase and Ca^{2+}-ATPase activities has been observed in a zero magnetic field; thus, zero fields significantly accelerated the aging of erythocytes. Effects of zero magnetic fields were further investigated on Zn and Cu concentrations in the human blood serum during *in vitro* aging of blood with a 48-h exposure (Ciortea et al., 2001). Blood samples were collected from both healthy donors and chronic bronchial asthma (BA) patients. While the Zn concentration was not found to be affected by the zero magnetic field exposure, Cu concentration was found to be sensitive to this field. It was also reported that the aging effect appeared to be decelerated for most BA types.

8.5 Medical Applications

8.5.1 Biomagnetic Phenomena

Biomagnetic phenomena for different intensities of magnetic fields and their frequency are shown in Figure 8.1. It is important to know the intensities and frequencies of magnetic fields involved in biomagnetic phenomena while discussing the relationship

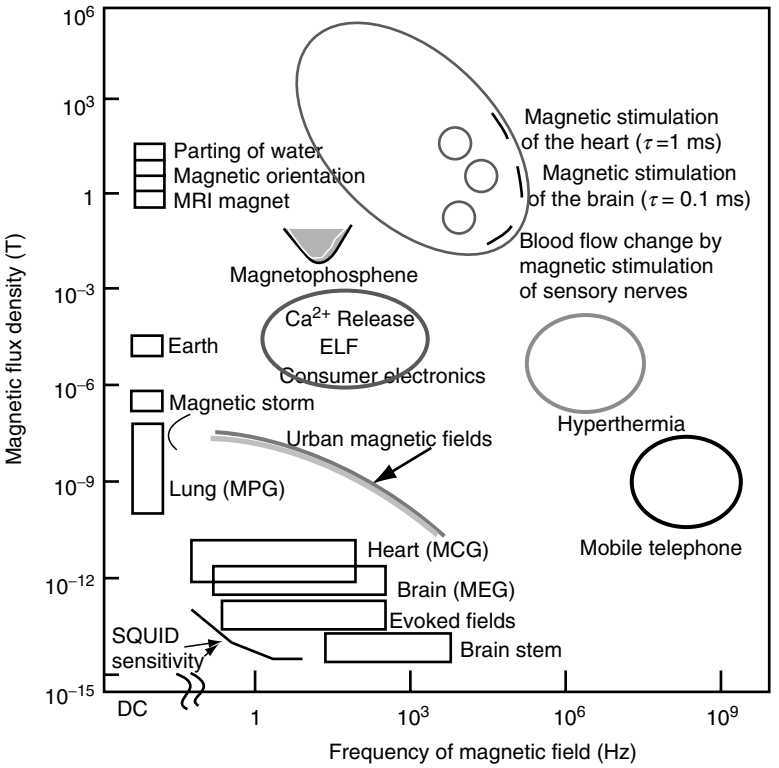

FIGURE 8.1
Biomagnetic phenomena for medical and therapeutic application.

between magnetism and living organisms. Regarding the effects of magnetism on living organisms, it should be realized that the actions of static and variable magnetic fields differ from each other in terms of the fundamental mechanism.

Studies on the biological effects of electromagnetic fields have resulted in significant developments in medical applications for electromagnetic fields, after the development of high-strength superconducting magnets. TMS, measurement of biomagnetic fields with the superconducting quantum interference device (SQUID), and MRI are the three mainstays of these medical applications. These techniques have also been leading the amazing progress in the understanding of the brain function. TMS locally stimulates the human cerebral cortex with millimeter-order spatial resolution from a figure-eight coil placed on the skull. A three-dimensional imaging of the brain neuron function has been enabled by utilization of SQUID in magnetoencephalography (MEG), functional magnetic resonance imaging (fMRI), and current-distribution MRI. Results from TMS and imaging studies indicate potential applications of biomagnetics in brain science and clinical neuropsychiatry.

In TMS, when a strong electric current is applied to a figure-eight coil positioned over the head for 0.1–0.2 ms, a pulsed magnetic field of 1 T is produced. This pulsed magnetic field generates eddy currents in the brain, which excite the targeted area of the nervous system.

Incidentally, unconscious and uncontrolled exposure of the brain to high-frequency electromagnetic waves has been increasing with the recent, rapid widespread use of cellular phones by the general public. Cellular phones in Japan are designed for operation with a frequency of 800 MHz and a microwave of 1.5 GHz (see Chapter 1 on environmental exposures by Mild and Greenebaum).

In biomagnetic measurements, MEG associated with auditory brain stem response is of the order of 10^{-15} T (1 fT), and it can be measured on the extremum of the sensitivity limitation of the SQUID gradiometer (Erne et al., 1988; Iramina and Ueno, 1995). In 10^{-12} T (1 pT)-order measurements, while α-wave spontaneous MEG can be detected without a signal-averaging technique, the technique is required to increase a signal-to-noise ratio (SNR) in order to detect various evoked responses and brain stem responses.

The recent development of noninvasive brain function measurement technologies, such as MEG and fMRI, has been contributing to the rapid progress in brain science research. Scientific discussions of mental problems such as thinking and psychomotor activities (e.g., joy, anger, sadness, and happiness) in terms of brain function became possible with the development of these new technologies.

In static magnetic fields of a few tesla, fibrin polymers, which are involved in blood coagulation, orient parallel to the magnetic fields in the course of polymerization (Yamagishi et al., 1989; Ueno et al., 1993). Furthermore, magnetic alteration of blood coagulation and dissolution processes by magnetic fields and magnetic orientation of biopolymers, such as fibrin and collagen, have been observed. These findings introduce a new aspect of biomagnetic applications in the regulation of living systems and biological materials.

8.5.2 Transcranial Magnetic Stimulation

TMS is the technique of locally applying magnetic stimulation by a strong pulsed magnetic field on the order of 1 T transcranially to the brain. When a strong electric current is applied to a figure-eight coil placed over the head for 150 μs, a pulsed magnetic field on the order of 1 T is produced that generates eddy currents in the brain, which excite the nervous system. The first study of magnetic stimulation in a human brain by Barker et al. (1985) utilized single coils; thus, localized magnetic stimulation of a targeted portion of the human brain was impossible. The localized vectorial magnetic stimulation of a human cortex using a figure-eight coil was developed by Ueno et al. (1978, 1986b, 1988, 1989, 1990a,b, 1991), which enabled stimulation of the motor cortex of a human brain at 5-mm resolution. Localized magnetic stimulation contributed to the creation of functional maps of the motor cortex related to hand and foot areas. An optimal direction of probe placement for the targeting of stimulating currents, which induce neural excitation in each functional area of the cortex, based on functional maps was observed, the so-called vectorial feature. Variations in the functional maps of the cortex with changes in orientation of the stimulating current were observed as well. It is proven that the vectorial feature allows for studies that reflect both functional and anatomical organizations of neural fibers in the brain. Localized magnetic nerve stimulation of the brain is suitable for investigations of brain function and construction without damaging any tissues.

Applications of TMS temporarily disturb brain function, which results in a virtual lesion in the brain. Zangaladze et al. (1999) showed that the disruption of the function of the occipital cortex with the use of focal TMS interferes with the tactile discrimination of grating orientation. Epstein et al. (2002) used TMS to investigate memory encoding and retrieval, particularly the role of the dorsolateral prefrontal cortex in associative memory for visual patterns. TMS disrupted associative learning of abstract patterns over the right frontal area, which suggests that the participating cortical networks may be lateralized in accordance with classic concepts of hemispheric specialization.

Traditionally, stimuli are applied at various scalp positions using a latitude- and longitude-based coordinate system referenced to Cz in the 10–20 international system at the vertex, while simultaneously, the amplitude of the motor evoked potentials generated in contralateral muscles is also measured (Ueno et al., 1989, 1990a). This gives a ''map'' of sites on the scalp from which responses can be obtained by each reference muscle.

Rothwell et al. (1987) revealed the enormous clinical importance of TMS, namely, for motor functional evaluation.

Recent developments in the navigated brain stimulation (NBS) stereotactic TMS devices allow noninvasive mapping of the spatial and temporal representation of any brain activity that reacts to magnetic stimuli (Krings et al., 2001), such as sensory, motor, language, and cognitive functions. Stereotactic TMS coil positioning and real-time visualization of the stimulating electromagnetic field effect using MRI allow precise replicability of stimulation parameters as well as accurate dose definition. Frameless NBS allows precise localization of a stimulation target in combination with other imaging modalities or by the use of anatomical landmarks. In a case where a brain tumor was resting adjacent to the precentral gyrus, the motor strip identified by TMS compared preoperative MRI and fMRI and revealed fine functional differences between results that were integrated on the navigation system. Distribution of the tumor margin and the motor cortex (both fMRI and TMS assisted) can be drawn on the patient's scalp using the navigation system. Skin incision, craniotomy, and operative approaches were considered from these results so as to avoid motor deterioration.

There has been no verification of which nerve cells are actually stimulated by TMS. There is one subject under discussion: whether a target neuron cell is directly stimulated by TMS (direct stimulation) or whether an interneuron is first stimulated and then a target neuron cell is stimulated indirectly (indirect stimulation). It is possible that alteration of eddy currents by heterogeneity of conductivity in the brain may affect the path of these currents and result in both neuronal excitation and excitatory directional changes at sites other than those targeted by the original intended direction of stimulation. Further investigation and analysis of TMS and construction of models using magnetic nerve stimulation are required to clarify how the relationship between a position of a coil and a site of stimulation can be affected by strength of stimulation, arrangement of neurons, heterogeneity of conductivity, and interneuronal participation. While a figure-eight coil is suitable for local stimulations at the surface of the cortex along the surface of the head, tridimensional localized stimulations are not possible with the coil at present.

Despite the problems described above related to TMS, there are high expectations for magnetic stimulation to contribute to a new era of brain science. A major and possibly very important future field of study is the application of TMS for obtaining therapeutic effects in neurological disorders. A number of animal studies testing the basic mechanisms of TMS-induced alterations of neurotrophic factors, gene expression, and changes in plasticity have been conducted (Fujiki and Stewart, 1997; Keck et al., 2000; Fujiki et al., 2003; Ogiue-Ikeda et al., 2003a).

There is strong evidence that the expression of certain genes such as the immediate early gene, astrocyte-specific glial fibrillary acidic protein mRNA (Fujiki and Stewart, 1997), and brain-derived neurotrophic factor is altered in response to repetitive TMS (rTMS). This indicates that the measurable effects of TMS reach the molecular and signaling levels. The most promising hypothesis is that magnetic field-induced neuroprotective or trophic factors may protect neurons from hypoxic insult (Fujiki et al., 2003). Long-duration rTMS modulates the monoamine neurotransmitter system in content and turnover and may also induce sprouting of mossy fibers in the hippocampus (Keck et al., 2000). Increased dopaminergic neurotransmission may contribute to the beneficial effects of rTMS in the treatment of affective disorders and Parkinson's disease.

The results of these studies provide strong evidence that noninvasive TMS can strongly modulate gene expression in neurons and astrocytes. Thus, TMS, originally used simply as a way to assess the function of descending motor tracts noninvasively, may in the end be used as a means to modulate gene expression and to induce restorative plasticity or tolerance against injury in the brain.

TMS does not cause any pain and requires no physical invasion of the body; therefore, it should become more important in functional, diagnostic, and therapeutic research of the brain. In brain functional research, application of magnetic stimulation for the temporary blockage or modification of the facultative information process and cognitive process of various sensory systems may be used to identify localization and connecting pathways of brain function. If a magnetic stimulation can effectively block and modify various sensory systems, it should be advantageous for pain treatment. Elucidation of the effects of magnetic stimulation on synaptic functions may lead to further research associated with brain plasticity. Further research for investigation of magnetic compensation and reconstruction of neuronal functions around damaged neurons may lead to the development of various magnetic field-based stimulation applications, including the treatment of depression, the prevention of dementia, and a safer and more effective magnetic pulse treatment, which may replace the current electroconvulsive therapy (ECT).

8.5.3 Magnetoencephalography

MEG measures the very weak magnetic fields of the order or 10^{-13} T (100 fT) generated by neuronal current flow, by the detection of magnetic signals measured by SQUID arrays. MEG can detect brain functions with high millisecond-order temporal resolution and high millimeter-order spatial resolution noninvasively; thus, it is useful for investigation of brain functions in humans, including higher brain functions such as memory and cognition. Since Cohen obtained a magnetoencephalogram for human α-waves with the use of a SQUID, a prototype developed by Zimmerman and Colleagues (1972), it was only until recently that the use of a whole-head MEG system that is able to carry out spontaneous measurement at multiple points has become practical (Squires, 1991; Ahonen et al., 1993; Vrva et al., 1993). In recent years, the whole-head MEG system has been incorporated into brain functional research all over the world and has accelerated progress in research.

Application of forward and inverse problems in MEG analysis is critical to estimate a localization of brain function. Ueno and Iramina (1991) measured MEG associated with short memory, cognition, and mental rotation in humans, constructed current-dipole and distributed intracerebral electrical source models, and carried out estimations for the localization of various brain functions during the processing of information. The electrical source of a visually evoked reaction with approximately 150 ms at latency localized in the primary visual cortex was described in a current-dipole model relatively well, while a distributed intracerebral electrical source model was more useful in estimation of the electrical source incident to a mental rotation with approximately 180 ms or higher at latency. In the distributed electrical source model, a chronological transition of electrical source groups from the occipital lobe area to the posterior temporal lobe area was captured. MEG is not only a tool for basic brain functional research, but is also applicable to medical research. Clinical applications of MEG include detection of epileptic spikes, measurements of slow waves associated with brain tumors and cerebrovascular diseases, and cerebroelectric activity of ELF induced by event-related potentials.

It is necessary to construct experimental paradigms that are able to perform more precise extraction of a specific brain function, allow understanding of brain function dynamics, and provide measuring techniques to assess the acquired information (Yoshida et al., 1995; Iwaki et al., 1999). It is also important to develop signal processing techniques for source determination of signals with very small SNRs and with distributed electrical sources, improve inverse problem approach methods, and construct suitable current source models (Ueno and Iramina, 1991; Iramina et al., 1994, 1995b). There are several factors to be taken into account in MEG inverse problem analysis: the shape of the head, heterogeneity of conductivity, alignment of neuron cells, interneurons, and

thalamocortical specific projection system. An ideal electrical source model possesses electrophysiological features of complex cranial nerve systems with consideration of these factors.

In a study on language-related brain activities, Kuriki et al. (1995, 1998) used MEG imaging to examine the temporal and topographical characteristics of neural activities in the comprehension of Japanese complex sentences with a clause structure. The Korean language was also used as an experimental language (Kwon et al., 2005). The Korean language has a subject–object–verb order structure, ending with a verb. Semantic and syntactic violations, that is, errors introduced in a sentence, can be made by altering a single word, that is, a verb, in an inappropriate manner. Neural activities in response to such a violation are measured as the response elicited by the final verb in the verb-ending sentence. This study is aimed to identify neural activities in the cerebral cortex that occur during a latency course, processing syntactic and semantic aspects of spoken sentences.

In another MEG study on music, Kuriki and colleagues used melodies to measure the responses that are elicited by an out-of-key tone in musical phrases (Hirata et al., 1999; Kuriki et al., 2005). The musical context is established by the sense of a key and melodic pitch sequence. The responses would reflect the perception of these restricted aspects of melody. The results of the present study should provide an understanding of the spatiotemporal characteristics of cortical activities involved in melody perception. MEG measurements were also performed for musical tones and chord stimuli for well-experienced musicians and nonmusicians. The principal purpose of this study was to explore how the brain activity reflected in late auditory evoked responses would behave when exposed to the successively presented tones and chords stimuli and also how the activity would vary according to experience of musical training.

Although there is still ambiguity in the analytical technique, MEG still attracts medical researchers because it can reflect the chronological change of source signals to that of magnetic fields. It is obvious that MEG will become an essential technique in human brain function research, since there is only one technique that is noninvasive with millisecond-order high temporal resolution, electroencephalography, available at this time for estimation of brain function localization,. Development of MEG with higher sensitivity and operativity, construction of an intracerebral electric source model, and improvement of inverse problem analysis may become more important.

8.5.4 Magnetic Resonance Imaging

Since Lauterber suggested a linear magnetic field gradient in 1973, MRI has been rapidly developed (Lauterbur, 1973). MRI utilizes fusion techniques of spatially uniform direct current magnetic fields, spatially gradient direct current magnetic fields, and RF electromagnetic fields. A guideline of static magnetic field exposure to a human body by the International Commission on Non-Ionizing Radiation Protection (ICNIRP) suggests 2 T as the ceiling value for body parts, except for arms and legs, in occupational exposure. In the application of clinical MRI, although the exposure is carried out under supervision of doctors, the current exposure level is confirmed to be 2 T or less. It is not feasible to obtain resonance images, except from hydrogen atoms, in static magnetic fields at this strength.

The use of MRI conducted at high static magnetic field levels is fast growing (Robitaille et al., 1998). With the advent of the 8-T/80-cm MRI scanner (Schenck et al., 1992; Kangarlu et al., 1999) the safety of the static magnetic field became a paramount issue for MRI researchers. While the primary concern in high magnetic field MRI has been excessive RF deposition in human subjects (Kangarlu et al., 2003, 2005), the static magnetic field could equally cause alarm for its potential for interaction with biological cells and molecules. One concern regarding human exposure to a high static magnetic field is the

orientation of the molecules. Magnetohydrodynamics, which describes the interaction of moving charged particles with the magnetic field, has also raised concern with high magnetic field applications. Investigation of this effect with its possible consequences on human cognition has not received enough attention. As such, Chakeres et al. (2003) have recently conducted a series of studies on the effect of high static magnetic fields on human cognitive function. In spite of the availability and use of high magnetic field instrumentation for three decades, high magnetic field exposures of human subjects for extended periods of time have not been conducted. Such exposures did not pose a significant biological hazard at field strengths of up to 8 T as measured within the capability of their experimental design. In addition, human neuropsychological performance as a measure of any possible static magnetic field modification of cognition was not detected (Chakeres et al., 2003). To our knowledge, such a study has not been performed in the past at a field strength of 8 T for such an extended period of exposure time (Schenck et al., 1992; Kangarlu et al., 1999). In spite of the complex nature of an investigation of such effects, our present lack of observation of any detectable change in human cognition as related to high magnetic field exposure is an important reason for further research. In this regard, studies such as this could serve as a good starting point for *in vivo* characterization of static field effects in humans, in light of the rapidly expanding applications of high magnetic field MRI.

A time-varying magnetic field with sufficient intensity may be excitatory to peripheral nerve stimulation (PNS) (Ueno et al., 1986a; Barker, 1991; Sandrey et al., 2002; So et al., 2004). The physiologic mechanism is presumably due to interaction of neuronal structures with the induced electric field, rather than a direct physiologic effect of the magnetic field (Reilly, 1989).

Relatively early in the development of MRI, it was recognized that the pulsed gradient magnetic fields might induce PNS or cardiac stimulation (Reilly, 1991; Ueno et al., 1992). The pulsed gradients are of audio frequency, and they modulate the frequency and phase of the signal from the precessing magnetization as part of the MRI image reconstruction process. Reilly (1989) projected that a long-duration (>1 ms) pulse of induced electric field of 6.2 V would be sufficient to stimulate a 20-μm-diameter nerve fiber. The same amplitude of electric field was estimated to be the 1-percentile rank for stimulation of the human heart. Because of the much longer chronaxie for cardiac muscle, about 3 vs. 0.38 ms, the gradient field intensity, expressed in terms of the time derivative dB/dt of the magnetic field, required to achieve cardiac stimulation is far greater than that for PNS. The large projected values of dB/dt required for cardiac stimulation were confirmed in measurements in dogs by Mouchawar et al. (1992) and by Bourland et al. (1999), who reported that cardiac stimulation by pulsed gradient fields requires a dB/dt amplitude in excess of 2000 T/s for a 530-μs period. These values compare with representative dB/dt intensities of less than 100 T/s in an MRI system. For healthy patients, cardiac stimulation in MRI is avoided by a wide margin.

Mild PNS in MRI is not thought to be harmful, but painful stimulation should be avoided. To determine the population distribution for physiologic response to the time-varying gradient fields, the MRI safety group at Purdue University undertook a study with 84 human volunteers (Bourland et al., 1999; Nyenhuis et al., 2001). The volunteers were exposed to magnetic field patterns similar to those that would be experienced in a cylindrical bore MRI system. (Nyenhuis et al., 1997). The volunteers were asked to rate their responses to a gradient pulse sequence on a scale covering the range of 1 = onset of PNS, 5 = uncomfortable but acceptable for the duration of a scan, and 10 = intolerable. The duration of the dB/dt pulses ranged from 50 to 1000 μs, in order to determine parameters for the strength duration given by:

$$\frac{dB}{dt} = b\left(1 + \frac{c}{d}\right)$$

where b is rheobase for a long-duration pulse, c is chronaxie, and d is the pulse duration. The measured responses were well fit by a chronaxie of 380 μs. For onset of PNS (score = 1), the median rheobase b was found to be 18.8 T/s for the y-coil and 28.8 T/s for the z-coil. Median dB/dt intensities for scores of 5 and 10 were approximately 50% and 100% greater than the score = 1 values, respectively. From the population distribution, the lowest 1-percentile value for PNS (score = 1) was about half the median value, and the lowest 1-percentile for uncomfortable (score = 5) was approximately equal to the median of the PNS threshold.

den Boer et al. (2002) found good agreement among the Purdue and other studies for the PNS thresholds by the switched gradients. Accordingly, the results of these studies were used for determination of the allowable gradient field intensities in MRI, which were set to be 80% of the mean PNS threshold (IEC, 2002).

The values of chronaxie and rheobase in the Purdue study were determined for rectangular waveforms. Models based on the physiologic response to rectangular pulses can be used to predict the threshold intensities for nonrectangular waveforms (Havel et al., 1997; den Boer et al., 2002).

So et al. (2004) recently reported results of calculations incorporating a realistic human model of the rheobase electric field intensity for PNS in the Purdue study. The rheobase electric field intensities in subcutaneous fat ranged from 3.3 to 4.4 V/m for the different body models and coil configurations. These values are in reasonable agreement with a rheobase electric field of 5.36 V/m for PNS with a solenoidal coil enclosing the arm (Havel et al., 1997).

MRI of electrical phenomena in living bodies is potentially useful for quantitative evaluations of the biological effects of electromagnetic fields and for direct detection of neuronal electrical activities in the brain. Magnetic fields in an object cause a shift in the resonant frequency (Manassen et al., 1988; Sekino et al., 2004b) and a change in the phase of magnetic resonance signals (Joy et al., 1989). Spatial distributions of an externally applied magnetic field and electrical current can be estimated from these changes in magnetic resonance signals. These methods have use in certain medical applications, such as the imaging of current distributions in electrical defibrillation (Yoon et al., 2003).

The fMRI developed by Ogawa et al. (1992) utilizes a technology that reflects various magnetic features of hemoglobin in blood on magnetic resonance signal patterns. Tomograms of brain function can be obtained from information on localized blood flow in the brain. fMRI utilizes a blood oxygenation level dependent (BOLD) effect of localized blood flow on brain activation for indirect imaging of brain activities. However, no information on electrical conditions *in vivo* can be obtained with current MRI and fMRI systems.

Detection of electrical currents associated with neuronal or muscular electrical activities requires extremely high measurement sensitivity. The sensitivity for detecting weak magnetic fields in the human brain was estimated using numerical simulations (Hatada et al., 2005). The theoretical limit of sensitivity was approximately 10^{-8} T. The effect of neuronal electrical activities on magnetic resonance signals was investigated in several experimental studies (Kamei et al., 1999; Xiong et al., 2003). These studies potentially lead to a new method for visualizing brain function with a spatial resolution of millimeters and a temporal resolution of milliseconds.

Impedance-weighted magnetic resonance images were obtained during applications of external oscillating magnetic fields, which induce impedance-dependent eddy currents in a sample (Ueno and Iriguchi, 1998). In another study, spatial distribution of electrical impedance was obtained from the electrical current distributions by using an iterative algorithm (Khang et al., 2002). The apparent diffusion coefficient reflects electrical conductivity of a tissue, which enables an estimation of anisotropic conductivity of that tissue (Tuch et al., 2001; Sekino et al., 2004a). This method was applied to imaging of electrical

conductivity in the human brain. Several regions in the white matter, such as the corpus callosum and the internal capsule, exhibited high anisotropy in conductivity. The magnitude and phase of magnetic resonance signals are affected by permittivity (Sekino et al., 2005). A distinctive signal inhomogeneity arises in images of objects whose dimension is comparable to the wavelength of the electromagnetic fields at the resonant frequency. This phenomenon, dielectric resonance, particularly appears in scanners with high static fields.

Once high-quality current distribution MRI of the detailed distribution of electric source incident to brain neural activities becomes available, comparison of results of MRI and fMRI will show the relationship between brain neural activities associated with BOLD effects and neural current distributions, which may lead to various new observations of dynamics in brain function localizations.

Impedance MRI may not be applied widely in brain function research; however, high-quality impedance MRI for impedance and admittance *in vivo* may lead to development of a new research field of impedance physiology. It is obvious that the information of impedance distributions is important for studying magnetic stimulation and MEG inverse problems.

8.5.5 Magnetic Orientation for Tissue Engineering

In the last decade, it has become possible to create static magnetic fields of 10 T and higher. With this development, studies regarding magnetic effects on macromolecules have increased. These studies include investigations into the magnetic effects on fibrin, collagen, erythocytes, and platelets (Higashi et al., 1993a,b; Iwasaka and Ueno, 1994; Iwasaka et al., 1998; Iino and Okuda, 2001). Recent research on effects of strong static magnetic fields includes their impact on morphogenesis, cell adhesion, and apoptosis (Tofani et al., 2001).

When technology for generation of stronger magnetic fields becomes available in the future, magnetic orientation research will be subdivided into several areas. Effects of magnetic orientation on cell functions such as morphogenesis, adhesion, motility, proliferation, differentiation, and apoptosis may become one of the important areas of research.

Macromolecules such as fibrin and collagen are oriented by static magnetic fields of several tesla. Fibrin polymers are diamagnetic materials that are oriented in a magnetic field. Collagen fibers orient perpendicular to the magnetic field orientation (Torbet and Ronziere, 1984). Polymerization and dissolution of fibrin in homogenous magnetic fields of up to 14 T have been investigated (Iwasaka et al., 1998). It was shown that the magnetic orientation of fibrin fibers accelerated both the polymerization and the dissolution of fibrin fibers.

Magnetic orientation of cells is associated with magnetic anisotropy of proteins and lipids. Erythrocytes orient the disk surface parallel to magnetic fields because of magnetic anisotropy of the biomembrane lipid bilayer. However, halophillic bacteria orient their membrane plane vertical to magnetic fields even though the purple membrane has a similar membrane structure as the erythrocyte membrane (Neugebauer et al., 1977). The purple membrane contains a membrane-bound protein (bacteriorhodopsin) that contributes 75% to the membrane weight. Since the magnetic anisotropy of bacteriorhodopsin is larger than that of the lipid bilayer, halophillic bacteria posses a different magnetic orientation from erythrocytes. Therefore, magnetic orientation is determined by the quantity and the alignment of cell components that possess magnetic anisotropy.

Higashi et al. (1996) found that an orientation of glutaraldehyde-fixed erythrocytes in strong static magnetic fields up to 8 T was perpendicular to the field. The effect was attributed to the paramagnetism of membrane-bound hemoglobin. The rates of

sedimentation and aggregation of human erythrocytes in a homogenous magnetic field of 6.3 T have been studied (Iino, 1997; Iino and Okuda, 2001). It was reported that the cell aggregation accelerated the sedimentation rate. Results have suggested that the enhancement was especially significant in anisotropic erythocytes, and the increase in an intermembrane adhesive area might be due to the magnetic orientation of anisotropic erythrocytes.

DNA, which occupies most of the head portion in bovine sperm, may be involved in magnetic anisotropy and orientation determination of sperm. Cricket sperm with an acicular head part show the same magnetic orientation (vertical) as bovine sperm in magnetic fields of 0.09 T (Suzuki et al., 1995); this is because DNA, which is folded lengthwise, possesses large diamagnetic anisotropy. If DNA in the head part of bovine sperm is orderly aligned as in cricket sperm, the magnetic anisotropy may contribute to the magnetic orientation of sperm.

A significant feature of magnetic orientation of bovine sperm is the direction of orientation. Platelets orient parallel to magnetic fields because of the microtubules inside, which have a magnetic orientation parallel to the magnetic fields. Thus, bovine sperm without motility are assumed to orient parallel to magnetic fields as platelets do, since the tail (flagellum) consists of microtubules. On the contrary, the whole body of bovine sperm shows magnetic orientation vertical to magnetic fields, and the flat surface of the head also orients vertically to magnetic fields. A sperm with the tail removed shows the same orientation. Since it is impossible to obtain a tail without damaging flagellum, the magnetic orientation of a tail alone cannot be observed. In two separate experiments, Emura et al. (2001, 2003) studied the orientation of bull sperm cells and *Paramecium* cilia in static magnetic fields and measured their anisotropic diamagnetic susceptibility ($\Delta\chi$). Bovine sperm consists of a very flat head part (5 μm) and a long tail part (flagellum, 50 μm), which consists of microtubules. Compared to sperm of other species, the head, which contains DNA, is notably larger. The sperm showed an orientation perpendicular to the field of 1 T or lower. The diamagnetic cell components, such as cell membrane, DNA in the head, and microtubule in the tail, were thought to contribute to this orientation. It was observed that *Paramedium* cilia became oriented in parallel to the magnetic field at the strength of 8 T. The author suggested that $\Delta\chi$ for each was the quantitative index of the effect.

Iwasaka et al. (2003a) reported the effects of 14-T fields on assemblies of A7r5 smooth muscle cells. It was shown that the field affected the morphology of smooth muscle cell assemblies and the shapes of the cell colonies extended along the direction of the magnetic flux. They speculated that the mechanism was a diamagnetic torque force acting on cytoskeleton fibers, which are dynamically polymerizing and depolymerizing during cell division and cell migration. They also investigated the effects of the static magnetic field on the convection flow in a cell culture medium and on cell adhesion patterns (Iwasaka et al., 2003b). The mouse osteoblast cell line MC3T3-E1 and HeLa cell line were used in this study. The magnetic field of 6 T with a gradient of 60 T/m affected the convection of floating cell aggregations in a cell culture flask and reversibly changed the direction of convectional flow. After the exposure of MC3T3-E1 cells to the magnetic field of 8 T for 1 d, the thermal convectional flow in the medium was found to promote the cell orientation.

Iwasaka and Ueno (2003) examined the displacement of intracellular macromolecules under a static magnetic field of 14 T using linearly polarized light. The changes in polarized light intensity through the lamellar cell assembly under magnetic fields corresponded to the behavioral changes in cell components. They speculated that intracellular macromolecules rotated and showed a displacement due to diamagnetic torque forces during the exposure to the 14-T magnetic field for 2–3 h.

Matrix proteins provide a permissive environment for the orientation of cells, as demonstrated, for example, with the testing of smooth muscle cells and endothelial cells in collagen fibers under strong magnetic fields (Stefano and Tranquillo, 1993; Tranquillo et al., 1996).

Eguchi et al. (2003) observed the effect of a static magnetic field on orientation of Schwann cells. After a 60-h exposure, cultured Schwann cells from dissected sciatic nerves of neonatal rats oriented parallel to the field of 8 T, whereas Schwann cells suspended in a medium with collagen oriented perpendicular to the field after a 2-h exposure. It was suggested that magnetic field-oriented collagen fibers were the key factor in the orientation of Schwann cells.

Kotani et al. (2000) studied the effect of an 8-T magnetic field generated by a superconducting magnet on the orientation of osteoblasts alone and a mixture of osteoblasts and collagen. It was found that osteoblast cells oriented parallel to the magnetic field, but a mixture oriented perpendicular to the field.

Hirose et al. (2003a) investigated the preferred orientation of human glioblastoma cells A172 after exposure to a 10-T static magnetic field, in the presence or absence of collagen. It was found that A172 cells embedded in collagen gel oriented perpendicular to the direction of the static magnetic field.

By placing dorsal root ganglia (DRG) explants onto one end of magnetically aligned collagen gel formed into 4-mm-diameter rods, Dubey et al. (1999) developed an *in vitro* assay to study neurite elongation. The depth of neurite elongation from chick embryo DRG neurons into these aligned rods was found to be substantially greater than that under the control condition. The depth increased as the magnetic field strength increased, as did the collagen gel rod birefringence; collagen fibril aligned along the rod axis. These results may translate into an improved method of entubulation repair of transected peripheral nerves by directing and stimulating axonal growth through a tube filled with magnetically aligned collagen gel. The same research group later reported the improvement of peripheral nerve regeneration in mice after the treatment of magnetically aligned collagen gel filling of a collagen nerve guide (Ceballos et al., 1999). The hypothesis of this study was that contact guidance of regenerating axons or invading nonneuronal cells to the longitudinally aligned collagen fibrils would improve nerve regeneration. It was reported that mice exhibited regeneration with magnetically aligned collagen gel, including the appearance of nerve fascicle formation.

Application of magnetic orientation in the production of biologically functional materials and artificial organs has been started. By attaching aligned vascular smooth muscle cells and endothelial cells to artificial vascular walls in an orderly fashion, rheologically rational biological functions can be obtained. As techniques in bionics and biomaterials improve, application of magnetic orientation should expand.

8.5.6 Treatments of Pain, Cancer, and Other Diseases

Static magnetic fields or ELF-modulated static magnetic fields potentially have therapeutic effects on several diseases (see also Chapter 11 on medical applications of pulsed fields by Pilla). A static magnetic field in the 10-mT range blocks sensory neuron action potentials, which suggests that the magnetic field alleviates pain (Cavopol et al., 1995; McLean et al., 1995). To characterize the inhibitory effect of a static magnetic field, action potentials were elicited by intracellular application of 1-ms pulses of depolarizing current to the somata of mouse DRG neurons. During the control period, less than 5% of stimuli failed to elicit action potentials. During exposure to an approximate 11-mT static magnetic field produced by an array of four permanent center-charged magnets of alternating polarity, 66% of stimuli failed to elicit action potentials.

The efficacy of a nonpharmacologic, noninvasive static magnetic device was assessed for knee pain in patients with rheumatoid arthritis (Segal et al., 2001). Magnetic devices with four steep field gradients or one steep field gradient were taped to the knee of each subject for 1 week. Both devices demonstrated statistically significant pain reduction in comparison to baseline. Comparison between the two groups demonstrated a statistically insignificant difference.

Prato et al. (2005) reported effect of a magnetically shielded environment on opioid-induced analgesia. Mice were placed in a Mu-metal-lined box or an opaque Plexiglas box (sham condition) for 1 h/d for 10 consecutive days. Nociception was measured as the latency time to a foot lift/lick in response to an aversive thermal stimulus before and immediately after exposure. It was shown that mice can detect and will respond to the repeated absence of the ambient magnetic field, with the maximum analgesic response occurring over days 4–6 of exposure and returning to baseline thereafter. The effect was robust, independent of pre-exposure and intermittent testing, and seems to be opioid related, since the results obtained on day 5 were similar to those from a 5-mg/kg dose of morphine and were abolished with the opioid antagonist, naloxone.

Exposure to pulsed magnetic fields has been shown to have a therapeutic benefit in both animals (e.g., mice and snails) and humans. Shupak et al. (2004b) investigated the potential analgesic benefit of magnetic field exposure on sensory and pain thresholds following experimentally induced warm and hot sensations. Subjects were assigned to 30 min of magnetic field or sham exposure, between two sets of tests of sensory and pain thresholds and latencies at 1°C above and 2°C above pain thresholds. Results indicated that magnetic field exposure does not affect sensory thresholds. Pain thresholds were significantly increased following magnetic field exposure but not following sham exposure. A significant condition by gender interaction existed for postexposure pain thresholds. Taken together, these results indicate that magnetic field exposure does not affect basic human perception, but can increase pain thresholds in a manner indicative of an analgesic response.

Shupak et al. (2004a) showed an induction of analgesia in mice equivalent to a moderate dose of morphine (5 mg/kg) and the effect of both pulsed magnetic field (complex neuroelectromagnetic pulse, Cnp) exposure and morphine injection on some open-field activity. Cnp exposure was found to prolong the response latency to a nociceptive thermal stimulus (hot plate). Cnp plus morphine offset the increased movement activity found with morphine alone. These results suggest that pulsed magnetic fields can induce analgesic behavior in mice without the side effects often associated with opiates like morphine.

The effects of static and sinusoidal (AC) magnetic fields on myosin light chain phosphorylation were studied (Markov et al., 1993). In a cell-free preparation, exposure to DC (0–200 μT, vertically or horizontally controlled) or AC (16 Hz, 20.9 μT) magnetic fields significantly influenced myosin phosphorylation. Variations of the DC magnetic field (in the absence of AC components) were not only sufficient to alter the rate of phosphorylation but also gave the maximum effect.

The possibilities that magnetic fields cause antitumor activities *in vitro* (Tofani et al., 2001), *in vivo* (Tofani et al., 2002), and in human subjects (Ronchetto et al., 2004) have been investigated. *In vitro* experiments were carried out to study the role of magnetic field characteristics (intensity, frequency, and modulation) on two transformed cell lines (WiDr human colon adenocarcinoma and MCF-7 human breast adenocarcinoma) and one non-transformed cell line (MRC-5 embryonal lung fibroblast). Increase in cell death morphologically consistent with apoptosis was reported exclusively in the two transformed cell lines. Cell-death induction was observed with magnetic fields of more than 1 mT. Two different *in vivo* experiments were carried out on nude mice bearing a subcutaneous

human colon adenocarcinoma (WiDr). In the first experiment, a significant increase in survival time (31%) was obtained in mice exposed daily to 70 min of modulated magnetic fields (static with a superimposition of 50 Hz) having a time average total intensity of 5.5 mT. In the second independent experiment, when mice bearing tumors were exposed to the same treatment for four consecutive weeks, significant inhibition of tumor growth (40%) was reported, together with a decrement in tumor cell mitotic index and proliferative activity. Human patients with heavily pretreated advanced cancer were enrolled in a pilot study, in which they were exposed to static magnetic fields that were amplitude modulated by ELF. Toxicity was assessed according to WHO criteria. ECG, chest x-ray, physical examination, blood cell count, and complete blood chemistry were performed before and at the end of the treatment. The results indicated that magnetic fields can be safely administrated according to the magnetic field exposure schedules.

Recently, several studies tested the application of pulsed magnetic stimulation as a form of cancer therapy. In one case, use of magnetizable beads and pulsed magnetic stimulation enabled targeted-cell destruction *in vitro* (Ogiue-Ikeda et al., 2003b). The cells were combined with the beads by an antigen–antibody reaction (cell–bead–antibody complex), aggregated by a magnet, and stimulated by a magnetic stimulator. The viability of the aggregated and stimulated cell–bead–antibody complexes was significantly decreased, and the cells were destroyed by the penetration of the beads into the cells or by rupturing of the cells by the beads. In another study, exposure to a pulsed magnetic stimulation caused a decrease of tumor weight in mice B16-BL6 melanoma models and induced the increase of cytokine (TNF-α and IL-2) production (Yamaguchi et al., 2006). These studies show the potential therapeutic possibilities of pulsed magnetic stimulation in cancer treatment.

Basic studies for magnetic stimulation treatment of depression, which has the potential to replace ECT, and also, magnetic treatment for a wide range of clinical problems, such as Parkinson's disease and various kinds of pain, are in progress. It is important to recognize the safety of magnetic stimulation and the limitations of its usefulness.

8.6 Conclusion

Over the last two decades, various studies have been carried out to examine the effects of static magnetic fields, including MRI fields, on biological systems. This chapter consisted of two parts. The first part focused on recent experiments covering behavior, cardiovascular system responses, reproduction and development, genotoxicity, molecular and cellular systems, cell-free systems, free radical and enzyme activity, etc. The second part concentrated on the recent development of medical and therapeutic applications of static magnetic fields.

There are many studies that have been mentioned in this chapter. With exposure to about 1 T and above, there are no adverse effects on reproduction and development, genotoxicity, and molecular and cellular systems, and no consistent evidence on behavioral effects. However, several studies suggest that static magnetic fields in millitesla ranges may affect microcirculation and blood pressure, and furthermore, higher-strength static magnetic fields at levels up to 10 T may reduce skin blood flow and lead to change in skin temperature. These findings need to be confirmed in further studies.

Although there are so many experiments to test the effects of static magnetic fields on the biology of living systems, using *in vivo* and *in vitro* techniques, the International Agency for Research on Cancer (IARC) has stated that static magnetic fields are *not*

classifiable as to their carcinogenicity to humans by inconclusive carcinogenic evidence (IARC, 2002).

There are many experimental findings that suggest that animals use the static magnetic field, that is, the geomagnetic field for orientation, navigation, and migration. In order to establish the existence of a magnetoreception system in animals, Phillips argued that there are several key points that require further investigation: (1) establishing the lower limits of sensitivity to static magnetic, ELF, and RF fields in biological systems; (2) localizing specialized receptors responsible for sensing the geomagnetic field; (3) characterizing the underlying molecular and biophysical mechanisms; (4) identifying the regions of the brain involved in processing magnetic stimuli; and (5) understanding how the animal's perception of the magnetic field is physiologically processed for determining compass direction and spatial positioning (Phillips, 2005).

With the increasing exposure of humans to environmentally higher static magnetic fields generated from magnetic field equipment of higher capacity, it is necessary to investigate the possibilities of high static field effects on human biological and physiological processes.

There are an abundance of review papers and books published in recent years describing the possible physical and biological interactions of electromagnetic fields (Polk and Postow, 1986, 1997; Ueno, 1996; Andra and Nowak, 1998; Jin, 1999; Takebe et al., 1999; Lin, 2000; Shellock, 2001; Binhi, 2002; McLean et al., 2003a; Stavroulakis, 2003; Rosch and Markov, 2004). In addition, there have been many short reviews on the biological effects of static magnetic fields (Holden, 2005; Miyakoshi, 2005), since the physical interactions of static magnetic fields with living tissues were described (Schenck, 2005). In a report on the biological effects of exposure to MRI, an overview of the safety concerns regarding exposure to static magnetic fields, RF fields, and time-varying magnetic field gradients has been discussed (Formica and Silverstri, 2004). Application of novel high-throughput screening techniques for transcriptomics, proteomics, and metabolomics to determine *in vitro* effects of static magnetic fields have been suggested (Leszczynski, 2005). This report emphasized the research beyond screening that is required for the assessment of any possible health consequences. Possible physical mechanisms underlying the biological effects and interactions of zero-frequency (DC) and oscillating (AC) magnetic fields with biological matter have been reviewed (Binhi, 2001; Volpe, 2003). Effects of static and ELF electric and magnetic fields on human health have also been discussed (Repacholi and Greenebaum, 1999; McKinlay and Repacholi, 2005). Zhadin (2001) has introduced the Russian literature on the biological effects of DC and LF AC magnetic fields. These articles offer multidisciplinary information and knowledge for the understanding of magnetic field effects within living systems.

Acknowledgments

The authors wish to thank Drs. Ben Greenebaum and Frank Barnes for their suggestions and comments for organizing this chapter. The authors also wish to thank Drs. Minoru Fujiki, Yngve Hamnerius, Masateru Ikehata, Masakazu Iwasaka, Saeko Kanagawa, Alayar Kangarlu, Yohsuke Kinouchi, Shinya Kuriki, Tatsuki Matsumoto, Junji Miyakoshi, John Nyenhuis, Chiyoji Ohkubo, Hideyuki Okano, Frank Prato, Masaki Sekino, Masao Taki, Yoshifumi Tanimoto, Sotoshi Yamada, and Sachiko Yamaguchi for their valuable discussions.

The Ion Cyclotron Resonance Hypothesis

A.R. Liboff

CONTENTS

9.1 Introduction

9.1.1 General Remarks

Ion cyclotron resonance (ICR) is one among a number of possible mechanisms that have been advanced to explain observed interactions between weak low-frequency electromagnetic fields and biological systems. Despite the failure to find a reasonable physical explanation, there remains an impressive body of experimental evidence that can be taken as an empirical basis for this hypothesis. The ICR suggestion has proven fruitful in framing both experimental and theoretical work, despite the biophysical situation being far from the literal cyclotron resonance model of an isolated classical charged particle moving in a vacuum under the influence of a magnetic field.

The properties of the applied fields that are used in ICR experiments include linear or circular polarization, the presence of a finite magnetostatic field, frequencies ranging from a few to several hundred hertz, magnetic intensities ranging from about 1 μT to 1 mT, and,

most important, a directional constraint on the relative orientation of the time-varying electromagnetic field to the magnetostatic (DC) field. This orientation requires that time-varying magnetic fields be parallel to the DC field or, equivalently, that time-varying electric fields are perpendicular to the DC field.

The ICR hypothesis holds that the physiological activity of those ions implicated in cell signaling processes, including, among others, Ca^{2+}, Mg^{2+}, and K^{+}, can be altered when the ratio of applied signal frequency to the static magnetic field is equal to the ionic charge-to-mass ratio. This is expressed as

$$\omega/B = q/m \tag{9.1}$$

where the radial frequency $\omega = 2\pi f$, as measured in radians per second, is used instead of f, the frequency measured in hertz. In SI units, B is the DC field intensity measured in tesla, and q/m is the ratio of the ionic charge to mass, in coulombs per kilogram. For any given ionic species, the specific frequency that equals the product of B and q/m is called the cyclotronic frequency, ω_c.

The resonance concept is attractive for a number of reasons. There is a potential connection to interactions involving the Earth's magnetic field (geomagnetic field [GMF]). Further, the ICR mechanism may help provide the basis for at least some of the reports of low-frequency electromagnetic interactions that otherwise lack explanation. Finally, given the wide variety of biological systems in which ICR effects are observed, it is reasonable to ask if there are fundamental scientific questions connected to this phenomenon.

The ICR hypothesis has especial significance attached to magnetostatic fields whose intensity is of the order of the GMF (20–60 μT). This becomes apparent when the charge-to-mass ratios of key biological ions are substituted into Equation 9.1. These ratios range from about 2 to 8×10^6 C/kg, implying that a static magnetic field of 50 μT corresponds to resonance frequencies of the order of 10–100 Hz (Figure 9.1). Such frequencies could

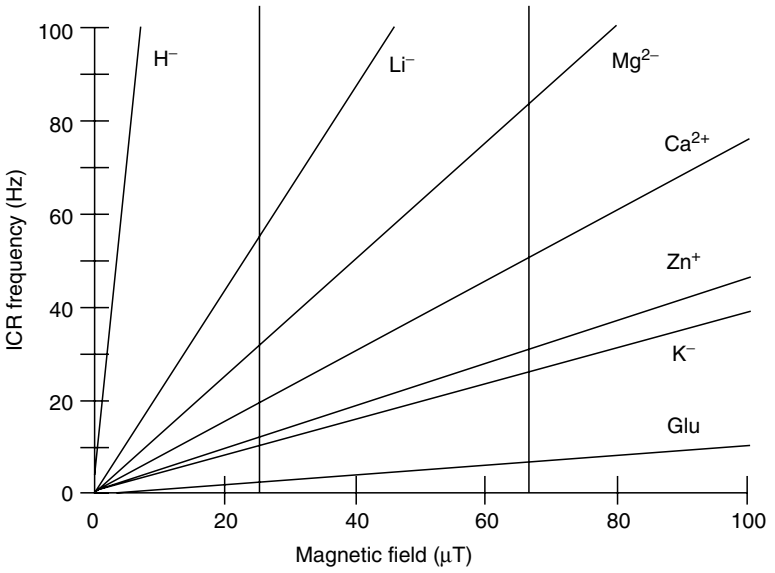

FIGURE 9.1
Ion cyclotron resonance frequencies for many biologically important ions in the Earth's magnetic field are in the ELF range.

TABLE 9.1

ICR Cation Possibilities

Ion	q/m (C/kg) $\times 10^{-6}$	f/B (Hz/μT)
H^+	95.76	15.241
Li^+	13.90	2.212
Mg^{2+}	7.937	1.263
H_3O^+	5.066	0.807
Ca^{2+}	4.814	0.766
Zn^{2+}	2.951	0.470
K^+	2.467	0.393
Arg^{2+}	1.235	0.197
Asn^+	0.838	0.133
Glu^+	0.747	0.119
Tyr^+	0.591	0.094

conceivably have physiological significance since they correspond approximately to the frequency range generated in the central nervous system [1]. This, coupled to the focus on the potential hazards attached to 50/60-Hz electromagnetic power delivery sources [2], has sparked study of the ICR hypothesis, in terms of both experiments specifically designed to test this hypothesis as well as theoretical models seeking an explanatory basis at the molecular level.

Some specific ions that have been implicated are listed in Table 9.1. Note that four polar amino acids and the hydronium ion are included. The ratios of frequency to DC magnetic field, as calculated from Equation 9.1, are shown in the right-hand column. This ratio can be regarded as an invariant characteristic for any given ion.

Although experimental evidence provides support for the ICR hypothesis [3], there is no widely accepted theoretical explanation. Indeed, because of constraints mainly arising from unfavorable damping conditions, there are strong arguments [4] against the occurrence in living tissue of any classical ICR mechanism [5], as occurs, say, for energetic charged particles moving in a vacuum under the influence of parallel static and AC magnetic fields. The circular and helical paths associated with such undamped motion are invariably the result of the Lorentz force, which imparts an acceleration **a** to a charged particle of mass m moving at velocity **v** in a magnetic field **B**:

$$\mathbf{a} = (q/m)(\mathbf{v} \times \mathbf{B}) \tag{9.2}$$

Nevertheless, arguments have been raised [6–11] that although the biological response may not correspond to the effects resulting from ICR-specific helical pathways of charged particles [4], the coupling is nevertheless a function of the ICR frequency as predicted by Equation 9.1. Although there has been no consistent experimental verification for any of these models, there is little question concerning the observed dependence on the cyclotron resonance frequency. Because the cyclotronic frequency is the common denominator in all these models, it is preferable to subsume all of them under the umbrella term ICR hypothesis.

The great variety of biosystems in which ICR effects have been observed implies a ubiquitous response that may have fundamental physiological significance. One can generalize this response R in terms of its functional dependence. From Equation 9.1, we can write

$$R = R(\omega, B, q/m) \tag{9.3}$$

Lednev [7] added a fourth variable, namely the intensity of the AC magnetic field, B_{AC}. Thus, the expanded expression for the response $R = R(\omega, B, B_{AC}, q/m)$, or, in terms of the two key variables,

$$R = R(\omega_c, B_{AC}) \tag{9.4}$$

There is no question as to the relevance of B_{AC} in studying the interactions between ICR field combinations and biological systems. However, it is not clear if the experimentally observed dependences on B_{AC} are a direct result of the underlying resonance mechanism, as has been suggested [7,9], or if there are other separate physiological factors that limit the levels of the AC field under which an ICR mechanism may be operative.

9.1.2 Background History

ICR was originally invoked [4] to explain an extraordinary set of observations by Blackman's group [12] indicating a strong dependence on the orientation of the magnetostatic field when studying the Ca-efflux model system [13]. The original discovery of the Ca-efflux effect [13] and subsequent studies [14–17] showed conclusively that the level of $_{45}Ca^{2+}$ efflux from preloaded chick brain was a nonlinear function of low-frequency (ca. 15 Hz) modulation signals when these brains were exposed to high-frequency carrier electric fields. Typically, this nonlinear signature (Figure 9.2), at first referred to as a ''window,'' has the appearance of a resonance curve. The Blackman experiment [12] discovered that this resonance signature appeared only when certain specific values of the vertical DC magnetic field were superposed on the system. In Table 9.2, ''Yes'' indicates the appearance of a resonance signature for a given combination of f and B.

In addition to Blackman's original set of results, a fourth column has been added in Table 9.2 to show the putative charge-to-mass ratio as determined from Equation 9.1. One sees that the sign of the magnetic field direction, either pointing up or down, does not affect the outcome. The specific combination of 15 Hz and 38 μT is positive, as is the combination of 30 Hz and 76 μT, suggesting that the ratio of frequency to field is involved as a key factor.

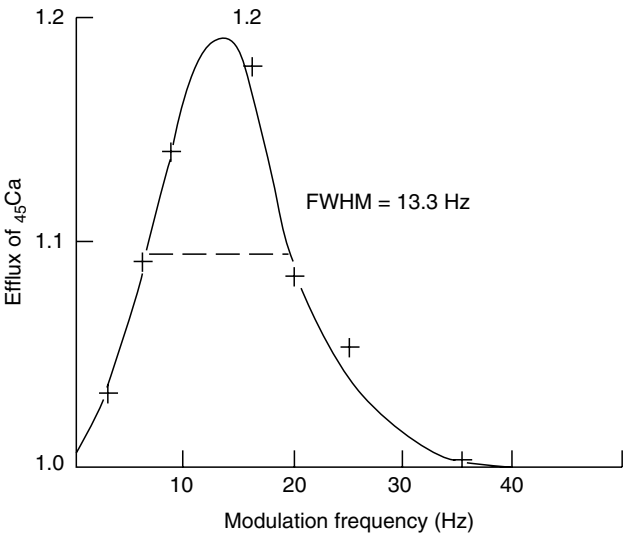

FIGURE 9.2
Comparison of shape of ''window'' data for Ca-efflux results [13] (seven points) with predicted resonance curve [18] (smooth curve). The best fit is for the charge-to-mass ratio for K^+, a magnetostatic field of 35.0 μT, and a collision time of 0.026 sec.

TABLE 9.2

Analysis of Blackman [12] Data

f (Hz)	B (μT)	Outcome	q/m (C/kg)
15	38	Yes	2.48×10^6
15	19	No	4.96×10^6
30	38	No	4.96×10^6
30	76	Yes	2.48×10^6
30	−76	Yes	2.48×10^6
30	50	No	3.77×10^6
30	25	Yes	7.54×10^6
30	−25	Yes	7.54×10^6
30	−83	No	2.27×10^6

Despite the fact that calcium was explicitly measured in this and the earlier Ca-efflux experiments, the data in Table 9.2 give reason to believe that the potassium ion was the primary target for the electromagnetic interactions. First, note that the charge-to-mass ratio of 2.48×10^6 C/kg is associated with positive outcomes. This ratio is less than 0.5% different from the q/m ratio for the potassium ion as shown in Table 9.1. The evidence linking K^+ to a positive outcome is further strengthened by examining the results obtained for the combination of 30 Hz and 25 μT. The positive outcome in this case suggests a q/m value of 7.54×10^6 C/kg, three times larger than the q/m ratio for K^+. In cyclotron resonance, one typically observes a set of resonance frequencies ω_n, where the fundamental at $n = 1$ is given in Equation 9.1, and the higher harmonic frequencies are restricted to the odd [19–21] harmonics $n = 3, 5, 7, \ldots$. The f/B ratio of 30/25 Hz/μT is nearly three times larger than the ratio 15/38 Hz/μT, again implying that the K^+ ion is interacting with the magnetic field, this time as a result of an excitation at the third harmonic.

There is further evidence that the K^+ ion is an important interactive factor in the nonlinear effects observed in the Ca-efflux experiments. McLeod and Liboff [18,22] derived the resonance signature for a charged particle as a function of frequency, showing that the relative conductivity, with and without the presence of an ion resonance field combination, is

$$\frac{\sigma_x}{\sigma_0} = \frac{(1 + (\omega_c + \omega)^2 \tau^2)}{\left(1 + [(\omega_c^2 - \omega^2)\tau^2]^2 + 4\omega^2\tau^2\right)} \tag{9.5}$$

This is a typical resonance expression that includes the effects of damping, expressed in terms of the collision time τ. By varying the choices of q/m ratios and collision times this expression can be directly compared to the results of Bawin and Adey [13], as shown in Figure 9.2. The smooth curve that best fits Equation 9.5 to the experimental points is also shown in Figure 9.2. This fitting procedure reveals that the most likely explanation for the data involves charged particles in cyclotron resonance with a q/m ratio equal to that of the potassium ion.

Thus, two independent sets of Ca-efflux data, one with DC magnetic fields applied as part of the experiment [12] and the other with the ambient magnetic field in the laboratory playing an unsuspected role [14], yield the same conclusion, that ICR stimulation of the K^+ ion results in the nonlinear resonance response.

9.2 Experimental Evidence

There is a surprisingly wide variety of biological systems in which ICR effects are observed. This suggests a heretofore unknown electromagnetic biological interaction. The model systems that have been examined in the literature can be conveniently divided into the categories of bone, cell culture, rat behavior, neural cell culture, diatom motility, complex biological systems, plants, and cell-free systems. These eight separate broad categories are listed respectively in Table 9.3 through Table 9.10. There is some

TABLE 9.3

ICR Effects in Skeletal Tissues

Frequency (Hz)	B_0 (μT)	Tuning	Ratio B/B_0	Comments	Reference
100	130	Ca^{2+}	1.0	Enhanced cell (fibroblast) proliferation; B varied between 50 and 500 μT	23
75	98	Ca^{2+}	1.0	Enhanced proliferation	23
16	42	Ca^{2+}	1.0	Enhanced proliferation	23
16	20.9	Ca^{2+}	1.0	Increases in rudiment length and midshaft diameter in embryonic chick femur	24
16	12.7	Mg^{2+}	1.0	Similar results to Ca^{2+} tuning	24
16	40.9	K^{+}	1.0	Results opposite to Ca^{2+} and Mg^{2+} cases: bone growth inhibited	24
80	20	Ca^{2+}/Mg^{2+}	1.0	Both fifth Ca^{2+} to third Mg^{2+} harmonics; enhanced collar thickness and length	24
72.6–80.6	20	Ca^{2+}	1.0	Resonance in IGF-II concentration at 76.6 Hz in osteosarcoma cell line	25
76.6	20	Ca^{2+}	1.0	Fifth harmonic: enhanced proliferation in osteosarcoma and human bone cells	25
15.3	20	Ca^{2+}	1.0	Reduction in tissue growth factor (TGF) β-1 inhibition in chondrocyte culture	26
25.4	20	Mg^{2+}	1.0	Reduction of TGF β-1 inhibition in chondrocyte culture	26
76.6	20	Ca^{2+}/Mg^{2+}	1.0	Reduction of TGF β-1 inhibition in chondrocyte culture	26
15.3	20	Ca^{2+}	1.0	Enhanced protoglycans synthesis in bovine cartilage	26
76.6	20	Ca^{2+}/Mg^{2+}	1.0	Mixed third and fifth harmonics reduce bone loss related to castration in rats	27
14.3–18.3	20		1.0	Increase in $_{45}Ca$ maximized at 16.3 Hz in osteosarcoma cell line	28
14.3–18.3	20		1.0	Increase in $_{45}Ca$ maximized at 15.3 Hz in a different osteosarcoma cell line	28
15.3	20	Ca^{2+}	1.0	370% increase in stiffness in ostectomized rabbit fibula after 24 h/28 d exposure	29
25.4	20	Mg^{2+}	1.0	137% increase in stiffness in ostectomized rabbit fibula after 24 h/28 d exposure	29
15.3	20	Ca^{2+}	1.0	Enhanced DNA synthesis and IGF-II levels in osteosarcoma cell line	30
13.3–17.3	20		1.0	Resonance maximum in IGF-II receptor number and affinity at 15.3 Hz	31
16	20.9	Ca^{2+}	1.0	Enhanced chick femoral diameter and glycosaminoglycans (GAGS) content	32
16	12.7	Mg^{2+}	1.0	Large (90%) GAGS enhancement	32
16	40.7	K^{+}	1.0	Opposite effects for Ca^{2+} and Mg^{2+} tuning, replicating Smith et al. [24]	32

TABLE 9.4

ICR Effects in Cell Culture

Frequency (Hz)	B_0 (μT)	Tuning	Ratio B/B_0	Comments	Reference
14.3	21	$_{45}Ca^{2+}$	1.0	Isotopic shift in q/m resonance confirmed, $_{40}Ca$ to $_{45}Ca$	33
14.3	21	$_{45}Ca^{2+}$	1.0	Threefold incorporation of $_{45}Ca$ into human lymphocytes	33
14.3	21	$_{45}Ca^{2+}$		Effect on human lymphocytes disappears at larger AC intensity	33
14.3	20.9	$_{45}Ca^{2+}$	1.0	2.3-fold uptake in $_{45}Ca$ disappears with addition of calcium blocker nifedipine	34
38.15	50	Ca^{2+}	1.0	No effect on Ca^{2+} in four different cell lines as observed using calcium fluorochrome fura-2	35
16	20.9	Ca^{2+}	1.0	Enhanced proliferation (46%) for fibroblast culture at Ca^{2+} ICR tuning	36
?	20.9	K^+	1.0	Reduced proliferation (18%) for Raji cells exposed to K^+ ICR; frequency not provided	36
13.6	16.5	$_{45}Ca^{2+}$	1.2	ICR frequency off by 3.5 Hz; enhanced $_{45}Ca^{2+}$ levels (75–126%) in three cell lines	37
60	20	$_{45}Ca^{2+}$	1.0	Fifth harmonic for $_{45}Ca^{2+}$ uptake is enhanced by 37%	37
16	23.4	$_{45}Ca^{2+}$	1.8	Decreased Ca^{2+} influx in mitogen-activated lymphocytes but no effect on resting cells	38
16	51.1	K^+	1.0	Third harmonic: enhanced proliferation of lymphoma cells; very narrow FWHM[a]	39
16	40.9	K^+	1.0	Enhanced proliferation of human lymphoma cells	39
16	23.4	Ca^{2+}	3.8, 5.3	No change in Ca^{2+} influx at AC/DC ratio of 3.8 but enhanced influx at ratio of 5.3	40
16	20.9	Ca^{2+}	1.4	No effect on mouse lymphocytes as observed using Ca fluorochrome Quin-2	41
50	65.3	Ca^{2+}	1.4	No effect on mouse lymphocytes with and without mitogenic stimulation	41
5–100	50–60	$?Ca^{2+}$	2.3–3.0	Enhanced calcium oscillations over broad frequency range, maximized at 50 Hz	42
32	42	Ca^{2+}	2.5, 5.0	Increased micronuclei formation in human lymphocytes at Ca^{2+} ICR tuning	43
32.50	0			No change in micronuclei formation when DC field is zero	43
15.3	20	Ca^{2+}	1.0	ICR effect on fura-2 calcium activity only found for added serum in cell medium	44
76.6	20	Ca^{2+}	1.0	Fifth harmonic is also successful	44
100	130	Ca^{2+}	1.9	Another ICR fundamental successful	44
100	130	Ca^{2+}	2.8	Repeating ICR application to primary bone cell culture at higher AC intensity	44

[a]FWHM, full width at half maximum.

unavoidable overlap among these, particularly in Table 9.3 (skeletal systems), where references to bone research in cell cultures and animals are grouped together.

Although most of the reports summarized in Table 9.3 through Table 9.10 lend considerable weight to the hypothesis that ICR magnetic stimulation can affect biological systems, the effects on diatom motility (Table 9.7) are not as clear-cut, in that a number of observers [62–65] failed to find any effects whatsoever. The explanation for the poor reproducibility in this case may rest with difficulties in handling the diatom model system, one that is especially sensitive to sample preparation.

TABLE 9.5

ICR Effects on Rat Behavior

Frequency (Hz)	B_0 (μT)	Tuning	Ratio B/B_0	Comments	Reference
60	26	Ca^{2+}	1.9	Third harmonic: loss of short-term (temporal) memory in rats	45
60	26	Ca^{2+}	1.9	Third harmonic: AC threshold observed (27 μT) for above results	46
60	27	Ca^{2+}	1.9	Third harmonic: learning inhibited relative to controls	47
60	48	Mg^{2+}	1.0	Learning enhanced relative to controls	47
60	26	Ca^{2+}	1.9	Third harmonic: no effect	48
50	65	Ca^{2+}		Reduced short-term memory and aggressiveness	49
630	500	Mg^{2+}	0.5	Enhanced exploratory activity	50

16	20.9	Ca^{2+}	0.7	Enhanced motility	59
32	20.9	Ca^{2+}	0.7	Even harmonic: no effect	59
48	20.9	Ca^{2+}	0.7	Third harmonic: enhanced motility	59
64	20.9	Ca^{2+}	0.7	Even harmonic: no effect	59
8	10.45	Ca^{2+}	1.4	Enhanced motility	60
12–64	15.7–83.6	Ca^{2+}		Additional ICR frequencies at 12, 16, 23, 31, 32, 46, 64 Hz also enhance motility	60
24, 40, 120	10.45	Ca^{2+}	1.4	Three ICR harmonics for 10.45 μT (n = 3, 5, 15) enhance motility	60
16–136	10.45	Ca^{2+}	1.40.73	Thirteen other frequencies (n = 2, 4, 6, 7, 8, 9, 10, 11, 12, 13, 14, 16, 17) fail to show effect	60
8	20.45	K^+	0.73	Motility inhibited	60
16	41	K^+	0.37	Motility inhibited	60
24, 40, 120	20.45	K^+	0.37	Three ICR harmonic frequencies for B_0 = 20.45 μT (n = 3, 5, 15) also inhibit motility	60
16–136	20.45	K^+	0.37	Thirteen other frequencies (n = 2, 4, 6, 7, 8, 9, 10, 11, 12, 13, 14, 16, 17) fail to show effect	60
16	21	Ca^{2+}	1.0	Enhanced motility	61
16	20.9	Ca^{2+}	1.0	No effect on motility	62
30	39.2	Ca^{2+}	1.0	No effect on motility	62
60	78.4	Ca^{2+}	1.0	No effect on motility	62
16	20.9	Ca^{2+}	1.0	No effect on motility	63
16	21	Ca^{2+}	1.0	No effect on motility	64
16	20.9	Ca^{2+}	1.0	No effect on motility as viewed with real-time video system	65

9.2.1 Rat Behavior

On the other hand, some of the experimental evidence merits special emphasis because of the way the results have been positively replicated and reinforced. This is particularly true of the work on rat behavior (Table 9.5), in which four independent groups [45,47,49,51] observed significant changes in behavior for ICR exposures that were tuned to either the calcium or the magnesium ion. The end points of these experiments included changes in short-term memory [45,51], learning capacity [47], and aggressiveness [49], behavioral factors that are conceivably interconnected. Most important, these were undoubtedly resonance effects, since changes were not observed when separate runs were made for exposures to either the AC magnetic field alone or the DC magnetic field alone. Only when the AC and DC magnetic fields were jointly applied and parallel and, moreover, when the combined field characteristics conformed to Equation 9.1 were the altered behavioral responses observed.

An interesting possible explanation for the neural interaction site in these experiments has been proposed by Lovely et al. [47,92]. Using a Y-maze setup this group observed precisely opposite learning abilities for Ca^{2+} tuning and for Mg^{2+} tuning. Since the ICR combined field affects learning capacity oppositely for Ca^{2+} tuning and Mg^{2+} tuning, it may be reasonable to assume that the glutamate receptor *N*-methyl D-aspartate (NMDA) is

TABLE 9.8

ICR Effects on Complex Biological Systems

Frequency (Hz)	B_0 (μT)	Tuning	Ratio B/B_0	Comments	Reference
3–770	10–220		0064–2.8	No effect on turtle colon transepithelial current as measured in Ussing chamber	66
33.7	44	Ca^{2+}	1.41	Synthesis and release of rat pineal melatonin is reduced by Ca^{2+} ICR tuning	67
15	21	Ca^{2+}	6.7	Fluctuations in heart rate in Daphnia are maximized at Ca^{2+} ICR frequency	68
60	78.4	Ca^{2+}	0.13	Cephalic regeneration in planaria is delayed by 48 h	69
60	51.1	K^+	1.0	Regeneration rate unchanged when K^+ tuning is used instead of Ca^{2+} tuning	69
60	78.4	Ca^{2+}	0.51	Regeneration anomalies occur at Ca^{2+} tuning when larger AC intensity is used	70
16	20.9	Ca^{2+}	1.8	Enhanced rate of blastema growth during cephalic regeneration in planaria	71
16	20.9	Ca^{2+}	0.24–9.6	Evidence that ICR effect on planaria regeneration has an intensity window	71
30	39.1	Ca^{2+}	1.8	Evidence corroborating Lednev [7] prediction: ICR effects are maximized at AC/DC ratio of 1.8	72
60	78.1	Ca^{2+}	1.8	Effect of light on ICR modulation of snail opioid analgesia is independent of frequency	72
120	156.2	Ca^{2+}	3.6	Effect due to light appears to scale with DC intensity	72
60	78	Ca^{2+}	0–5.3	Ca^{2+} ICR variations with AC intensity support Lednev [7] model	73
30	76	K^+	0–2.8	K^+ ICR effects on snail opioid analgesia are reversed with K^+ channel blocker	73
35	45	Ca^{2+}	1.8	Maximum influence on bioluminescence of dinoflagellate, agreement with PRM model	74
35	45	Ca^{2+}	5.3	Influence reversed, again in agreement with PRM model	74
35	45	Ca^{2+}	3.8	No effect at ratio of 3.8, again in agreement with PRM model	74

involved. NMDA receptors act as a graded switch for memory formation, to enhance learning and memory [93], and it is well established that NMDA activity is differently sensitive to calcium and magnesium concentrations [94,95]. Similar reversals of behavioral outcome depending on which ions are tuned have been observed by Zhadin et al. [51].

This explanation also serves to reinforce the original suggestion [4] concerning the molecular explanation for ICR stimulation, namely, in terms of enhanced ionic permeability within ion channels. Further support for locating the ion channel as the site of magnetic interaction is the fact that the changes in Ca^{2+} concentration within the cell that result from ICR stimulation tuned to the Ca^{2+} ion are not observed with the addition of nifedipine [34], a well-known calcium ion channel blocker (Figure 9.3).

9.2.2 Plants

Highly consistent results have also been independently obtained in studying the effects of ICR stimulation on plant growth [75–77,96] and seed germination [20,78] (Table 9.9,

TABLE 9.9

ICR Effects on Plants

Frequency (Hz)	$B_0(\mu T)$	Tuning	Ratio B/B_0	Comments	Reference
60	78.3	Ca^{2+}	0.26	Ca^{2+} ICR field combination stimulates radish growth after delaying germination	75
60	153.3	K^+	0.13	K^+ ICR field enhances germination while reducing growth	75
60	0			No effect	75
60	78.4	Ca^{2+}	0.26	Ca^{2+} fundamental stimulates growth but slows down germination	20
60	39.2	Ca^{2+}	0.51	Ca^{2+} second harmonic: no effect	20
60	26.1	Ca^{2+}	0.77	Ca^{2+} third harmonic: same result as Ca^{2+} fundamental	20
60	153.3	K^+	0.13	K^+ fundamental results opposite to those of Ca^{2+}: growth inhibited, germination enhanced	20
60	76.6	K^+	0.26	K^+ second harmonic results weakly opposite to fundamental and third harmonics	20
60	51.1	K^+	0.39	K^+ third harmonic: effect same as K^+ fundamental	20
60	47.5	Mg^{2+}	0.42	Mg^{2+} fundamental stimulates growth	20
60	9.5	Mg^{2+}	2.11	Mg^{2+} fifth harmonic stimulates growth	20

60	78.3	Ca^{2+}	0.26	Replication of Smith et al.'s [75] work	76
60	78.3	Ca^{2+}	0.26	No effect on mustard plant; possible effect on barley plant	76
50	65.3	Ca^{2+}	0.61	Replication of Smith et al.'s [75] work on radish, for the 50-Hz Ca^{2+} ICR condition	77
50	39.6	Mg^{2+}	0.60	Replication of Smith et al. [75] for 50-Hz Mg^{2+} condition	77
60	76.3	Ca^{2+}	0.26	Germination weakly enhanced following Ca^{2+} ICR exposure of dry radish seeds	78
60	153.5	Mg^{2+}	0.13	No effect on germination	78
60	47.6	K^+	0.42	Significantly greater (earlier) germination of dry seeds following K^+ ICR exposure	78
35.8	46.5	Ca^{2+}	1.84	Gravitropic response in millet, flax, and clover seedlings enhanced by Ca^{2+} ICR	79
58.7	46.5	Mg^{2+}	1.84	Gravitropic response unaffected by Mg^{2+} tuning	79
54.7	46.5	K^+	1.84	Gravitropic response inhibited by K^+ ICR	79
33.8–37.8	46.5	Ca^{2+}	1.84	Frequency-dependent gravitropic response exhibits Ca^{2+} peak: FWHM[a] = 1.6 Hz	80
60	48	Mg^{2+}	1.48	CO_2 uptake significantly below control in radish, replication of Smith et al. [75]	81

[a]FWHM, full width at half maximum.

Figure 9.4). The approach in the earlier reports [75] involved direct observations of aspects of plants that are readily measurable: plant height, aboveground height, root mass, stem diameter, leaf length, and width. Remarkably, all aspects related to growth are significantly affected, suggesting that magnetic fields play some unknown role in plant physiology. As observed in other systems (see Table 9.3), Ca^{2+} and Mg^{2+} tuning tends to enhance growth while tuning to the potassium ion acts as an inhibitor. Radish (*Raphanus sativus*) was used because of its rapid growth cycle (21 d), ease of handling, and seed availability. Davies [76] observed positive results when stimulating radish with ICR

TABLE 9.10

ICR Effects in Cell-Free Systems

Frequency (Hz)	B_0 (μT)	Tuning	Ratio B/B_0	Comments	Reference
8–20	20.9		1.0	Three frequencies (13.0, 14.0, and 16.0) affect calmodulin-dependent phosphorylation	82
100	0–260		>0.45	No Ca^{2+} ICR effect on conductance in pure bilipid layer	83
50–120	0–299		>0.31	Binding of Ca^{2+} to calmodulin is not enhanced using Ca^{2+} ICR fields	84
20	50	K^+	1.4	No changes from ICR tuning in gram A channel conductance in lipid bilayer	85
760	50	H^+	15.2	No changes from ICR tuning in gram A channel conductance in lipid bilayer	85
0.1–40	25	Asn^+	0.002	Enhanced aqueous conductivity in asparagine solution at 2.9 Hz; ICR prediction 2.9 Hz	86
0.1–40	25	Arg^{2+}	0.002	Enhanced aqueous conductivity in arginine solution at 4.4 Hz; ICR prediction 4.4 Hz	86
0.1–40	25	Glu^+	0.002	Enhanced aqueous conductivity in glutamic acid solution at 2.5 Hz; ICR prediction 2.6 Hz	86
0.1–40	25	Tyr^+	0.002	Enhanced aqueous conductivity in glutamic acid solution at 1.9 Hz; ICR prediction 2.1 Hz	86
0.1–40	25		0.2	ICR effect disappears at higher ratio of AC to DC intensities	86
0.1–40	0		0.002	ICR effect disappears for very small DC fields	86
0.1–40	25		0.002	ICR effects disappear when AC magnetic field is at 90° to DC field	86
12–60	20.9		1.0	No change in Ca^{2+} transport through patch-clamped cell membrane	87
10–22	20.9		1.0	No change in Ca^{2+} transport through patch-clamped system, measured over loner times	87
1–10	20–40	Glu^+	625–1.25 (×.001)	Changes in glutamic acid conductivity in solution; good agreement with Glu^+ ICR q/m prediction	88
1–10	40		0.25–2.0 (×.001)	Confirmation of earlier work; amino acid response at AC levels of 0.02–0.04 μT	88
0–10	40	Arg^{2+}	0.001	Sharp change in conductivity observed at 7.1 Hz, the ICR tuning point for Arg^{2+}	11
20.6	48	$H_3O^+(H_2O)$	0.02	ICR fields trigger long-term increases in electrical conductivity in pure water	89
40.1	48	H_3O^+	0.02	Data in agreement with ICR effect in hydronium ion	89
530	35	H^+	0.03	Data in agreement with ICR effect in proton	89

24	37		0–3.2	Agreement with Blanchard and Blackman's [9] IPR model	91

magnetic fields but reported observing no similar effect in mustard plants, implying that the influence on growth may be species specific. ICR effects on radish metabolism were also reported by Yano et al. [81] using a distinctly different assay, the rate of uptake of CO_2 as a surrogate for photosynthesis activity. Still another assay [97] that responds to ICR magnetic stimulation in radish is the optical transmittivity in leaf.

The work in radish was extended [96] to four species of orchid (*Brassavola*, *Encyclium*, *Phalaenopsis*, and *Bulbophuyllum*) (Figure 9.4 and Figure 9.5), with the magnetic exposures tuned to Ca^{2+} ICR lasting months instead of days. In all treated cases, plant heights were significantly higher compared to controls.

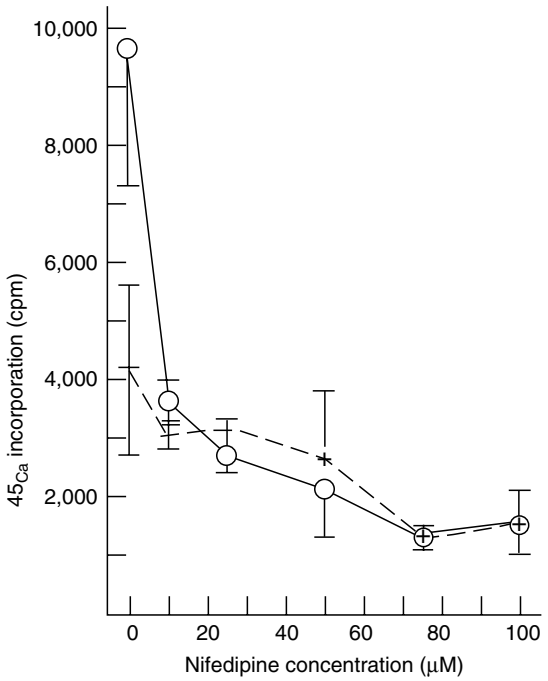

FIGURE 9.3

Incorporation of $_{45}Ca$ in human lymphocytes for unexposed cells (dashed line) and for ICR exposure tuned to the isotopic mass of $_{45}Ca$ (solid line) after 1 h. In the absence of calcium blocker nifedipine, there is a greater than twofold increase in calcium concentration over controls. The addition of nifedipine completely blocks the calcium uptake resulting from ICR stimulation, providing evidence that the ICR mechanism is related to ion channel transport. (From Rozek, R.J., Sherman, M.L., Liboff, A.R., McLeod, B.R., and Smith, S.D., Nifedipene is an antagonist to cyclotron resonance enhancement of $_{45}Ca$ incorporation in human lymphocytes, *Cell Calcium*, 8, 413, 1987.)

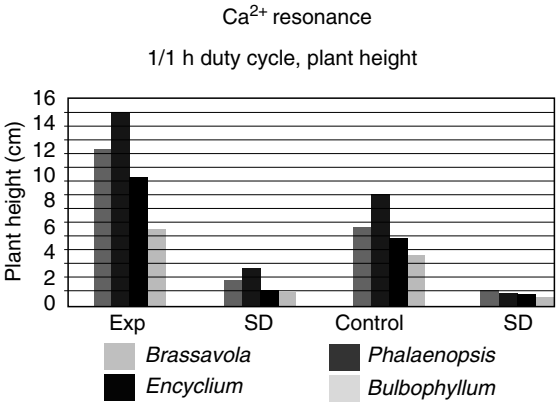

FIGURE 9.4
Comparisons of mean plant heights for four orchid varieties between unexposed controls and plants subjected to Ca^{2+} ICR stimulation. SD, standard deviation. (From Smith, S.D., Liboff, A.R., and McLeod, B.R., Calcium ICR and seedling growth in orchids (abstract), 20th Annual Meeting, Bioelectromagnetics Society, St. Petersburg Beach, FL, 1998.)

A distinctly different type of plant experiment has examined the rate of seed germination [21,78] instead of growth. In this case the assay simply involves a comparison of the time it takes for the seedling to be observed after the exposed seed is planted to the time it takes for a nonexposed seed to emerge. Unlike what is observed when examining growth rates, germination rates are significantly enhanced under K^+ stimulation and inhibited for Ca^{2+} tuning.

9.2.3 Bone

Elaborating on earlier work that used high-intensity pulsed magnetic fields [98] to treat bone disorders, ICR stimulation, operating at a much lower intensity, has proven very useful in repairing bone nonunions [29,99] and as an adjunct in enhancing spinal fusion following surgery [99]. Both these medical applications are approved by the U.S. Food and Drug Administration (FDA) and have been used to treat more than 100,000 patients in the United States [99]. There are two great advantages in these applications compared

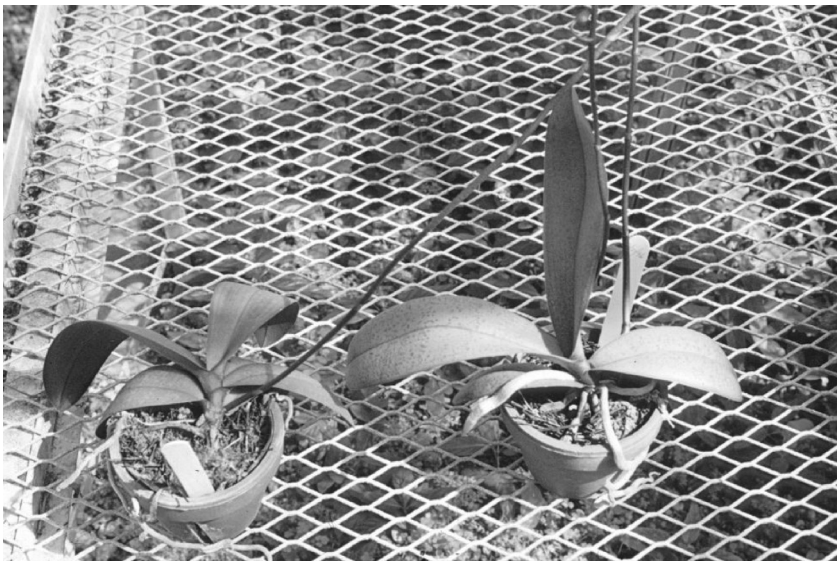

FIGURE 9.5
Typical example of difference between treated (right) and unexposed (left) orchid (*Phalaenopsis*) plants. (From Smith, S.D., Liboff, A.R., and McLeod, B.R., Calcium ICR and seedling growth in orchids (abstract), 20th Annual Meeting, Bioelectromagnetics Society, St. Petersburg Beach, FL, 1998.)

to pulsed magnetic fields therapy. Much weaker AC magnetic field intensities, less than 0.1 mT in amplitude, are employed, requiring very small power and providing the patient with greater portability. The treatment is also more efficient, requiring only 30 min/d during the therapeutic regimen.

This FDA-approved ICR device (Figure 9.6) also makes use of harmonic frequencies. The orientation of the local GMF relative to the plane of the AC coil is sensed, and the frequency of the applied sinusoidal magnetic signal generated by the coil is automatically adjusted to be in cyclotron resonance with the GMF following the relation $\omega_n = nqB/m$, where n is an integer representing either the third or the fifth ICR harmonic. Table 9.11 lists the ICR harmonics for a number of ions. In the case of bone, tuning to either Ca^{2+} or Mg^{2+} tends to stimulate bone growth [24] (Figure 9.7 and Figure 9.8). The FDA-approved device makes use of this fact by employing one resonance condition (3.80 Hz/μT) that fits both types of stimulation, namely the third harmonic for Mg^{2+} and the fifth for Ca^{2+}.

It is likely that the level of efficacy of ICR magnetic treatment in repairing bony nonunions is far from optimal. There is good evidence [9,73,82] that the ICR response may depend on the ratio of the AC to DC magnetic fields that are used in combination. As such, one can expect the search for improvements in therapeutic signals for bone repair to continue.

FIGURE 9.6
Device used to assist repair of bony nonunions. The two rectangular parallel coils are clamped over the defect, and the GMF component normal to the plane of these coils is automatically determined regardless of limb orientation. An AC magnetic field is applied parallel to the GMF field that is in ion resonance tuned to harmonics of calcium and magnesium. (Courtesy of OrthoLogic Corp., Tempe, AZ.)

TABLE 9.11

ICR Harmonics for Selected Ions

Ion	Fundamental (Hz/μT) f/B	Higher Harmonics (Hz/μT) $3f/B$	$5f/B$	Subharmonics (Hz/μT) $f/3B$	$f/5B$
Mg^{2+}	1.26	3.79	6.31	0.421	0.253
Ca^{2+}	0.77	2.30	3.83	0.255	0.153
Zn^{2+}	0.47	1.41	2.35	0.157	0.094
K^{+}	0.39	1.18	1.97	0.131	0.026

In attempting to further probe the response of skeletal tissues to resonant magnetic fields, Ryaby and colleagues [25–28,30,31] reported a number of associated metabolic changes in bone cells, most notably an increase in insulin-like growth factor-II (IGF-II) expression (Figure 9.9 and Figure 9.10) under ICR tuning for Ca^{2+}. This body of work was rather complete in that separate experiments were carried out to justify Equation 9.1. With the magnetostatic field held at one value the frequency was varied as shown in Figure 9.10. In addition, separate runs were made with a fixed frequency and different values of the DC magnetic field. Resonance peaks were observed for both arrangements in accordance with Equation 9.1.

9.2.4 Harmonics

In general, the question of which harmonics are observed in the experimental data remains unresolved. McLeod et al. [59], studying diatom motility, showed that when the DC field is kept constant, odd multiples of the ICR fundamental frequency also result in enhanced motility. The same type of frequency harmonic dependence was found for ICR stimulation of plant growth [21]. Similar experimental results were obtained by Blackman et al. [100] in determining the degree of radioactive calcium flux from chick

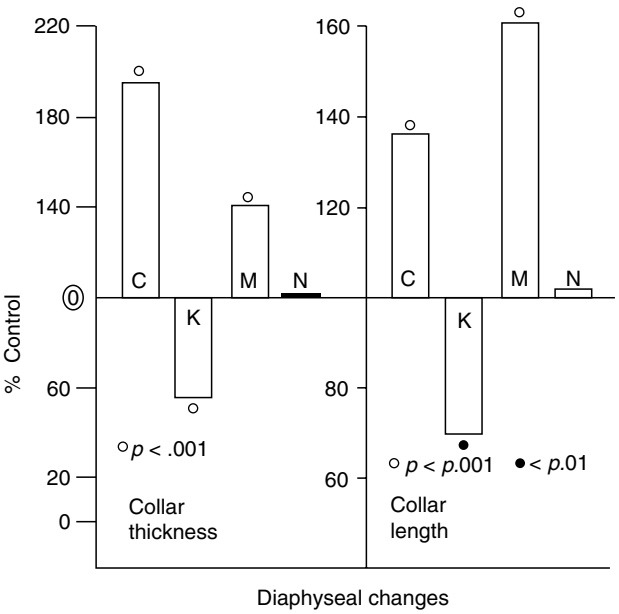

FIGURE 9.7
Ca^{2+} and Mg^{2+} ICR exposures aid bone growth. Changes in diaphysis of embryonic chick femur due to ICR stimulation are shown as percentage of controls. C and M correspond to Ca^{2+} and Mg^{2+} tuning, and K represents the effects of tuning to the q/m ratio for K^{+}. Note the reversal of effect following exposure to potassium-tuned magnetic fields. (From Smith, S.D., Liboff, A.R., and McLeod, B.R., Effects of resonant magnetic fields on chick femoral development *in vitro*, *J. Bioelectr.*, 10, 81, 1991.)

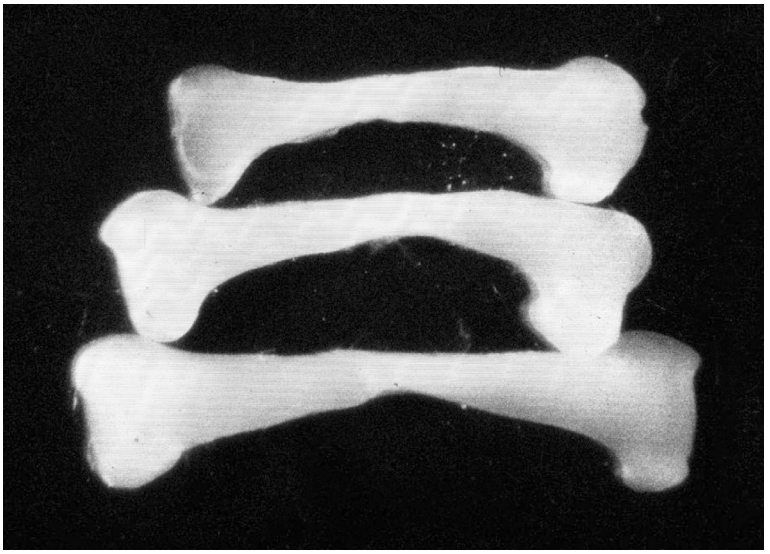

FIGURE 9.8
Typical examples of changes in embryonic chick femora with different ICR exposures. The longest femur corresponds to calcium ion stimulation, the shortest femur to potassium tuning, and the in-between size is the control. (From Smith, S.D., Liboff, A.R., and McLeod, B.R., Effects of resonant magnetic fields on chick femoral development *in vitro*, *J. Bioelectr*., 10, 81, 1991.)

brain as a function of electric-field modulation frequency. These various findings are in reasonable agreement with the predicted higher harmonic ICR signatures listed in Table 9.11.

Because subharmonics are predicted [7,101] in several theoretical models, the first two predicted odd subharmonic characteristics are also listed for convenience in Table 9.11. It

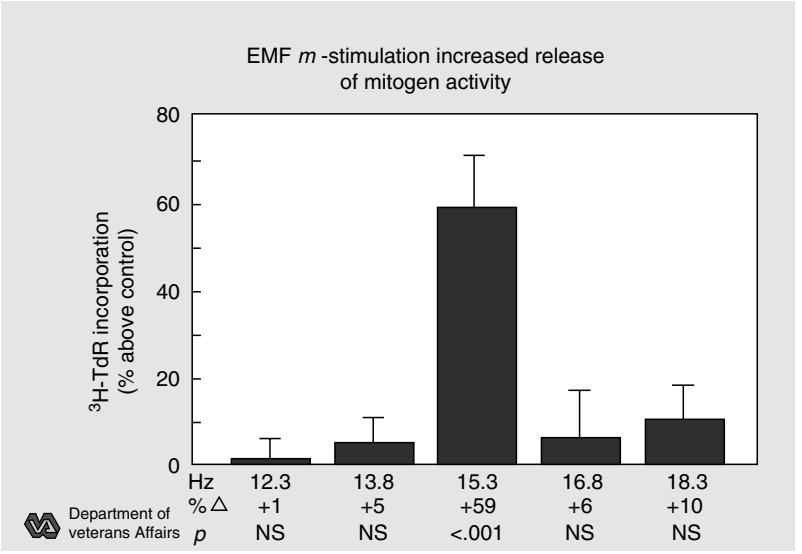

FIGURE 9.9
A sharp increase in mitogen expression in osteosarcoma cells exposed to a 20-μT DC magnetic field occurs when the AC magnetic field frequency is 15.3 Hz, corresponding to Ca^{2+} resonance. (Courtesy of Veterans Administration Hospital, Phoenix, AZ.)

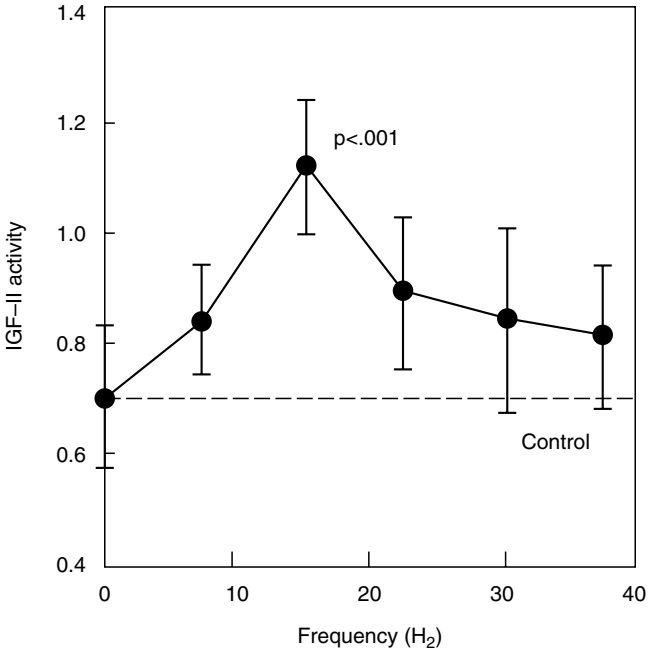

FIGURE 9.10
Peak in IGF-II expression at the fifth harmonic for Ca^{2+}. (Courtesy of J. Ryaby.) Fitzsimmons, R.J., Ryaby, J.T., Magee, F.P., and Baylink, D.J., Combined magnetic fields increase insulin-like growth factor-II in TE-85 human octeosarcoma bone cell cultures, *Endocrinology*, 136, 3100, 1995.)

is clear that a better fit between the theoretical predictions of harmonics and the nature of their experimental observations could be an important factor in further understanding of ICR phenomena in living things.

9.2.5 Physiological Reversals

There is substantial evidence [102] that changing the ICR tuning from one ionic species to another has the capacity to completely reverse physiological outcomes (Figure 9.8 and Figure 9.11). This has been reported in a number of separate fascinating observations in widely different ICR experiments. The effect is manifested by applying, at the same frequency, relatively small shifts in the local magnetic field or, equivalently, applying a changed frequency with the local magnetic field kept the same, both variations made according to Equation 9.1. Eight such sets of results are given in Table 9.12.

This type of opposite response in the data may provide an important clue in trying to understand the ICR effect at the molecular level. Such a response might be expected when looking at the effects of competitive ion concentrations on cell metabolism and signaling. One such example, mentioned above [47], is the difference in the effects of binding Ca^{2+} and Mg^{2+} to NMDA. The concentration of Ca^{2+} in the cytoplasm, itself an implicit function of other ionic concentrations, is carefully regulated through the use of calcium pumps. The production of key enzymes such as cyclic AMP is enhanced or inhibited depending on the cytoplasmic calcium ion concentration. Because of this it is reasonable to think that the action of ICR fields has its origin in membrane-bound ion channels or in those proteins involved in the cell-signaling process.

9.2.6 Water

There have been numerous puzzling reports [103–105] claiming that the physical properties of water (e.g., conductivity) can be sufficiently altered by exposure to magnetic

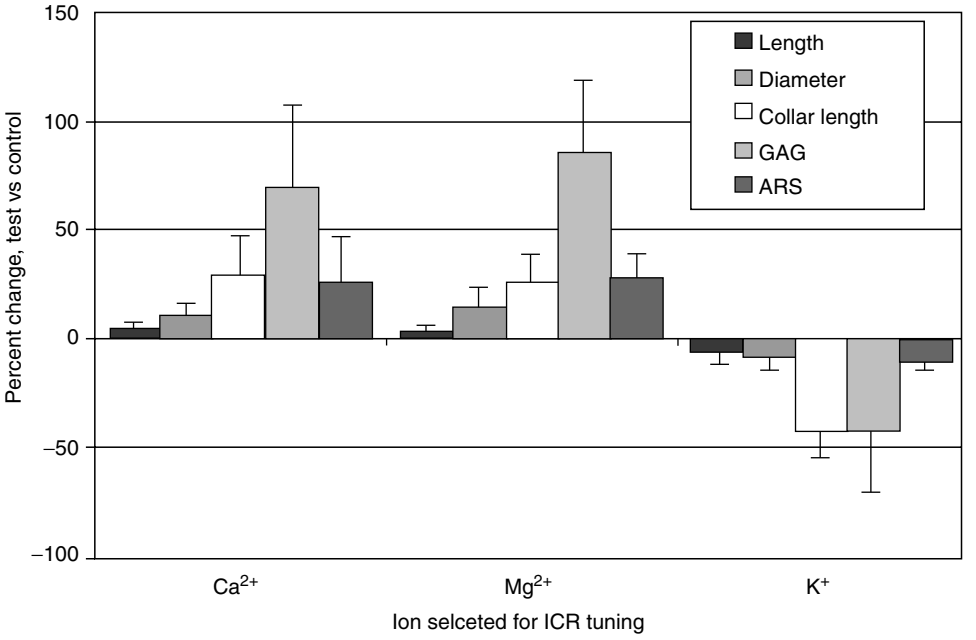

FIGURE 9.11
Independent confirmation of the results shown in Figure 9.8 for embryonic chick femur [32]. The additional assay for glycosaminoglycans (GAGS) reveals a greatly increased production of cartilage with Ca^{2+} or Mg^{2+} ICR stimulation and reduced cartilage production with K^{+} tuning.

fields to alter biological properties. Zhadin [86,88] explored this question using combined AC and DC magnetic fields, to see if there might be an ICR response. The conductivity of polar amino acids in solution (Table 9.1 and Table 9.10) was chosen as an assay. The frequency of the magnetic field was swept slowly, and a single sharp current peak was observed at the cyclotronic frequency, determined from Equation 9.1 using the naked (unhydrated) molecular mass. Originally made in glutamic acid solutions [86], these observations were subsequently extended to additional amino acids, even to the case

TABLE 9.12

Opposite Responses Resulting from Shifts in Frequency or Field

Model System	Frequency (Hz)	B_0 (μT)	Ion	Response	Reference
Diatom motility	16	20.9	Ca^{2+}	Motility ↑	58
	16	41.0	K^{+}	Motility ↓	
Embryonic bone	16	20.9	Ca^{2+}	Growth ↑	24
	16	40.7	K^{+}	Growth ↓	32
Plant growth	60	78.3	Ca^{2+}	Growth ↑	75
	60	153.3	K^{+}	Growth ↓	
Rat behavior	60	48	Mg^{2+}	Learning ↑	47
	60	27	Ca^{2+}	Learning ↓	
Rat behavior	63	50	Mg^{2+}	Activity ↑	51
	38	50	Ca^{2+}	Activity ↓	
Gravitropic response	35.8	46.5	Ca^{2+}	Response ↑	79
	54.7	46.5	K^{+}	Response ↓	
Glycosaminoglycans (GAGs) concentration	16	20.9	Ca^{2+}	GAGs ↑	32
	16	40.7	K^{+}	GAGs ↓	

where it was possible to shift the ICR peak by changing the pH of the solution, and therefore the valence of the ion. This work has been independently confirmed in two-other laboratories [11,105]. One interesting aspect of these observations is the remarkably small AC magnetic field intensity required to see this effect, on the order of 0.05 μT.

It has also been shown [89] that very short (minutes) applications of ICR-tuned magnetic fields act to trigger large (days) continuing increases in conductivity in highly purified water. The required AC intensities (1 μT) are greater than that was found necessary in the Zhadin experiments, but they are still far less than reported elsewhere as interactive. The ions that are presumably affected are hydronium (H_3O^+) and its water clusters. One intriguing aspect of this work are the long-term changes in conductivity that are observed, even after removal of the magnetic field, a phenomenon somewhat akin to that of water ''memory'' [106,107].

9.3 Theoretical Approaches

9.3.1 Physical Constraints

The conditions in living things are such that charged particles are not free but subject to damping forces. If a particle such as an ion carries charge q and mass m and is moving with velocity $\mathbf{v}$, damping is manifested in the form of a retarding force, above and beyond the Lorentz force q($\mathbf{v} \times \mathbf{B}$) and the Coulomb force $q\mathbf{E}$:

$$\mathbf{F} = q(\mathbf{v} \times \mathbf{B} + \mathbf{E}) - m\mathbf{v}/\tau \tag{9.6}$$

The last term in Equation 9.6 is the mean damping force acting on the particle expressed in terms of the collision rate τ^{-1}.

The possibility of ICR occurring in living systems is counterintuitive, mainly because of damping. Cyclotron resonance, whether involving ions [108] or electrons [109], is usually associated with motion in a vacuum, or at least a low-pressure gas. In sharp contrast, the biological milieu is generally approximated as a liquid. Electron cyclotron resonance is observed in metals [109], but only at extremely high frequencies ranging from megahertz to gigahertz, many orders of magnitude greater than the typically observed frequencies listed in Table 9.3 through Table 9.10. At very high frequencies, the periodic motion of charged particles in cyclotron resonance can take place because the periods are shorter than the collision times. At 15 Hz, however, one loop is executed in 70 ms, a time over which one might expect as many as 10^{12} collisions because of thermal scattering [110]. The problem of explaining ICR effects in living systems is indeed challenging.

A second argument against the ICR hypothesis is that ions in solution are never totally free but are surrounded by layers of water. Therefore, one would think that the values of the q/m ratio indicated in Equation 9.1 would have to be lowered to reflect the extra mass that is part of the overall ionic package.

One further criticism lies in estimates of the path radius for (free) charged particles in cyclotron resonance. This is based on equating the kinetic energy $mv^2/2$ of the charged particle to the thermal energy kT, and then arguing that the radius of the particle path must necessarily reflect the resulting velocity, because this radius is given as $\rho = v(m/qB)$. At a temperature of 37°C this results in radii that are of the order of meters, much larger than the extent of the system itself. However, it is hardly clear that one can use classical kinetics to discuss low energy charged particle interactions with

molecular structures. Further, it must be noted that the cyclotronic frequency ω_c, as given in Equation 9.1 under the condition of vanishing damping, is entirely independent of particle radius and energy.

ICR tends to somewhat mute one of the strongest arguments against the likelihood of weak extremely low-frequency (ELF) magnetic interactions with biosystems. For an electric signal to initiate a biological effect, this signal must be greater than the electric potential generated by thermal noise [111]. The mean square thermal noise voltage $(\delta V)^2$ generated is proportional to Boltzmann's constant k, the temperature T, the tissue resistance R, and the bandwidth $\Delta\nu$ as follows:

$$(\delta V)^2 = 4RKT\Delta\nu \tag{9.7}$$

The original interaction site suggested by Weaver and Astumian [111] was the plasma membrane of the cell. The lipid membrane, however, is a highly electrically insulating material, with physical properties that are not conducive to any low-frequency interaction mechanism [112] except at high voltages. When more conductive substances such as proteins are considered as weak-field interaction sites, the effective resistance R can be many orders of magnitude lower than that found in lipids. Further, experimental evidence indicates that much narrower bandwidths, $\Delta\nu$, are encountered in ICR applications [39,106] than was previously [111,113] assumed. If the product $R\Delta\nu$ is reduced in Equation 9.7 by a factor of 10^{-4}, this lowers δV by a factor of 10^{-2} below the original estimates. The ''kT'' question becomes even less of a problem if one considers electric-field ICR [114], where the frequency of oscillation in Equation 9.1 is derived from endogenous sources within the living system.

9.3.2 Ion Channels

Placing the site of the ICR interaction within the lumen of membrane-bound ion channels deals with the problems of damping and hydration layers but leaves other questions unresolved. It is clear that damping within channels is quite different from that in liquids. The very function of ion channels helps define their intrinsically small effective resistivity, often less than 0.1 Ωm [115], and therefore their vanishing damping. Channels function as shunts across the insulating cell membrane, allowing ions to percolate through, often in single file [116]. The passage of ions is determined less by collision rate, as in the solution-like regions external to channels, but is more dependent on the molecular architecture [117] of the channel proteins: the gating mechanisms that permit entry into the channel lumen and the electrical potential of the atoms lining the lumen walls.

Further, this passage of ions is unencumbered by the layers of hydration that surround all ions in solution. These waters are replaced upon entry into the channel by an equivalent fixed cage lining the lumen (Figure 9.12). Although the energetics of this water replacement is still puzzling [118], there is little question that ions can pass through ion channels in a naked fashion, with no attached waters [119]. The path of ions in a channel is clearly determined in a manner that does not permit one to apply kT arguments in trivial ways.

Although one can readily deal with the two problems associated with first, damping and second, ionic hydration layers, it is not as easy to dismiss the disparity in relaxation times when one compares the very rapid passage of ions through channels to the far slower movements associated with resonance frequencies. The ratio of these times can be well in excess of 10^{10}. To illustrate the problems raised by this disparity, consider the argument that the helicity of ionic paths occurring under ICR might be such as to match the helicity of the electric potential in the lumen [120].

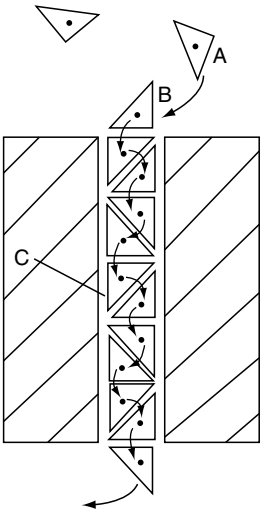

FIGURE 9.12
Hydrated ions near the mouth of an ion channel exchange their layers of water for an equivalent potential distribution within the lumen of the channel.

The electric field in Equation 9.6 can have a number of distinctly different origins. In living tissue, the electric field can be the result of endogenous sources independent of **B**. If **B** is time varying, and of sufficiently large intensity or frequency, an electric field will in addition be induced by Faraday's law. There are also experimental situations in which an electric field may be applied independently of the first two sources. When an electric field **E** is present, whatever the source, and it is at right angles to both **v** and **B**, then the circular motion becomes helical (Figure 9.13). It is then convenient to treat the velocity of the particle as composed of two components: $v_{\|}$, directed parallel to the direction of **E**, and

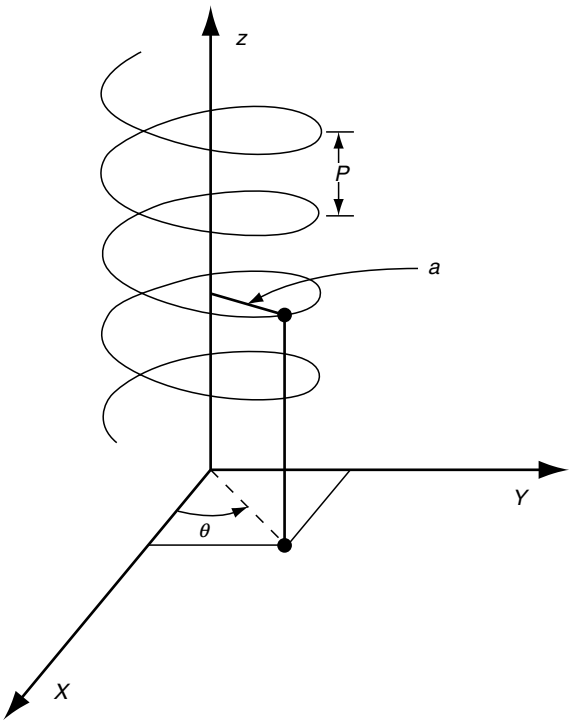

FIGURE 9.13
The Lorentz force acting on a charged particle often results in helical motion.

$v_\perp$, directed within the plane perpendicular to **E**. Then the radius of the helix is $a = mv_\perp/qB$, and its pitch is $p = 2\pi mv\|/qB$. It is not difficult to show that the total velocity v is

$$v = f_c(4\pi^2 a^2 + p^2)^{1/2} \tag{9.8}$$

The ICR frequency f_c is often only 15 Hz, and for ion channels the dimensions a and p are of the order of ångstroms (10^{-10} m). This implies a velocity of about 10^{-9} m/sec, a value that is totally inconsistent with the much greater experimentally observed speeds with which ions are transported across membranes.

Even though transit times directly through the channel lumen are very rapid, much longer relaxation times are found in other compartments of the larger channel structure. Times as long as, if not longer than, 10 ms are associated with voltage gating [121], making it conceivable that ICR could play an interactive role in channel-gating mechanisms.

9.3.3 Dependence on AC Magnetic Field

Borrowing from the theory of atomic spectroscopy [122], Lednev [7] hypothesized a functional relationship between the strength of the ICR signature and B_{AC}. When the calcium ion is bound to a calcium-binding protein such as calmodulin, the energy levels for the ion protein complex will be split, Zeeman-like, by the application of a magnetostatic field B, such that the difference in frequency between the two new levels is equal to the cyclotron resonance frequency ω_c.

Application of an AC magnetic field at this frequency then leads to a resonant condition that can alter the transition to the ground state. The ICR response itself then becomes a function of the peak value of B_{AC} expressed in terms of the probability $p(B_{AC})$ for Ca^{2+} transitions to the ground state. The field-dependent part of this probability is

$$p(B_{AC}) = (-1)^n K J_n\left(n\frac{B_{AC}}{B_0}\right) \tag{9.9}$$

where K is a constant, B_0 is the DC magnetic intensity parallel to B_{AC}, and J_n is the nth-order Bessel function having the argument nB_{AC}/B_0.

One great advantage of this expression for the probability is that one can readily design experiments that can test the predicted dependence on the AC magnetic field. Thus, the first extremum of $J_1(B_{AC}/B_0)$ occurs when the ratio B_{AC}/B_0 is equal to 1.84 (Figure 9.14). By varying this ratio while maintaining the same ICR condition, Prato et al. [72] obtained data tending to confirm this prediction. The effectiveness of this numerical ratio was also reported [74] in connection with studies on changes in calcium concentrations under ICR stimulation.

An alternative formulation to Equation 9.9 has been proposed by Blanchard and Blackman [9]. Termed ion parametric resonance (IPR) this approach considers a wider range of potential ELF interactions with metallic ions, beyond merely those processes associated with the activation of calcium-binding proteins. In the IPR formulation the probability $p(B_{AC})$ has the dependence $J_n(2nB_{AC}/B_0)$. The factor of 2 in the argument of the Bessel function has the effect of altering where the first extremum occurs, in this case at the B_{AC}/B_0 ratio of 0.92 (Figure 9.14). This ratio is close to the value of 1.0 successfully used by Smith [21,24,58,75] in all his experiments. However it is not clear in Smith's body of work whether further manipulation of the AC magnetic intensity away from this ratio of unity might have enhanced the responses that were observed. Koch et al. [91] were also able to obtain good agreement with the IPR predictions. One set of experimental results in sharp

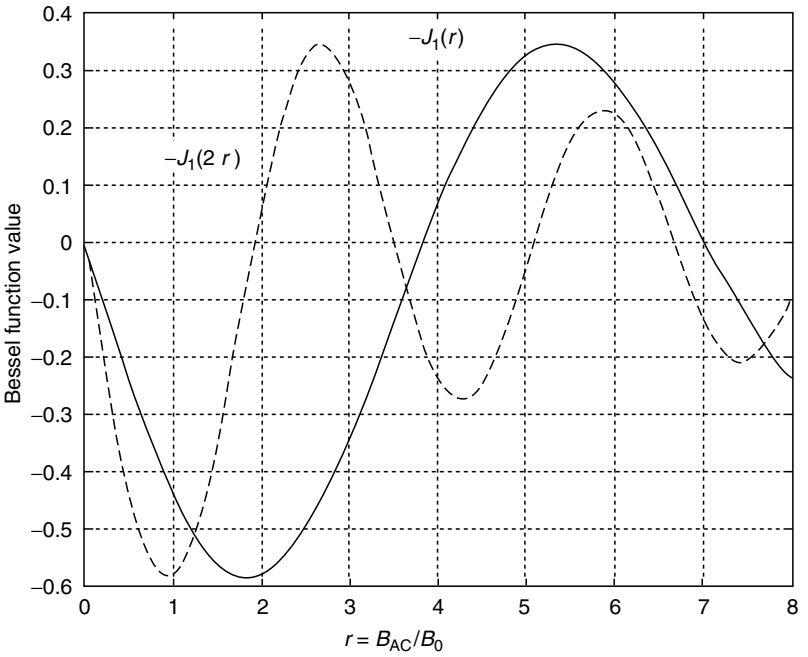

FIGURE 9.14
Comparing first-order Bessel functions with arguments B_{AC}/B_0 (solid line) and $2B_{AC}/B_0$ (dotted line). The first extremum is of experimental interest. By doubling the argument, the ratio where this extremum occurs is shifted from 1.84 to 0.92. In principle, one holds B_0 and the ICR frequency fixed and varies B_{AC} to determine where the maximum biological response occurs.

contrast with the predictions of parametric resonance are the consistent reports by Zhadin's group [86,88] and others [11], in which ICR exposures of polar amino acids in solution lead to narrow resonances, but only for B_{AC}/B_0 ratios of approximately 0.002.

The question of the dependence of the ICR interactive response on AC magnetic intensity is clouded by two additional possibilities. First, there is the problem of experimentally sorting out effects due to Faraday induction with larger AC fields [70]. Second, it is conceivable that biological responses to different AC fields may have little to do with the ICR response but rather with poorly understood physiological and energetic constraints. In any event, there is a clear record in the literature (e.g., Figure 9.15) of ICR threshold effects that do not appear to be related to functional variations such as Equation 9.9.

Adair [123,124] has criticized the parametric resonance approaches. Similar to earlier arguments [111,113] related to energetic constraints imposed by thermal noise, it was pointed out that the transition energy is only 10^{-11} of the thermal energy, kT, which would greatly suppress any meaningful effects due to Zeeman splitting. For this and other reasons [123], he concludes that application of the cyclotronic frequency ω_c cannot affect the transition rate of Ca^{2+}.

A very different approach to the problem of whether resonant magnetic fields can influence the binding of calcium has been suggested by Binhi [101]. Using Schrodinger's equation, it has been shown that ICR magnetic field combinations may redistribute the ionic probability density when one takes into account interference effects between quantum states. However, there is some question as to how much the wave function must shrink to allow ions as large as Ca^{2+} to escape.

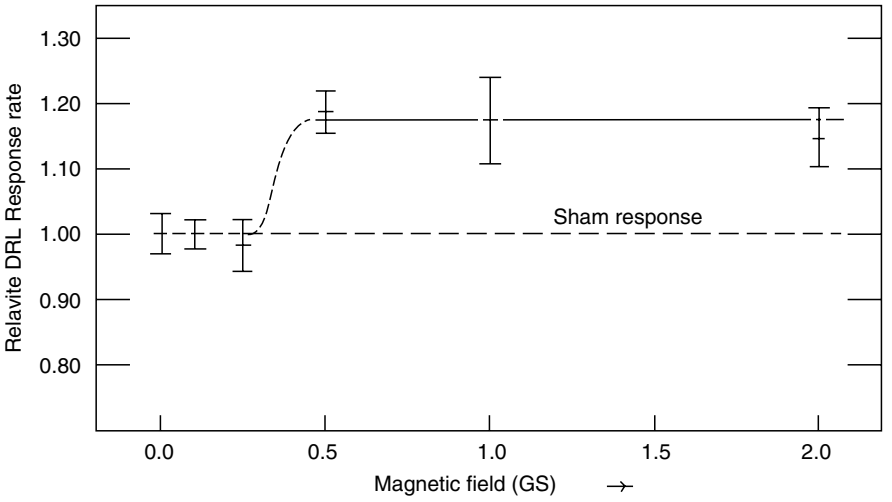

FIGURE 9.15
ICR-induced changes in rat behavior as a function of the AC magnetic field intensity. A clear threshold is evident, below which there is no effect on rat behavior. (From Liboff, A.R., Thomas, J.R., and Schrot, J., Intensity threshold for 60-Hz magnetically induced behavioral changes in rats, *Bioelectromagnetics*, 10, 111, 1989.)

9.3.4 Precessional Effects

It has been shown [8,10] that Larmor precessional effects can result from the application of weak ICR magnetic field combinations. In principle, these effects might carry physiological consequences, although no evidence along these lines has been reported. One interesting aspect of this approach [10] suggests the possibility of magnetically induced changes in the thermal energy distribution. The altered biological response in this model would not be the result of dissociative processes between ion and protein but would rather follow transfers of energy to the protein by the ion, resulting in appropriate conformational changes.

9.3.5 Coherence Domains

Del Giudice [11] has employed the principles of quantum electrodynamics (QED) in attempting to explain biological ICR, especially those results obtained in connection with the ''Zhadin Experiment'' [11,86,88]. The great advantage in this approach is that it finesses the limitations caused by Maxwell–Boltzmann statistics predictions [111,113], which require kT as a minimal threshold informational energy for electromagnetic interactions. In the QED model it is argued that in the case of electromagnetic interactions with water, coherent, highly ordered spherical domains are formed, with diameters close to 100 nm and embedded in a surrounding noncoherent water phase. An applied ICR frequency in this case couples to ions on the perimeter of the coherent spheres stimulating circulatory motion, allowing ions to escape into the noncoherent phase, where they act to enhance the measured conductivity.

One interesting aspect of this model is that because phase transitions are involved, temperature is expected to play a prominent role in the experimental outcome. The changes in amino acid conductivity under ICR conditions first reported by Novikoff and Zhadin [86] were temperature sensitive. Similar observations regarding the experimental relevance of temperature were reported in earlier [125,126] Ca-efflux studies.

9.4 Discussion

Accepting the abundant evidence that biological systems are sensitive to ICR-tuned field combinations, the question remains as to the molecular explanation. There is also the more subtle question dealing with the implications of this effect. From the physical standpoint, the seeming inability of theorists to come to grips with this phenomenon may not mean that a new physics is called for. But there is certainly good reason to believe that something is missing in the way we categorize biological function.

The fact that a low-frequency ion resonance interaction is found in an extraordinarily wide variety of organisms argues against the commonly held notion that this phenomenon merely represents one fortuitous example of the Lorentz force acting on materials that happen to occur within a biological context.

Indeed, the reports listed in Table 9.10 lend strength to another notion, that the weak-field ICR phenomenon is not limited to biological systems, but is actually a subtle physical effect that has not heretofore been recognized. For example, one can argue that this effect is particularly evident in water, which in turn results in the biological effects that are observed. In other words, because of the ubiquity of water in biological systems, any ELF-induced change in the properties of water might help explain the variety of biological effects that have been reported.

Whatever its molecular origin, it is likely that the ICR-related biophenomenon is an evolutionarily well-conserved property of the physiological armory, one that is enabled by the interaction of the ubiquitous Earth's magnetic field with the equally ubiquitous electric fields that are found throughout living things. This concept is embodied in the reasonable likelihood [114] that electric-field ICR processes were incorporated into living things over evolutionary times. Unlike the laboratory experiments involving the applications of parallel combined AC and DC magnetic fields, *E*-field resonance occurs maximally for time-varying electric and magnetostatic fields at right angles. This naturally occurring interaction therefore relates the GMF and the AC electric fields found within the biosystem. It has been hypothesized [127], for example, that this putative interaction mechanism can be used to explain the problem of bird navigation.

One can speculate that this ICR phenomenon conserved very early in living things has evolved into a number of separate biological expressions, where the physics is always the same but the physiological pathway leads to different end points. For example, two sharply different possible end points, both apparently relying on ICR, are the magnetic compasses in animals [124] and growth and repair mechanisms [24,37,75]. A third intriguing possibility is found in the ICR interactive changes in the central nervous system [45,47,49,51], an area where there are obvious effects but where the end points are still unresolved.

It is also tempting to speculate on the larger implications of the work that is detailed in Table 9.3 and Table 9.9, on bone and plants, respectively. In both cases there is evidence that ICR signals affect growth and repair responses more than they affect stasis. Drawing on possible endogenous mechanisms related to *E*-field ICR, it is conceivable that the interactive relation of the GMF to living systems is especially important as regards growth and repair during development.

Whatever be the explanation for the ICR effect, it is clear that while nothing new may be required in our understanding of physical law, new approaches are necessary in comprehending how physics has been incorporated in biology, particularly with regard to cell signaling and regulation. This is strongly implied by the remarkable data indicating reversed physiological outcomes with minor changes in electromagnetic field conditions. There are protein systems in physiology that are switch-like in their function. Two such

examples are the calcium-binding proteins and NMDA. Another example is found in synaptic transmission. The electromagnetic reversal effects observed in ICR experiments are evocative of the way such switch-like proteins function.

This begs the fascinating question as to whether the ICR stimulus merely serves as an adjunct to an existing biochemical process, perhaps acting to sharpen enhancement or inhibition, or whether it acts in a totally different manner, as a separate and distinct class of interactions, one that is completely electromagnetic in its operation. In this regard, note that the GMF preceded by far the first appearance of living things on Earth and would therefore have been part of the original physical template that determined the course of early evolution.

Computational Methods for Predicting Field Intensity and Temperature Change

James C. Lin and Paolo Bernardi

CONTENTS

10.1 Introduction

Electromagnetic energy at both high and low-frequencies can be transmitted into biological materials through the use of antennas or applicators. Antennas launch the electromagnetic energy into the medium. They serve to couple the generating source of electromagnetic energy into the medium, which surrounds it. The spatial distribution of electromagnetic energy from an antenna is directional and varies with distance from the antenna. At distances sufficiently far from an antenna, so that local field distribution changes predictably and varies mostly with distance, the region is called a far field or radiation zone. In the near field or near zone close to the antenna, the electromagnetic energy distribution varies as a function of both angle and distance. Moreover, the behavior of electromagnetic fields (EMFs) and their coupling and interaction with biological systems are very different, depending on whether they are in the near or far zone. In fact, these differences constitute the major variances between radio frequency (RF) and low-frequency energy deposition into biological systems. As shown in subsequent sections, the induction of electric and magnetic fields, deposition of electromagnetic power, absorption of electromagnetic energy, and their penetration into tissue, all are functions of the source and its frequency or wavelength. In general, when considering the interaction of EMFs with biological systems, it is necessary to account for the frequency or wavelength and its relationship to the physical dimensions of the body.

In addition, the interaction of EMFs with biological systems is characterized by the electromagnetic properties of tissue media, specifically, dielectric permittivity. Biological materials have magnetic permeability values close to that of free space and are independent of frequency. In a medium such as biological tissue with a finite electrical conductivity σ, a conduction current, $\mathbf{J} = \sigma\mathbf{E}$, can be induced to flow, giving rise to energy loss by joule heating. Clearly, fields must be coupled into tissues, and energy must be deposited or absorbed in the biological systems, regardless of the mechanism that is accountable for an effect, for the system to respond in some manner. Thus, to achieve any biological response, the electric field, magnetic field, or EMF that is exerting its influence must be quantified and correlated with the observed phenomenon.

The purpose of this chapter is to present an account of electromagnetic interactions in biological media, with special emphasis on the energy coupling and distribution characteristics in models of biological structures. Such information is essential for analyzing the interrelationships among various observed biological effects, for separating known and substantiated effects from those that are speculative and unsubstantiated, for assessing

the therapeutic effectiveness of electromagnetic waves, and for extracting diagnostic information from field effects.

There exist a wide variety of methods for quantifying fields in biological bodies. The extent of computer usage varies, depending on the specific information sought and the complexity of tissue geometry. This chapter outlines a number of techniques that have been successfully employed to analyze the propagation and absorption characteristics of electromagnetic energy in tissue structures. There are two general approaches: one involves extensive use of analytical development and the other relies more heavily on numerical formulation. Analytical computations are most suited for calculation of the distribution of absorbed energy in simplified tissue geometries such as plane slabs, cylinders, and spheroids, whereas numerical methods offer the opportunity of analyzing the coupling of electromagnetic energy to animal and human bodies, which is difficult, if not impossible, to approach analytically. The advantages and limitations of various methods for field computations, along with representative results, are provided in this chapter. In some cases, for additional details, the reader is referred to previous editions of this handbook [1,2]. This chapter will begin with a brief introduction to the concepts of induced field and power deposition and the characteristics of field intensities and dosimetric quantities.

10.1.1 Induced Field Intensity and Dosimetric Quantities

The quantities of import to characterize coupling of electromagnetic energy into biological systems include the incident field, induced field, power deposition, and absorbed energy. The metrics of specific absorption rate (SAR) and specific absorption (SA) in biological systems or tissue models have been adopted as the dosimetric quantities, especially at RF frequencies. The metric SAR (in W/kg) is defined as the time derivative of the incremental energy absorbed by (or dissipated in) an incremental mass contained in a volume of a given density. SA (in J/kg) is the total amount of energy deposited or absorbed and is given by the integral of SAR over a finite interval of time. Information on SA and SAR is of interest because it may serve as an index for comparison and extrapolation of experimental results from tissue to tissue, from animal to animal, from animal to human, and from human to human exposures. It is also useful in analyzing the relationships among various observed biological effects in different experimental models and subjects. This is in clear contrast to incident field or any other external measures of exposure, which often do not provide the same field inside biological systems of different sizes, species, or constitutions.

Moreover, determination of the induced field would be preferred because it (1) relates the field to specific responses of the body, (2) facilitates understanding of biological phenomena, and (3) is independent of mechanisms of interaction. Once the induced field is known, quantities such as SAR (in W/kg) can be derived from it by a simple conversion formula. For example, from an induced electric field E (in V/m), the SAR can be derived as

$$\mathrm{SAR} = \frac{\sigma E^2}{\rho_{\mathrm{m}}} \tag{10.1}$$

where σ is the bulk electrical conductivity (S/m) and ρ_{m} is the mass density (kg/m^3) of tissue. However, at present, a small, isotropic, implantable electric field probe has yet to be developed with sufficient sensitivity for practical use. Consequently, a common practice in experimental dosimetry relies on the use of temperature elevation produced under a short-duration ($<$30 sec), high-intensity exposure condition. The short duration is not enough for

significant convective or conductive heat contribution to tissue temperature rises. In this case, the time rate of initial rises in temperature (slope of transient temperature response curve) can be related to SAR through a secondary procedure, that is,

$$\text{SAR} = \frac{c\Delta T}{\Delta t} \tag{10.2}$$

where ΔT is the temperature increment (°C), c is the specific heat capacity of tissue (J/kg °C), and Δt is the duration (sec) over which ΔT is measured. Thus, the rise in tissue temperature during the initial or a transient period of RF energy absorption is linearly proportional to the value of SAR. It is important to distinguish the use of SAR and its derivation from temperature measurement. The quantity of SAR is merely a metric for energy deposition or absorption, and it should not be construed to imply any mechanism of interaction, thermal or otherwise. However, it is a quantity that pertains to a macroscopic phenomenon by virtue of the use of bulk electrical conductivity in its derivation (Equation 10.1).

It is of particular significance to emphasize the use of bulk electrical conductivity, the specific heat capacity, and the mass density (kg/m^3) of tissue in the derivation of SAR from electric field strength or temperature elevation. Their use in the definition means that a volume of tissue mass must be selected over which SAR is determined. It is self-evident that the numerical value of SAR would be the same, regardless of what volume is chosen, if the induced field or power deposition is uniform in a tissue medium. A difficulty arises when the absorption is not uniform or when tissues with differing properties and conductivities are within the same volume. Thus, in general, a smaller averaging mass or volume would allow SAR—as a metric—to provide a closer representation of its variation inside the body or tissue medium.

10.1.2 Characterizing EMFs

The space surrounding a source antenna can be divided into near and far zones as a function of distance from the antenna [3]. The demarcating boundary occurs at a conservative distance of $R = 2D^2/\lambda$, where D is the largest dimension of the antenna. Furthermore, the near zone can be divided into two subregions: the radiative region and the reactive region. In *the radiative region*, the region closer than $2D^2/\lambda$, the radiated power varies with distance from the antenna. The vicinity of the antenna where the reactive components predominate is known as *the reactive region*. The precise extent of these regions varies for different antennas. For most antennas, the transition point between reactive and radiative regions occurs from 0.2 to $0.4D^2/\lambda$. For a short dipole antenna, the reactive component predominates to a distance of approximately $\lambda/2\pi$, where the radiative and reactive components are equal to each other. However, the outer limit is on the order of a few wavelengths or less in most cases.

A typical wavelength in free space at extremely low-frequencies (ELF between 3 Hz and 3 kHz) is ~5000 km. The $\lambda/2\pi$ distance is about 800 km for the induction and radiation fields to have equal amplitudes. Therefore, for most purposes, ELF transmission line fields are not radiative but are inductive and quasi-static in nature. This fact governs the coupling and induced field characteristics of ELF and other low-frequency electric and magnetic fields in biological tissue. In particular, (1) the electric field is enhanced at the surface of the biological body and is nearly perpendicular to the surface of the body, (2) electric and magnetic fields are decoupled inside a biological body, (3) the electric field applied through air is weakened by a large dielectric permittivity (by about 10^{-6}) upon penetration into biological tissues, (4) the magnetically induced electric field encircles the

magnetic field and produces an eddy current whose magnitude increases with distance from the center of the body, and (5) an eddy current appears in each region inside the body with a different conductivity and behaves as a unit with its own body center and radius or an equivalent radius. These observations apply to all frequencies where the wavelength is high or the largest dimension of the body is small compared with the wavelength [2]

In contrast, the $2D^2/\lambda$ distance is approximately 6 cm for a 10-cm RF antenna operating at 900 MHz in free space. Clearly, both near-zone reactive and far-zone radiative interactions are encountered in the vicinity of wireless RF telecommunication systems. In the near zone, the coupling of RF energy into the human head is substantial. As much as 40% to 50% of the radiated RF power is transferred back and forth between the radiating antenna and the head. SAR will vary with specific antenna configuration and its placement next to the head. The bulk of power deposition is on the side of the head nearest to the radiating structure of the cellular mobile telephone and follows an exponential trend away from the antenna side. The anatomy of the head and tissue inhomogeneity can influence the maximum value and distribution of SAR in the head of a mobile telephone user. However, the integrated SAR in the head is similar for a homogenous or inhomogenous model. Some of the major features of near-zone field are that (1) RF electric and magnetic fields are decoupled and are not uniform, (2) wave impedance varies from point to point, (3) beam width from the antenna is divergent and is small compared with the head or human body, (4) electric field ffect is weaker since dielectric permittivity of tissue is relatively high, and (5) inductive coupling of antenna-current-generated magnetic field dominates power deposition.

In the far field, coupling is characterized by plane wave RF field interaction and is independent of source configurations. Electric and magnetic fields are uniquely defined through the intrinsic impedance of the medium. Thus, determination of the electric field behavior is sufficient to characterize the interaction. The coupling of RF power from air into planar tissue ranges from 20% to 60% at wireless communication frequencies. However, enhanced coupling can occur at a greater depth in bodies with curved surfaces. In fact, RF energy is resonantly absorbed by the head at 400 to 1500 MHz, and SAR peaks or hot spots may occur near the center of the head. The interaction of RF energy with biological systems depends on electric field polarization for elongated bodies whose height-to-width ratio is large. It is significant to observe that the integrated SAR or total absorption in the biological body is similar for a homogenous and inhomogenous model.

10.2 Planar Tissue Models

When the radius of curvature of the body surface is large compared to the wavelength and beam width of the impinging radiation, planar tissue models may be used to estimate the absorbed energy and its distribution inside the body. As a first-order approximation, the plane wave configuration is often used for its simplicity to assess EMF interaction with planar biological tissues. This section presents a summary of specific results that have been obtained, using analytical approaches, for thick or semi-infinite layers and for multilayered planar models of biological tissue structures.

10.2.1 Thick or Semi-Infinite Layers

The reflection and transmission of a plane wave at a planar tissue interface depend on the frequency, polarization, and angle of incidence of the wave and on the dielectric constant and conductivity of the tissue. For a linearly polarized plane wave impinging normally on

a boundary separating two semi-infinite media, the reflection and transmission coefficients are given by

$$\Gamma = \frac{\eta_2 - \eta_1}{\eta_2 + \eta_1} \tag{10.3}$$

and

$$T = \frac{2\eta_2}{\eta_2 + \eta_1} \tag{10.4}$$

respectively, where η_1 and η_2 are the intrinsic impedances ($= \sqrt{(\mu/\varepsilon)}$) of media 1 and 2. If intrinsic impedances of the two media are approximately equal or if the dielectric permittivities are comparable, most of the energy is transmitted into the second medium, and the reflected field is relatively small. Conversely, if intrinsic impedances differ greatly, or if the dielectric permittivities are very different, the transmitted field is small, and the quantity of reflected energy is large.

Table 10.1 summarizes the magnitude of the reflection coefficient at the boundary separating various tissues. The fraction of normally incident power reflected by the

Power transmission coefficients at three tissue interfaces as functions of frequency.

discontinuity is given by Γ^2. Clearly, about one half of the incident power is reflected at these boundaries. Further, the reflection coefficient for tissue–tissue interfaces generally is smaller than for air–tissue interfaces. The percent reflected power for tissue–tissue interfaces ranges from a low of 5 for muscle–blood to a high of 50 for bone–biological fluid interfaces. This suggests that the closer are the dielectric properties on both sides of the interface, the smaller is the power reflection.

The fraction of power transmitted is related to the power transmission coefficient, T^2. It is readily apparent from Table 10.1 that the power transmitted at air–tissue interfaces is quite substantial at RF and microwave frequencies. Moreover, Figure 10.1 shows that the power transmission coefficient is highly frequency dependent, especially at lower frequencies.

As the transmitted wave propagates in the tissue medium, energy is extracted from the wave and absorbed by the medium. This absorption will result in a progressive reduction of the power density of the wave as it advances in the tissue. This reduction is quantified by the depth of penetration, which is the distance in which the power density decreases by a factor of e^{-2}. Table 10.2 presents the calculated depth of penetration in selected tissues using typical dielectric constants and conductivities. A graphical representation of penetration depth vs. frequency for blood, muscle, and fat is given in Figure 10.2. It is seen that the penetration depth is frequency dependent and takes on different values for different tissues. In particular, the penetration depth for fat and bone is nearly five times greater than for higher-water-content tissues.

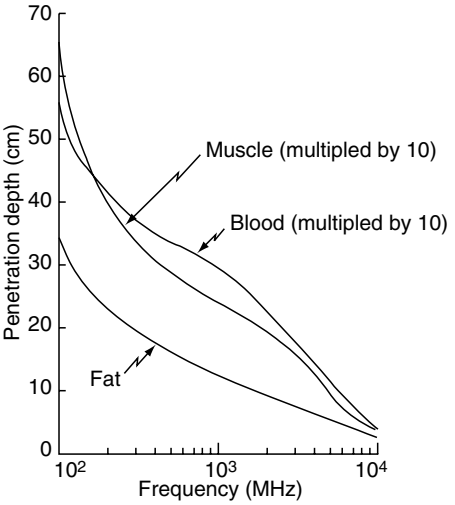

FIGURE 10.2
Depth of penetration for blood, muscle, and fat as functions of frequency.

A wave of general polarization usually is decomposed into its orthogonal linearly polarized components whose electric or magnetic field parallels the interface. These components can be treated separately and combined afterward. Figure 10.3 and Figure 10.4 illustrate the magnitude and phase of the reflection coefficients of representative tissue interfaces at a temperature of 37°C for irradiation at 2450 MHz. The figures clearly show the difference between *E* and *H* polarization. *E* polarization, also called perpendicular polarization, and *H* polarization, also referred to as parallel polarization, are defined in Chapter 1. For *E* polarization, there is only a slight variation in magnitude and phase of the reflection coefficient with incidence angle. For *H* polarization, however, there is a

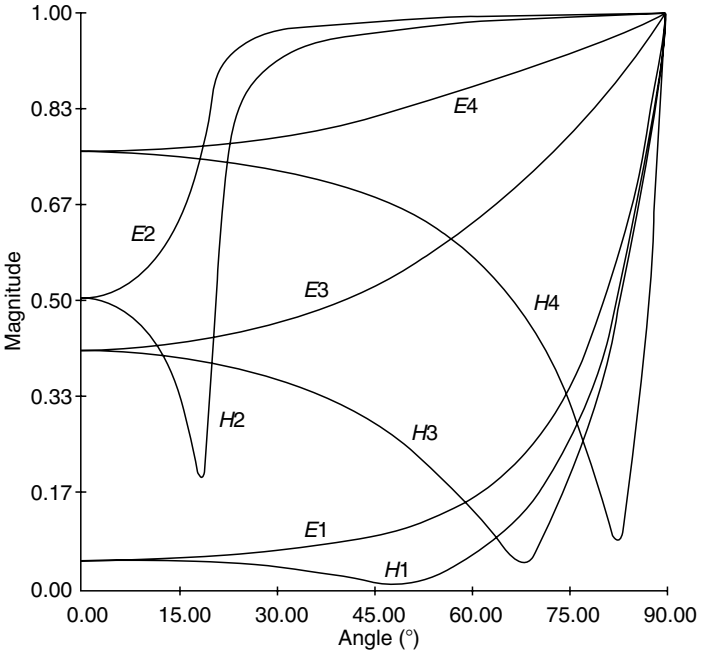

FIGURE 10.3
Magnitudes of reflection coefficients for *E*- and *H*-polarized plane waves at 2450 MHz.

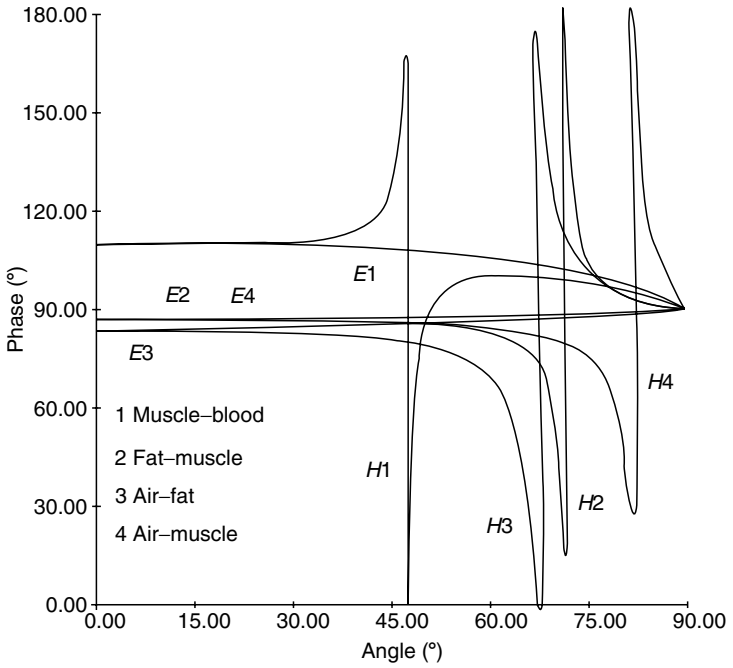

FIGURE 10.4
Phase of reflection coefficients for *E*- and *H*-polarized 2450 MHz plane waves.

pronounced dependence on incidence angle. The reflection coefficient reaches a minimum magnitude and has a phase angle of 90° at Brewster's angle. Thus, the *H* polarized wave is totally transmitted into the muscle medium at Brewster's angle.

10.2.2 Multiple Layers

When there are several layers of different tissues, the reflection and transmission characteristics become more complicated. Multiple reflections can occur between the skin and subcutaneous tissue boundaries, with a resulting modification of the reflection and transmission coefficients [4–7]. In general, the transmitted wave will combine with the reflected wave to form standing waves in each layer. This phenomenon becomes especially pronounced if the thickness of each layer is less than the penetration depth for that tissue. Plane waves impinging on the human body, considered as consisting of parallel layers of subcutaneous fat and more deeply lying muscle, have been studied in detail by Schwan and Li [5,6].

For the tissue model depicted in Figure 10.5, the electric field strength in the fat layer is given by

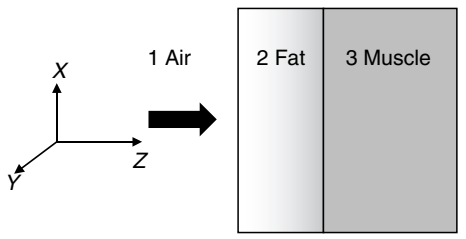

FIGURE 10.5
Plane wave impinging on a composite fat–muscle layer.

$$E_f = F_1 E_0 \left[e^{-(\alpha_2 + j\beta_2)z} + \Gamma_{32} e^{(\alpha_2 + j\beta_2)z} \right] \tag{10.5}$$

and the electric field in the underlying muscular tissue is given by

$$E_m = F_t E_0 e^{-(\alpha_3 + j\beta_3)z} \tag{10.6}$$

where α_2, β_2 and α_3, β_3 are the attenuation and propagation coefficients in fat and muscle, respectively. The layer function F_1 and the transmission function F_t are given by

$$F_1 = \frac{T_{12}}{e^{(\alpha_2 + j\beta_2)l} + \Gamma_{21}\Gamma_{32} e^{-(\alpha_2 + j\beta_2)l}} \tag{10.7}$$

$$F_t = \frac{T_{12}T_{23}}{e^{(\alpha_2 + j\beta_2)l} + \Gamma_{21}\Gamma_{32} e^{-(\alpha_2 + j\beta_2)l}} \tag{10.8}$$

where T_{12} and T_{23} are the transmission coefficients at the air–fat and fat–muscle boundaries, respectively. Γ_{21} and Γ_{32} denote the reflection coefficients at these boundaries, respectively; l is the thickness of the fat layer. The power deposition in a given layer can be obtained from Equation 10.1.

Figure 10.6 shows the results of SAR distribution obtained using the dielectric data given in part 1. The values are normalized to the SAR in muscle at the fat–muscle boundary. Note that the absorbed energy is much lower in fat than in muscle. The standing-wave maximum becomes bigger in fat, and the penetration into muscle becomes less as the frequency increases.

The electromagnetic energy absorbed in models composed of planar layers of skin, fat, and muscle can be analyzed in a similar manner [5–8], except that the distribution of

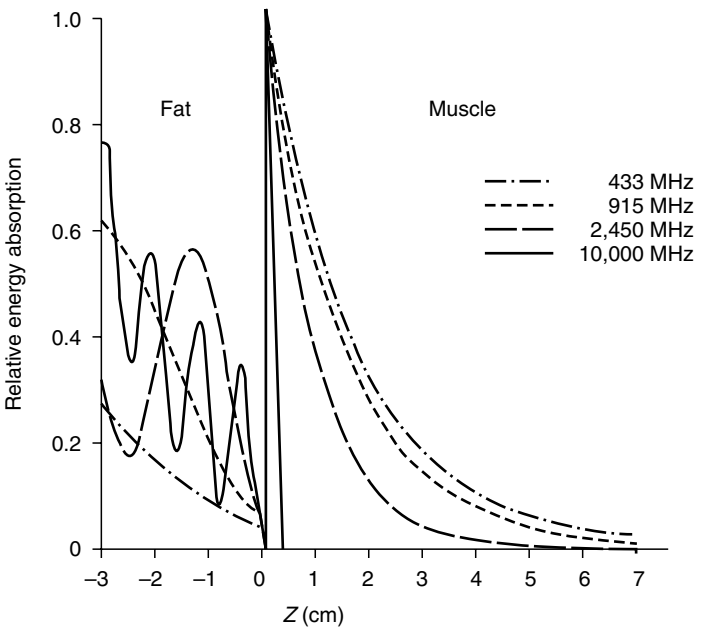

FIGURE 10.6
SAR (absorbed power density) in plane fat–muscle layers.

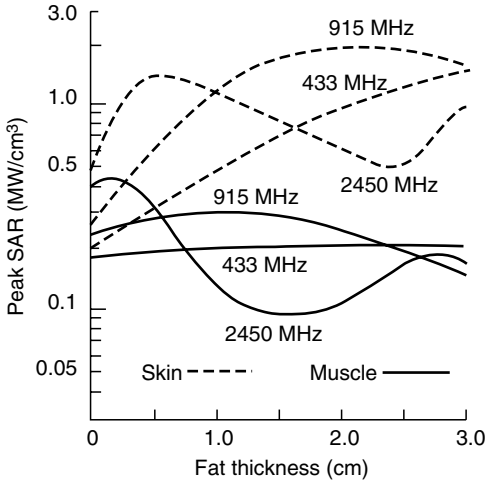

FIGURE 10.7
Peak SAR (absorbed power density) in models composed of fat–skin–muscle layers.

absorbed energy becomes more complex. Figure 10.7 shows that in addition to frequency dependence, the peak SAR exhibits considerable fluctuation with thickness of the subcutaneous fatty layer. The incident power density is, in this case, $10\,W/m^2$, and the skin layer is 0.2 cm thick. Note that the peak SAR is always higher in the skin layer for planar models at microwave frequencies. The depth of penetration for 10 GHz radiation in skin is less than 0.5 mm—the transmitted energy is almost completely absorbed in the skin, and the SAR is rather unaffected by changing fatty layer thickness. The fact that SAR is highest in the skin is significant, since skin is populated with thermosensitive free nerve endings, which may be excited along with cutaneous pain receptors when the absorbed energy exceeds the normal range that can be handled by thermoregulation.

Figure 10.8 shows the distribution of induced electric field strength in a layer of muscle beneath layers of fat, muscle, and bone for two frequencies [5–8]. It is seen that in addition

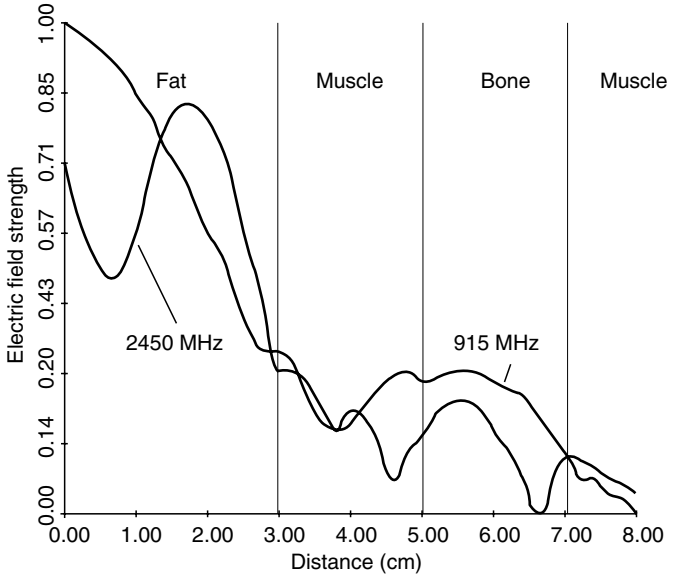

FIGURE 10.8
Distribution of electric field strength in planar layer of fat–muscle–bone–muscle tissue model.

to frequency dependence, the electric fields exhibit considerable fluctuation within each tissue layer. While the standing-wave oscillations are larger at 2450 than at 915 MHz, microwave energy at both frequencies penetrates to deeper tissues. This result, together with Figure 10.6 and Figure 10.7, implies that at frequencies between 300 and 3000 MHz, sufficient energy may be transmitted and reflected to allow examination of organs within the body. Furthermore, at these frequencies, electromagnetic energy can penetrate into more deeply situated tissues, making it especially desirable for therapeutic applications. They also call for special attention for safety considerations since electromagnetic energy in this frequency range can produce higher SAR at greater depth compared to superficial tissues.

10.3 Bodies of Revolution

Although depth of penetration and reflection and transmission characteristics in planar tissue provide considerable physical insight into the coupling and distribution of electromagnetic energy, biological structures generally are more complex in form and exhibit substantial curvature that can modify electromagnetic energy transmission and reflection. For bodies with complex shapes, the propagation characteristics depend critically on polarization and on orientation of the incident wave with respect to the body, as well as on the ratio of body size to wavelength. These complications place severe limitations on calculations of reflected and transmitted energy for bodies of arbitrary shape and complex permittivity. This section presents a summary of results for homogenous and multilayered models based on bodies of revolution that approximate certain mammalian tissue structures.

10.3.1 Spherical Models

Some representative calculations of the SAR are shown in Figure 10.9 for four different-sized models at 918 and 2450 MHz [7,8]. The 6-cm diameter sphere approximates a cat or rhesus monkey brain, and the 10-cm diameter sphere approximates the head of a child, while the 14- and 18-cm diameter spheres are more typical of human adult heads. The figures illustrate the SAR distributions along the three perpendicular axes whose origin coincides with the center of the sphere. An incident plane wave power density of $10\,\mathrm{W/m^2}$ is assumed. The plane wave is propagating in the positive z direction and is polarized along the x axis. It is seen that for 918 MHz, maximum absorption occurs near the center or inside of all the brain spheres. When the frequency is increased to 2450 MHz, the location of peak SAR for the cat-size brain sphere remains near the center, whereas that for a human-size brain sphere is moved to an anterior location.

In general, standing-wave patterns with many oscillations are observed. Note that while peak and average SARs in the cat brain are larger by a factor of 2 than in the human brain at 918 MHz, at 2450 MHz the peak absorption is four times and the average absorption is three times greater in the cat brain than in the human brain. Other studies [9–12] indicate that the peak absorption may be as much as five times greater than the average, and the enhanced absorptions near the center of these brain models may be two to three orders of magnitude greater than that expected from the planar tissue models. The increased absorptions are due to a combination of high dielectric constant and curvature of the model, which produces a strong focusing of energy toward the interior of the sphere that more than compensates for the transmission losses through the tissue.

The peak absorption per unit volume, average absorption per unit volume, and average absorption per unit surface area as functions of frequency and radius of the spherical brain model are illustrated in Figure 10.10. It can be seen that the absorbed energy varies widely with sphere size and frequency. In general, the absorption increases rapidly with increasing radius and is then followed by some resonant behavior. The peaks of these resonant oscillations are related to the maxima, or hot spots, in the distribution of absorbed energy inside the head model, as shown in Figure 10.9. Therefore, for $(2\pi a/\lambda_0) < 0.4$, where a is the sphere radius and λ_0 is the wavelength in vacuum, hot spots do not occur inside the sphere. However, for some combinations of irradiation frequency and radius, hot spots will occur, for example, in spheres with radii between 2 and 8 cm at 918 MHz and between 0.9 and 5 cm at 2450 MHz. For spheres whose radii exceed the size ranges mentioned above, the maximum absorption appears at the anterior portion (exposed surface) of the sphere, and the penetration depth at the surface becomes a dominating factor for exposures at frequencies in this range. The planar model discussed previously may be applied to obtain a theoretical estimation of the absorbed energy in this case.

The frequency dependence of energy absorption is illustrated in the upper graphs in Figure 10.10 for the head of a small animal, such as a cat or rhesus monkey, and a sphere the

size of a human head. Besides the occurrence of resonant peaks, with increasing frequency, energy is absorbed in a decreasing volume as a result of shortened penetration depth.

The effects of skin, fat, bone, dura, and cerebrospinal fluid on the absorption of RF radiation by the brain have been investigated in several laboratories [9,13–15], using more complex spherical structures where the spherical core of brain is surrounded by five concentric shells of tissues. It is interesting to note that if brain sizes remain unchanged, but the overall sphere diameter is increased to account for the outer tissue layers, absorption in brain tissues may be increased by 25% for human- and cat-size heads at 918 MHz or decreased by 70% or more in the case of 2450 MHz. Moreover, surface absorption is greatly increased in the case of layered models, while fat and bone always absorb the least amount of energy.

If the outer diameter of the sphere remains the same, while the tissue layers are allowed to be either layered or homogenous, the peak and average SARs show very little change except when the radius of the spherical head is between 0.1 and 1.0 times the wavelength in air. The peak and average SARs for layered models may be several times greater than for homogenous models. Enhancement is apparently the result of resonant coupling of energy into the sphere by the outer tissue layers.

A study also has been made of the interaction of circularly polarized plane electromagnetic waves with six-layered spherical models of the mammalian head [15]. The approach is a classic one; Mie equations were modified to account for the two polarizations that are orthogonal in space. For example, calculations at 918 and 2450 MHz for a 7-cm diameter sphere representing a cat or monkey head and a 20-cm diameter sphere typical of a human adult head indicated that the maximum absorption for 918 MHz occurs near the center of a cat-size head, whereas the maximum absorption for a human-size head is at the surface, as in the case of linearly polarized plane waves. However, at 2450 MHz the location of maximum absorption for both the smaller and the larger spheres shifts to the leading surface. The distribution of absorbed energy for circularly polarized waves is more uniform compared with the linearly polarized case. In fact, the absorbed energy distribution in the planes transverse to the direction of propagation is rotationally symmetric, that is, it is independent of angular variation. Note also that the maximum energy absorbed in the spherical head models varies only slightly between these two frequencies. However, a greater quantity of energy is deposited in the inner sphere (representing the brain of a human head) for 918- than for 2450-MHz radiation.

Spherical models of muscle [16,17] have been used as a first-order approximation for the extrapolation to human beings of results obtained from laboratory animals and as an index of whole-body absorption of electromagnetic energy as a function of frequency. The spherical model is attractive since exact solutions for absorbed energy can be obtained for all frequencies and body sizes. While in this case the peak absorption is of very limited utility, the average absorption per unit surface area is related to the time and power required to overload the thermoregulatory capacity of an exposed subject. The absorptions for homogenous muscle spheres, whose volumes correspond to small animals, such as a rat, and standard man, computed as functions of frequency, showed that the average absorption for the rat model is at least ten times higher than for a muscle sphere representing a human body at frequencies greater than 500 MHz. The absorption increases rapidly with frequency until the free space wavelength of the impinging radiation approaches the diameter of the sphere. A number of resonant oscillations appear that tend to increase the amount and nonuniformity of absorbed energy. Above this range the absorption falls off slowly, indicating that details of body surface curvature are of little significance.

We have, thus far, dealt mainly with situations where the diameter of the sphere is comparable to or larger than the wavelength in air. It is interesting to note that when the sphere is small compared with the wavelength, the absorbed energy distribution varies

almost as the square of the radius or distance from the axis parallel to the direction of the magnetic field vector. If the sphere is extremely small compared with the wavelength, the absorbed energy distribution becomes nearly uniform in the transverse directions but decreases continuously with distance from the exposed surface. This behavior can be explained by a quasi-static field theory [16]. The electric component of the incident field couples to the object in the same fashion as an electrostatic field. This gives rise to a constant induced electric field inside the sphere that has the same direction but is reduced by $3/\varepsilon$ from the applied electric field for biological materials and is independent of sphere size. Similarly, the magnetically induced electric field inside the body is identical to the quasi-static solution whose magnitude is given by $E = \pi f \mu r H$, where f is the frequency, μ is the permeability, r is the radius, and H is the magnetic field component. Thus, the magnetic component of the incident field produces an internal electric field that varies directly with distance from the axis and in proportion to the frequency. This magnetically induced electric field encircles the magnetic axis and gives rise to an eddy current whose magnitude increases with distance from the y axis. It indicates that while the H-induced energy absorption in a mouse or larger animal is much greater than the E-induced component, electrically and magnetically induced absorption may be equally significant in smaller animals at lower frequencies (below 30 to 40 MHz). Moreover, for a small insect or pupae the electric field will be the predominant factor.

The variation of average and maximum energy absorption with frequency for a human-size sphere is illustrated in Figure 10.11. In the frequency range from 1 to 20 MHz, the maximum absorption rate is only 10^{-6} to 10^{-3} (W/kg)/(W/m^2) of incident power. Inspection of the maximum absorption rate induced by a plane wave, a quasi-static electric field, and a quasi-static magnetic field shows that absorption at frequencies below 20 MHz is primarily due to the magnetically induced eddy current and is characterized by a square-of-frequency dependence. The approximate frequency dependence of average or total energy absorption throughout the frequency range from 1 MHz to 10 GHz is indicated by the dashed line. For frequencies below 20 MHz the average absorption varies as the square of the frequency. In the frequency range of 20 to 200 MHz, the average absorption increases directly in proportion to frequency and attains a maximum of about 2×10^{-3} (W/kg)/(W/m^2) of incident power at 200 MHz. The average absorption rate remains fairly constant with increasing frequency. (Its slow variation is inversely proportional to frequency for higher frequencies.) There is thus little doubt that electromagnetic energy absorption varies both with frequency and with body size, and in a predictable manner.

10.3.2 Prolate Spheroidal Models

Since the bodies of humans and experimental animals are seldom spherical in shape, a better geometric model is needed to analytically and numerically describe the induced fields and absorbed energy inside experimental subjects. A prolate spheroid emulates more closely the shape of mammalian bodies, but most analyses have been restricted to homogenous models for humans and experimental animals [18–22]. As in the case of spherical models, for frequencies below resonance, long-wavelength formulations [19,20] and quasi-static approximations [22] have been used to obtain absorption information. Geometric optics approximations also have been developed for computation of absorption characteristics of prolate spheroidal models of humans at frequencies whose wavelengths are short compared with body size [21].

Three orientations of the impinging plane wave with respect to the body must be distinguished: E-polarization, in which the electric field is parallel to the major axis of

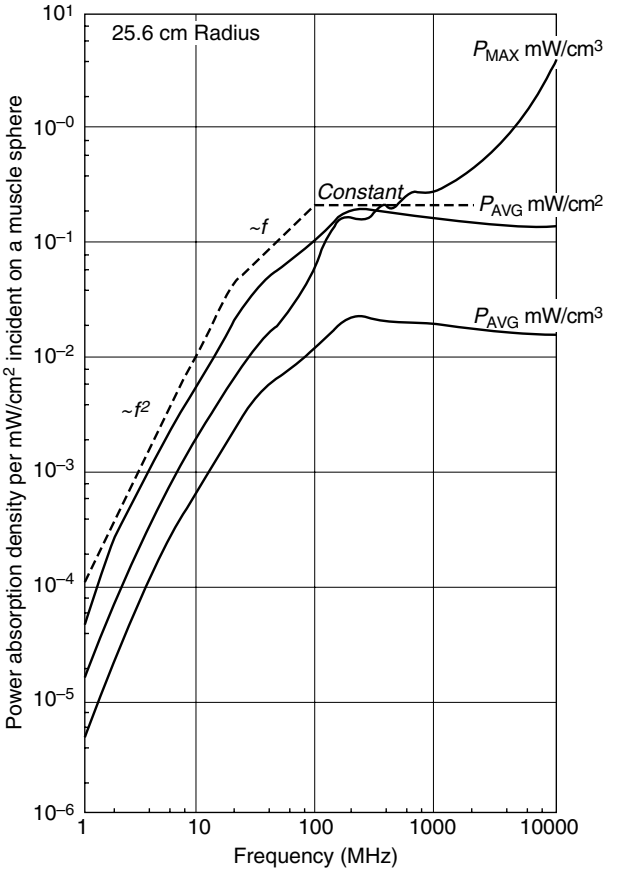

FIGURE 10.11
Frequency dependence of absorption in a spherical model of the human body.

the spheroid; *H*-polarization, in which the magnetic field vector is parallel to the major axis; and *K*-polarization, in which both electric and magnetic field vectors are perpendicular to the major axis of the spheroid. In general, *E*-polarization produces the highest energy absorption for frequencies up to and slightly beyond the resonance region.

For a plane wave with long wavelength, that is, $\lambda > a$, where a is the semimajor axis of the prolate spheroid, the induced fields within the spheroid are uniform and independent of size when the external field is uniform. For $\varepsilon_r > 1$, the field inside the spheroid is weaker than the applied field. Moreover, the whole-body energy absorption depends not only on the strength of impressed fields but also on the orientation of the field with respect to the major axis of the body. As in the case of spherical models, the absorption is produced by an electrically induced current in the direction of the applied *E*-field vector, combined with a circulating eddy current induced by the incident magnetic field [16]. One would therefore expect the electrically induced absorption to be uniform, whereas the absorption due to the circulating eddy current would be zero at the center of the body and increase as the square of the distance from the center.

Note that for a given incident field orientation, the average SAR for humans may be either higher or lower than for rats, depending on the frequency. For example, at 70 MHz, the average SAR is the highest for humans, having a value of 0.25 W/kg for an incident power density of 10 W/m^2; the average SAR for a rat is only 0.0125 W/kg. In contrast, the average SAR of 0.8 W/kg at 700 MHz is the highest for rats; the corresponding value for humans is less than 1/25. It is thus extremely important to take into account the body size

and operating frequency to draw any relationship between the biological effects that arise in the laboratory and the corresponding effects that might occur in humans at a given incident power density [1,2].

The frequency for maximal absorption (resonance frequency) depends on the subject and its orientation with respect to the incident field. In general, the shorter the subject, the higher the resonance frequency and vice versa. Further, the frequency dependence of whole-body or average absorption may be partitioned into three regions. This may be illustrated using the orientation that is most efficient in energy coupling, *E*-polarization. For frequencies well below resonance such that the ratio of the longest body dimension (L) to free space wavelength (λ) is less than 0.2, the average SAR is characterized by an f^2 dependence. The average absorption goes through a resonance in the region where $0.2 < L/\lambda < 1.0$. In this case, the average SAR rapidly increases to a maximum near $L/\lambda = 0.4$ and then falls off as $1/f$. At frequencies for which $L/\lambda > 1.0$, the whole-body absorption decreases slightly but approaches asymptotically the geometrical optics limit of about one half of the incident power (1 − power reflection coefficient).

It should be noted that the resonant absorption length of 0.4λ is in good agreement with results from antenna analysis. In addition, whole-body absorptions for *H*- and *K*-polarizations are totally different. The resonances are not nearly as well-defined as for *E*-polarization. In fact, the whole-body absorption curve for *H*-polarization gradually reaches a plateau and stays at that plateau for higher frequencies.

At 10 MHz, the size of the spheroidal model approximating an average human body—height equals 1.75 m with a major-to-minor axis ratio of 6.34 and a 70-kg mass—is small compared with the wavelength. The distribution of absorbed energy in the spheroidal model is qualitatively similar to that for spherical models. But quantitatively, the difference could be as much as one order of magnitude. As expected, the absorbed energy is highest for *E*-polarization. There is a strong coupling of the applied electric field into the interior of the prolate spheroid, and a relatively weak eddy current contribution due to a smaller cross section for intercepting the magnetic flux. The current distribution along the direction of incident field indicates that the electrically and magnetically induced field components are nearly equal. The electric polarization field and the circulating eddy current add at the front side and subtract on the back side of the spheroid to render an absorption pattern that peaks at the front surface and is reduced to almost zero deeper inside the spheroid.

For *H*-polarization, the electrically induced current flows along the x axial direction of incident **E** field, and the eddy current field encircles the z axial direction of incident **H** field. The relatively low power on the z axis comes solely from the incident electric field. The combination of *E*- and *H*-induced components generates a displaced parabolic energy absorption pattern along both the x and the y axes. Clearly, the magnetically induced eddy current predominates in this case, and the absorption is highest along the transverse circumference at the middle of the prolate spheroid. For *K*-polarization, both the electric and the magnetic components of the incident field are along the minor axes of the spheroid: the electrically induced current flows along one axis, and the incident magnetic field induces an eddy current electric field that encircles another axis. The absorption is lowest at the center. Whereas in both *E*- and *H*-polarization cases, the peak absorption occurs at the front surface of the spheroid irradiated by the incident field, this is not the case for *K*-polarization. Maximum absorption appears at the surface of the narrow cross section, and the absorbed energy varies parabolically. This is the result of the large quantity of magnetic flux intercepted by the broad cross section (and the resulting concentration of eddy current). It should be noted that the results match very well with experimental measurements [23]. Moreover, the peak absorptions may be two orders of magnitude higher than those for dielectric spheres of equal mass.

10.4 Anatomically Based Models

We have summarized above some of the computational approaches to quantify the absorbed energy in simple models of biological objects. It should be recognized that while spheres and spheroids are good models of some animal bodies and certain body parts, they may not always be adequate for humans and experimental animals under a variety of exposure situations. More realistic models, such as models of human bodies formed from small-sized, computational-cell volumes have been developed to account for the irregular shapes [24–28]. These models, based on numerical techniques have been a great asset in efforts to accurately predict energy absorption and its distribution in biological objects exposed to EMFs and RF radiation. In what follows we shall summarize a number of computer techniques that have been applied with some success in solving electromagnetic energy absorption and SAR distribution problems. We shall also describe some results obtained using these methods.

10.4.1 Brief Survey of Numerical Methods

The numerical methods used to predict induced fields in biological bodies of realistic shape and composition include the quasi-static impedance method, the method of moments (MoM), the finite element method (FEM), and the finite difference time domain (FDTD) method. Note that the quasi-static impedance method is restricted to lower frequencies (<30 to 40 MHz for the human body), but the MoM, the FEM, and the FDTD method may be used for any frequency of interest. In addition, both the finite element and the FDTD methods involve solving Maxwell's equations in the differential form for the computation of induced fields.

10.4.1.1 Quasi-Static Impedance Method

For low-frequency situations, where the dimensions of the biological body are small compared to the wavelength, the impedance method has been found to be highly efficient as a numerical procedure for calculating internal current densities and induced electric fields [29–33]. In this method, the biological body or the exposed part thereof is represented by a three-dimensional (3-D) network of impedances whose individual values are obtained from the complex conductivities $\sigma + j\omega\varepsilon$ for the various locations of the body. The impedances for various directions for the 3-D network can be written as

$$Z_m^{i,j,k} = \frac{\delta_m}{\delta_n \delta_p (\sigma_m^{i,j,k} + j\omega\varepsilon_m^{i,j,k})} \tag{10.9}$$

where i, j, k indicate the cell index; m is the direction in x, y, or z for which the impedance is calculated; and σ_m and $j\omega\varepsilon_m$ are the conductivities and the dielectric permittivities for the cell (i,j,k). δ_m is the thickness of the cell in the mth direction, and δ_n and δ_p are the widths of the cell in directions at right angles to the mth direction.

In the impedance method formulation, it can be seen that the cells need not be identical so that fairly thin features of the body can be modeled as well as the interfaces between the various tissues and organs. Also, the conductivity for a given cell can be directionally dependent. This feature will be useful in allowing for the highly anisotropic conductivities of the tissues that have been reported for low-frequencies including the power-line frequencies [34,35].

Employing anatomically based models of the human body, the impedance method has been used for the following applications:

1. Calculation of SAR distributions for operator exposure to spatially variable fields of induction heaters [31]
2. SAR distributions for linearly or circularly polarized RF magnetic fields representative of magnetic resonance imagers [32]
3. SAR distributions due to capacitive-type electrodes used for hyperthermia [33]
4. SAR distributions for interstitial RF needle applicators for hyperthermia [36]

Some calculations using the impedance method are listed below:

1. Internal electric fields and current densities induced in the human body by exposure to magnetic fields of high-voltage power transmission lines [37]
2. Electric fields and current densities induced in the human head by magnetic fields of a hair dryer [38]
3. Current densities induced in the arm and the body by magnetic fields of an electric hand drill [39]
4. Currents induced in the anatomically based model of the human body by the electric and magnetic fields of electric blankets [40].

In the section that follows, the use of the impedance method is described for calculating currents in models of the human body exposed to electric and magnetic fields of both the conventional (pre-1990) electric blanket and the new low-magnetic-field electric blanket.

10.4.1.2 Volume Integral Equation MoM

The MoM [41] is used in conjunction with either the volume integral equation method or the surface integral equation method for finding solutions to the unknown fields inside the body. The approaches differ, however, in specifics, in that the surface integral equation MoM (SMoM) finds the unknown currents on the body surface and calculates the interior fields from the surface currents, the reciprocity theorem, and a ''measurement matrix.'' In contrast, the volume integral equation MoM (VMoM) requires determination of unknown fields throughout the volume of the body using the volume equivalence principle and the MoM.

The numerical technique that has been adopted for most of the early field intensity computations is the VMoM, employing the volume equivalence principle [26,27,42,43]. The MoM is used to transform the integral equation into a matrix equation by subdividing the body into N simply shaped cells. This is accomplished with the aid of an appropriate set of expansion functions, chosen to satisfy the boundary conditions, and a set of weighting (testing) functions to reduce the matrix fill-in time. The total electric field in each of the N cells is given by matrix inversion. A more detailed description of the volume integral equation method is included in the next section.

However, it should be noted that a fundamental limitation of this method is the use of full or nearly full matrices and, therefore, the requirement of extensive computer storage and long running time. Even with the availability of larger and faster computers, this difficulty is not completely resolved. The need for excessively large numbers of mathematical cells to render a more accurate representation of the body will give rise to an equally large and full matrix. The inversion of large, full matrices often leads to numerical instabilities in the solution. Nevertheless, the method does allow the use of inhomogenous models

with up to 1000 cells. In fact, this method has been employed, successfully, to calculate whole-body averaged absorption and to obtain regional distribution of absorbed RF energy using inhomogenous block models composed of rectangular cells [29–28,44]. This method also has been used to study the interaction of the near-zone field of an antenna with biological bodies [45,46].

10.4.1.3 SMoM

Another approach for predicting the distribution of absorbed electromagnetic energy is the SMoM [47–50]. This method makes use of two coupled integral equations, that is, the electric field and magnetic field integral equations for the tangential components of the field on the surface separating the biological body from air. The unknown surface currents are found by Fourier decomposition and the moment method. The fields inside the biological body are calculated using the previously computed surface currents, the reciprocity theorem, and the concept of measurement matrix [48,51–53].

The method begins with the matrix representation of the coupled integral equations. If the body is assumed to be rotationally symmetric, the incident wave and the induced current could then be expanded in a Fourier series expansion in the angle of rotation. This reduces the problem to that of solving a system of orthogonal modes. The method further expands the surface components in terms of triangular expansion or basis functions and allows the testing functions to be the complex conjugate of the basis functions taking advantage of the orthogonality property. Thus, the major advantage of introducing the Fourier series is to enable each mode to be treated completely independently of all other modes. This results in a much smaller-size, manageable matrix equation to be evaluated for the unknown expansion coefficients that determine the surface currents. It should be noted that for biological bodies, triangular expansion and testing functions are preferred over flat pulse expansion functions [47,48]. In fact, an expansion function with a continuous first derivation may constitute an even better choice for the expansion basis function. In any event, once the surface currents are obtained, the fields everywhere, or SAR at each point inside the body, can be calculated using the reciprocity theorem [52,53]. The total absorption can be found by integrating the surface Poynting vector.

The validity of SMoM has been substantiated by using a dielectric sphere [47]. Calculations for a human torso modeled by a homogenous muscle body of revolution with a height of 1.78 m at 30, 80, and 300 MHz showed enhanced absorption in the neck region for all three frequencies and both vertical and horizontal polarizations [48]. Note that the vertical direction is aligned with the long dimension of the torso and serves as the axis of symmetry. The strongest absorption in the torso model was found to occur with vertical polarization and near the first resonance frequency of the torso (80 MHz). In general, the surface integral equation method is applicable to any arbitrarily shaped homogenous body of revolution. The method can be used not only with incident plane waves but also with a wide variety of other field exposure conditions, including direct contact situations and near-zone sources.

Since both the surface and volume integral equation methods for field intensity prediction rely on the MoM for implementation, it is instructive to compare the relative advantages of these two techniques. For simplicity, consider a homogenous cube with N samples on each side: the computer storage requirements are N^2 and N^3 for the surface and volume integral methods, respectively [48]. For sufficient sampling to ensure accurate description of field variations, N is usually a large number. Thus, the surface integral equation method requires significantly fewer unknowns for homogenous models. Moreover, in cases where permittivity and conductivity values are large, such as in biological bodies, the wavelength becomes contracted inside the body, and a much larger number of cells than that indicated above may actually be needed. If the model is inhomogenous,

then the volume integral equation would prove to be more suitable. It is possible, however, to generalize the surface integral equation technique to account for inhomogeneities by employing the invariant imbedding procedure [54].

10.4.1.4 FEM

The FEM has been a preferred numerical algorithm in many fields of application. However, its use and popularity in predicting field intensities in biological systems have been modest until recent progress in mesh generation, boundary conditioning, and large matrix solvers. The FEM method is a near-neighbor, volume method for solving Maxwell's differential equations and is associated with a sparse system of equations [55,56]. Aside from the low memory requirement (on the order of N), an inherent attraction of FEM is its adaptability in modeling inhomogeneities and complex geometries. The feature of conforming and the variable-sized cell elements of the computational volume are extremely important in bioelectromagnetics.

The basic approach of the FEM method for predicting EMF distributions inside biological bodies starts by subdividing the physical space and biological body of interest into meshes of small volumes or cells of tetrahedral elements. This step is very important since the manner in which the volume is subdivided will dictate the computational resources required and the speed of the computation and accuracy of the results. Each cell element and node location will have to be systematically numbered and described. Once the volume has been subdivided, labeled, and the appropriate property values ascribed, the unknown field within each element is then approximated using linear extrapolation. A major step in FEM is the formulation of the system of linear equations using either the Ritz or the Galerkin algorithm with proper boundary conditions. There are two approaches to solve the system of linear algebraic equations: the direct method of Gaussian elimination or the iterative method that starts with an initial guess. In practice, either method can produce an approximate solution to the unknown field intensity with a prescribed accuracy.

It should be noted that a large region exterior to the biological body is often encountered in bioelectromagnetic situations, where the biological body, or portion of it, is part of a region into which electromagnetic energy is radiated and scattered. The region of space exterior to the biological body and applicator must be truncated with an artificial boundary to limit the volume elements and the number of unknowns. Consequently, an appropriate boundary condition needs to be established at this artificial boundary for a unique finite element determination of the induced fields inside the body. The most common boundary conditions selected for this purpose are the absorbing boundary conditions that minimize the nonphysical reflections from the artificial boundaries by making boundaries transparent to the scattered field.

Fairly large-scale calculations, on the order of 200,000 elements, have been conducted effectively in the workstation-computing environment. Specifically, detailed power deposition patterns have been simulated in full and partial models of the human body undergoing electromagnetic hyperthermia treatment for cancer [57]. In this case, the cell elements were generated from computerized tomographic data obtained on human patients.

10.4.1.5 FDTD Method

The FDTD approach is an attempt to solve Maxwell's curl equations by directly modeling propagation of waves into a volume of space containing the biological body. By repeatedly implementing a finite difference representation of the curl equations at each cell of

the corresponding space lattice, the incident wave is tracked as it first propagates to the body and then interacts with it through surface current excitation, transmission, and diffraction. This wave tracking process is completed when the steady-state behavior is observed at each lattice cell. Considerable simplification is achieved by analyzing the interaction of the wavefront with a part of the body surface at a time, rather than attempting a simultaneous solution of the entire problem.

The FDTD method has become one of the most successful methods for SAR calculations. The method was first proposed by Yee [58] and later developed by Taflove [59–61], Holland [62], and Kunz and Lee [63]. Several books [64–66] are devoted to the FDTD method and some of its applications. For bioelectromagnetic applications the FDTD method has been found to be extremely versatile and has been used for whole-body or partial-body exposures due to spatially uniform or nonuniform fields (far or near fields), sinusoidally varying EMFs, and transient fields such as ultra-wide-band (UWB) and electromagnetic pulses (EMPs) [67–71]. Accordingly, some details of FDTD are included in this section.

10.4.1.5.1 The Traditional FDTD Method

In this method, the time-dependent Maxwell's curl equations

$$\nabla \times \mathbf{E} = -\mu \frac{\partial \mathbf{H}}{\partial t} \tag{10.10}$$

and

$$\nabla \times \mathbf{H} = \sigma \mathbf{E} + \varepsilon \frac{\partial \mathbf{E}}{\partial t} \tag{10.11}$$

are implemented for a lattice of subvolumes or Yee ''cells'' that may be cubical or parallelepiped with different dimensions, δ_x, δ_y, and δ_z in the x-, y-, or z-directions, respectively. The components of **E** and **H** are positioned about each of the cells as shown in Figure 10.12 and calculated alternately with half-time steps where the time

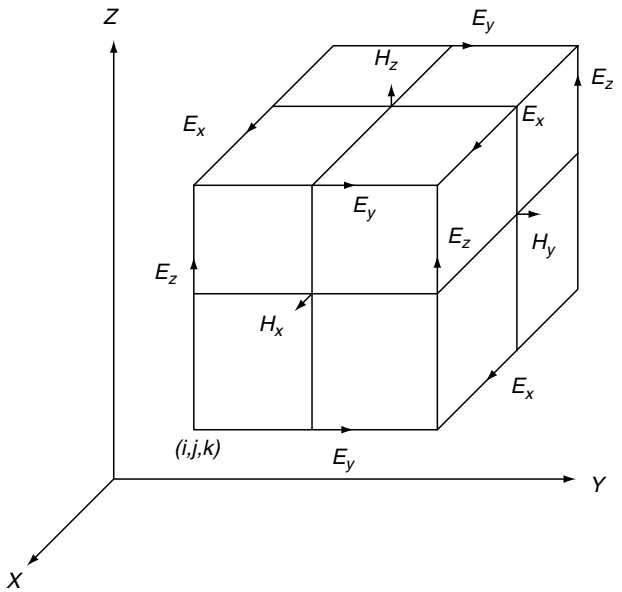

FIGURE 10.12
Unit cell of Yee lattice indicating positions for various field components.

step $\delta t = \delta/2c$. Here δ is the smallest of the dimensions used for any of the cells, and c is the maximum phase velocity of the fields in the modeled space. Since some of the modeled volume is air, c corresponds to the velocity of EM waves in air.

In the FDTD method, it is necessary to represent not only the scatterer or absorber, such as the human body or a part thereof, but also the EM sources, including their shapes, excitations, etc., if these sources are in the near-field region [70,71]. The far-field sources, on the other hand, are described by means of incident plane wave fields prescribed for a ''source'' plane [68,69], typically six to ten cells away from the exposed body. The source–body interaction volume is subdivided into Yee cells of the type shown in Figure 10.12. The interaction space consisting of several hundred thousand to a few million cells is truncated by means of absorbing boundaries. The prescribed incident fields are tracked in time for all cells of the interaction space. The solution is considered completed when either the fields have died off or, for sinusoidal excitation, when a sinusoidal steady-state behavior for **E** and **H** is observed for the interaction space.

The body of interest is mapped into the lattice space by first choosing the lattice increment and then assigning values of permittivity and conductivity to each cell. The boundary conditions at media interfaces are naturally generated by the curl equations. Thus, once a computer program is developed, the basic routines need not be changed for different model geometries. In fact, inhomogeneities and fine structural details could be modeled with a maximum resolution of one unit cell.

Time stepping for the FDTD method is accomplished by an explicit finite difference procedure [58,64]. For a cubic-cell lattice space, this procedure involves positioning the electric and magnetic field components about a unit cell of the lattice and then evaluating the components at alternate half-time steps. In this manner, centered difference expression can be used for both the space and the time increments without solving simultaneous equations to compute the fields at the latest time step.

The explicit formulation of the FDTD method is particularly suited for execution with minimum computer storage and run time using current array-processing computers. The required computer storage and run time increase only linearly with N, the number of cells. In fact, it has been shown that the FDTD method is capable of solving for more than 1 million unknown field components within a few minutes on an array-processing computer. Field intensities have been predicted to within 2.5% accuracy relative to known analytical and experimental bench marks. Recently, this FDTD technique has been improved to allow solutions for field penetration and absorption in large, complex, inhomogenous, and irregularly shaped biological bodies in three dimensions, with millimeter range spatial resolution. With the exception of a few early attempts with lossy biological objects [59,67], a majority of early efforts have been directed toward application of the FDTD method to electromagnetic interaction in time-varying inhomogenous media [60], and with metallic bodies of revolution [61]. However, during the last decade, the FDTD method has become the most extensively used numerical procedure for bioelectromagnetic computations.

10.4.1.5.2 Frequency-Dependent FDTD Formulation

For short pulses where wider bandwidths are generally involved, a frequency-dependent FDTD or $(FD)^2TD$ method is needed. Two general approaches have been used for the $(FD)^2TD$ method. One approach is to convert the complex permittivity from the frequency domain to the time domain and convolve this with the time domain electric fields to obtain time domain fields for the dispersive material. This discrete time domain method may be updated recursively for some rational forms of complex permittivity, which removes the need to store the time history of the fields and makes the method feasible. This method has

been applied to materials such as water, for which the permittivity may be described by a first-order Debye relaxation equation [72–74] or more complex materials with dielectric properties given by a second-order Lorentz equation with multiple poles [75].

A second approach is to add a differential equation relating the electric flux density **D** to the electric field **E** and solve this new equation simultaneously with the standard FDTD equations. This method has been applied to 1-D and 2-D examples with materials described by a first-order Debye equation or second-order single-pole Lorentz equation [76], and to a 3-D sphere and homogenous two-thirds muscle-equivalent man model with properties described by a second-order Debye equation [77,78]. In the following we describe this differential equation approach, which has now been used for induced current and SAR calculations for a heterogenous model of the human body [79].

The time-dependent Maxwell's curl equations used for the FDTD method have already been given as Equation 10.10 and Equation 10.11. The curl ***H*** can also be written as follows:

$$\nabla \times \mathbf{H} = \frac{\partial \mathbf{D}}{\partial t} \tag{10.12}$$

where the flux density vector **D** is related to the electric field through the complex permittivity $\varepsilon^*(\omega)$ of the local tissue by the following equation:

$$\mathbf{D} = \varepsilon^*(\omega)\mathbf{E} \tag{10.13}$$

Since Equation 10.10 and Equation 10.12 are to be solved iteratively in the time domain, Equation 10.13 must also be expressed in the time domain. This may be done by choosing a rational function for $\varepsilon^*(\omega)$, such as the Debye equation with two relaxation constants (see Chapter 1):

$$\varepsilon^*(\omega) = \varepsilon_0 \left[\varepsilon_\infty + \frac{\varepsilon_{s1} - \varepsilon_\infty}{1 + j\omega\tau_1} + \frac{\varepsilon_{s2} - \varepsilon_\infty}{1 + j\omega\tau_2} \right] \tag{10.14}$$

Rearranging Equation 10.14 and substituting in Equation 10.13 gives

$$\mathbf{D}(\omega) = \varepsilon^*(\omega)\mathbf{E}(\omega) = \varepsilon_0 \frac{\varepsilon_s + j\omega(\varepsilon_{s1}\tau_2 + \varepsilon_{s2}\tau_1) - \omega^2\tau_1\tau_2\varepsilon_\infty}{1 + j\omega(\tau_1 + \tau_2) - \omega^2\tau_1\tau_2}\mathbf{E}(\omega) \tag{10.15}$$

where the static (zero frequency) dielectric constant is given by

$$\varepsilon_s = \varepsilon_{s1} + \varepsilon_{s2} - \varepsilon_\infty \tag{10.16}$$

Assuming $e^{j\omega t}$ time dependence, Equation 10.15 can be written as a differential equation in the time domain:

$$\tau_1\tau_2 \frac{\partial^2 \mathbf{D}}{\partial t^2} + (\tau_1 + \tau_2)\frac{\partial \mathbf{D}}{\partial t} + \mathbf{D} = \varepsilon_0 \left[\varepsilon_s \mathbf{E} + (\varepsilon_{s1}\tau_2 + \varepsilon_{s2}\tau_1)\frac{\partial \mathbf{E}}{\partial t} + \varepsilon_\infty \tau_1\tau_2 \frac{\partial^2 \mathbf{E}}{\partial t^2} \right] \tag{10.17}$$

For the $(FD)^2TD$ method, Equation 10.10 and Equation 10.12 need to be solved subject to Equation 10.17. These equations can be written in the difference form [77,78] and solved to find **E**, **H**, and **D** at each cell location. The $\mathbf{E} \rightarrow \mathbf{H} \rightarrow \mathbf{D}$ loop is then repeated until the pulse has died off.

10.4.2 Human Bodies Exposed to EMFs

Computational algorithms based on numerical techniques described in the previous section have been applied to predict field intensities and SAR distributions in anatomically realistic models of human bodies. However, the use of a given numerical method and the number of computational cells involved in the models typically dictate the applicability of the techniques, how real the model is, the degree of accuracy attainable, and its domain of applicability. In the following sections, a few of the models will be described, and they will be followed by some representative results obtained using the models.

10.4.2.1 Realistic Models of the Human Body

Models proposed as better representations of the complex geometry and composition of the human body include constructions using small-volume cubic cells or cell meshes and anatomically based models generated from computerized tomographic and magnetic resonance image data.

10.4.2.1.1 Cubic-Cell Models

Models of the human body consisting of 200 to 1000 cubic cells that account more realistically for the gross anatomic and biometric characteristics of human bodies have been used by several investigators [24–28]. The models are 1.75 m tall and can be made either homogenous or inhomogenous by choosing an equivalent or a volume-weighted complex permittivity for each cell. The cubic-cell model has been employed successfully to calculate whole-body averaged absorption. It is important to note that for subdivision with less than three cells per wavelength, the magnitude and phase resolutions would be such that even with convergence the reliability of the MoM-computed SAR would be questionable. Therefore, if the interest is primarily in whole-body SAR, this model may provide quite adequate results for frequencies lower than 30 MHz. To achieve more accurate structural representation of the human body, anatomically based models have been offered in recent years.

10.4.2.1.2 Millimeter-Resolution Model Based on Magnetic Resonance Imaging Scans of the Human Body

A new millimeter-resolution model of the human body has been developed from the magnetic resonance imaging (MRI) scans of a male volunteer of 176.4-cm height and 64-kg weight [80,81]. The MRI scans were taken with a resolution of 3 mm along the height of the body and 1.875 mm for the orthogonal axes in the cross-sectional planes. Even though the height of the volunteer was quite appropriate for an average adult male, the weight was somewhat lower than an average of 71 kg, which is generally assumed for an average male. This problem can, to some extent, be ameliorated by assuming that the cell dimensions for the cross sections are larger than 1.875 mm by the ratio of $(71/64)^{1/2} = 1.053$. By taking the larger cell dimensions of $1.053 \times 1.875 = 1.974$ mm for the cross-sectional axes, the volume of the model can be increased by $(1.053)^2 = 1.109$, that is, by about 10.9%, which results in an increase of its weight by approximately the same percentage, that is, to a new weight of approximately 71 kg. The MRI sections were converted into images involving 29 tissue types whose electrical properties can then be prescribed at the exposure frequency. The tissue types are fat, muscle, bone, cartilage, skin, brain, nerve, cerebrospinal fluid (CSF), intestine, spleen, pancreas, heart, blood, eye, eye humor, eye sclera, eye lens, ear, liver, kidney, lung, bladder, stomach, ligament, compact bone, testicle, spermatic cord, prostate gland, and erectile tissue. As described above, this

model has been used to calculate the electromagnetic absorption in the human head, neck, and shoulders for cellular telephones operating at frequencies of 800 to 900 MHz. Because of the localized nature of EMFs, it was possible to use the model corresponding to the top 42 cm of the body for SAR calculations.

10.4.2.1.3 The ''Visible Human'' Model

The Visible Human (VH) Project, developed by the National Library of Medicine, is a 3-D digital image library representing an adult human male and female [82]. The dataset for both male and female includes photographic images obtained through cryosectioning of human cadavers and digital images obtained by computer tomography and MRI of the same cadavers. In particular, the photographic images represent a highly accurate and realistic counterpart of the anatomical cross sections contained in human anatomy atlases. The male dataset, the first to be constructed, consists of 1871 digital axial images obtained at 1.0-mm intervals, with a pixel resolution of 1 mm, while the female one contains 5189 digital axial images, obtained with a finer spatial step of 0.33 mm. While these digital datasets represent a unique tool to explore human anatomy, their direct use for computational electromagnetic dosimetry is limited by the fact that images cannot be directly used as an input for a numerical electromagnetic tool but must be converted to a so-called ''segmented'' version. A segmented model is a model where every pixel, usually called in such models ''voxel,'' does not contain information about the color (like in digital images) but rather a label that is uniquely associated to a given tissue. In such a way, it is possible to know which tissue fills each of the model voxels and hence assign the correct complex permittivity values to be used in numerical simulations.

Segmentation of the original image sets is a complex and time-consuming activity, which is difficult to carry out making exclusive use of automatic procedures, such as contour recognition algorithms, but inevitably requires intervention by experts in human anatomy. The segmentation procedure has been carried out for the male model by researchers at the Air Force Research Laboratory, Brooks Air Force Base, TX [83]. The final segmented model, made freely available to the scientific community, comprises $586 \times 340 \times 1878$ voxels with a resolution of $1 \times 1 \times 1$ mm, and is segmented in about 40 different tissue types [84]. The model has been widely used to study both whole-body and localized human exposure to EMFs radiated by different types of sources and is now being included in many commercially available electromagnetic simulation tools with capabilities for dosimetric evaluation.

10.4.2.2 Currents Induced in the Human Body by Low-Frequency EMFs

This section reports the results obtained for low-frequency EMF. Specifically, it includes the use of the impedance method to calculate currents induced in the human body by the EMFs of electric blankets. It also includes the use of the FDTD method for calculations of internal **E** and **H** fields and induced current densities for exposure to electric, magnetic, or combined electric and magnetic fields at power-line frequencies. The results given below were obtained using a 1.31-cm resolution, anatomically based model of the human body. Since the term $j\omega\varepsilon$ can be neglected as compared to σ for the various tissues at ELF including electric power frequencies (50/60 Hz), the impedances for the various cells of the model given by Equation 10.9 can be replaced by resistances. It is recognized that the conductivities of various tissues, for example, skeletal muscle, heart, and bone, are anisotropic for power-line frequencies [34,35,85]. This has been neglected in this case, however, and average values of conductivities given in Table 10.3 have been taken for the various tissues for the calculations.

TABLE 10.3

Tissue Conductivities Used for Calculations at the Power-Line Frequency of 60 Hz

Tissue Type	σ (S/m)
Air	0
Muscle	0.52 or 0.11
Fat, bone	0.04
Blood	0.6
Intestine	0.11
Cartilage	0.04
Liver	0.13
Kidney	0.16
Pancreas	0.11
Spleen	0.18
Lung[a]	0.04
Heart	0.11
Nerve, brain	0.12
Skin	0.11
Eye	0.11

[a]The dielectric properties of the lung consist of 33% lung tissue and 67% air.

10.4.2.2.1 Electric Blankets

To illustrate the use of the impedance method, currents induced in the human body by the EMFs of two types of electric blankets have been calculated [1,2]. The two models used for the blanket are (a) a low-magnetic-field blanket and (b) a conventional (pre-1990) electric blanket. The low-magnetic-field blanket uses two parallel leads carrying equal and opposite currents to reduce the net magnetic field around the conductors. The two leads are separated typically by 1.5 mm and are embedded in a positive temperature coefficient (PTC) conductive polymer and insulated by polyvinyl chloride (PVC). The PTC conductive polymer surrounding the two leads may be represented by a set of distributed resistors, which would result in linearly decreasing equal but opposite currents flowing through the two leads over the length of the wiring used for the blanket. By comparison, the conventional electric blanket uses a resistive alloy wire wrapped on a nylon cord and insulated with PVC. Because of the distributed resistance of the wire, this blanket would therefore have a linearly diminishing voltage and identical magnitude of current over the length of the wiring used for the blanket.

The validity of the calculated results has been established by comparing the results obtained using the impedance algorithm and those reported by others. The calculated fields are in excellent agreement with the data given by Florig et al. [86] and Hayashi et al. [87].

Currents are induced in the body by the following sources:

1. Time- and spatially varying magnetic fields of the blanket induced voltages in the various resistance loops of the body.
2. Currents launched into different subareas at the body surface by means of the capacitively coupled currents from the various conductors of the blanket.

The spatial variations of the magnetic fields were calculated from Biot-Savart's law for a short current-carrying conductor [2]. By integrating it over the entire length of the

current-carrying conductors, one can obtain the vector magnetic fields at the centers of the cells representing the model of the human body or any of the other points in space. From the vector magnetic fields thus calculated for each of the cell centers for the impedance model of the human body, the induced voltages for each of the faces of the cells can be written [32]. This information is then used to calculate the induced currents for the various impedances, that is, resistances. The average current densities J_x, J_y, and J_z for each of the cell centers can be obtained by taking the average of the currents through the resistances representing each of the four edges of the cell in the respective directions and dividing the same by the cross-sectional area δ^2 ($= 1.31 \times 1.31$ cm).

To calculate the electric field distribution in air, a 3-D impedance model consisting of capacitors representing the space between the various faces of the cells was used. For cubic cells of dimension $\delta = 1.31$ cm, the capacitances used are $\varepsilon_0 \delta^2/\delta = 0.116$ pF.

For currents induced in the human body due to electric fields, it should be recognized that the energized conductors of the blanket are capacitively coupled to the body. The capacitance between a given conductor and the highly conducting human body can be obtained by using an expression similar to that for a conductor at a distance S from the ground plane. Capacitance per unit length C of a wire of diameter d parallel to but separated at a distance S from the ground plane is given by

$$C = (2.73\varepsilon_{\text{eff}})/[\log_{10}(4S/d)], \quad \text{pF/m} \tag{10.18}$$

For a spacing $S = 5$ mm and a wire diameter $d = 0.8$ mm, and for $\varepsilon_{\text{eff}} = 2.5\varepsilon_0$, which is a value intermediate between the permittivity ε_0 for air and $4\varepsilon_0$ for the material of the blanket, we can calculate $C = 43.1$ pF/m. For a cell length $d = 1.31 \times 10^{-2}$ m, the coupling capacitance C_c between the wire and the cell can be calculated to be 0.565 pF. Since the interconductor spacing of 1.5 mm for a PTC blanket is fairly small as compared to the cell size, a proportionately smaller resistance is taken for the tissue-equivalent cells immediately underneath the conductors for the direction parallel to the interconductor spacing. Capacitances of 0.565 pF are taken from each of the conductors of the PTC blanket to the appropriate points on the impedance model of the human body. In the presence of an electrical grounding surface, the space underneath the model is represented by a 3-D network of capacitors, each of value 0.116 pF, representing the air space between the various faces of the cubic cells of dimension $d = 1.31$ cm for each of the sides.

For the PTC low-magnetic-field blanket, a constant voltage of 110 V AC is taken between the conductors of the twin-lead wiring for calculation of currents induced or injected into the human body as a result of electric fields. For calculating the magnetic fields, an input current of 1 A is taken. On account of the conductive polymer surrounding the parallel wires, this current diminishes linearly to zero at the end of the PTC wiring. This assumes a blanket input power of 110 W under normal operating conditions. If magnetic fields or induced current densities due to higher input powers are desired, the numbers calculated for 1 A input current may then be multiplied by the appropriate factor.

The conventional blanket, on the other hand, uses a resistive conductor for which the voltage diminishes linearly from 110 to 0 V over the length of the wiring. For this blanket the current throughout the length of the wiring is the same as at the input, that is, 1 A, which is assumed for the calculation of magnetic fields.

The magnetically induced, section-averaged magnitudes of the total current densities from head to feet for the two types of blankets are shown in Figure 10.13a and b, respectively. For these calculations, the wiring of the blanket was taken to be 0.5 cm from the surface of the body. Nearly identical current densities were also obtained for a grounding plate underneath the body at distances of 0.25, 0.5, and 1.0 m. It is interesting to

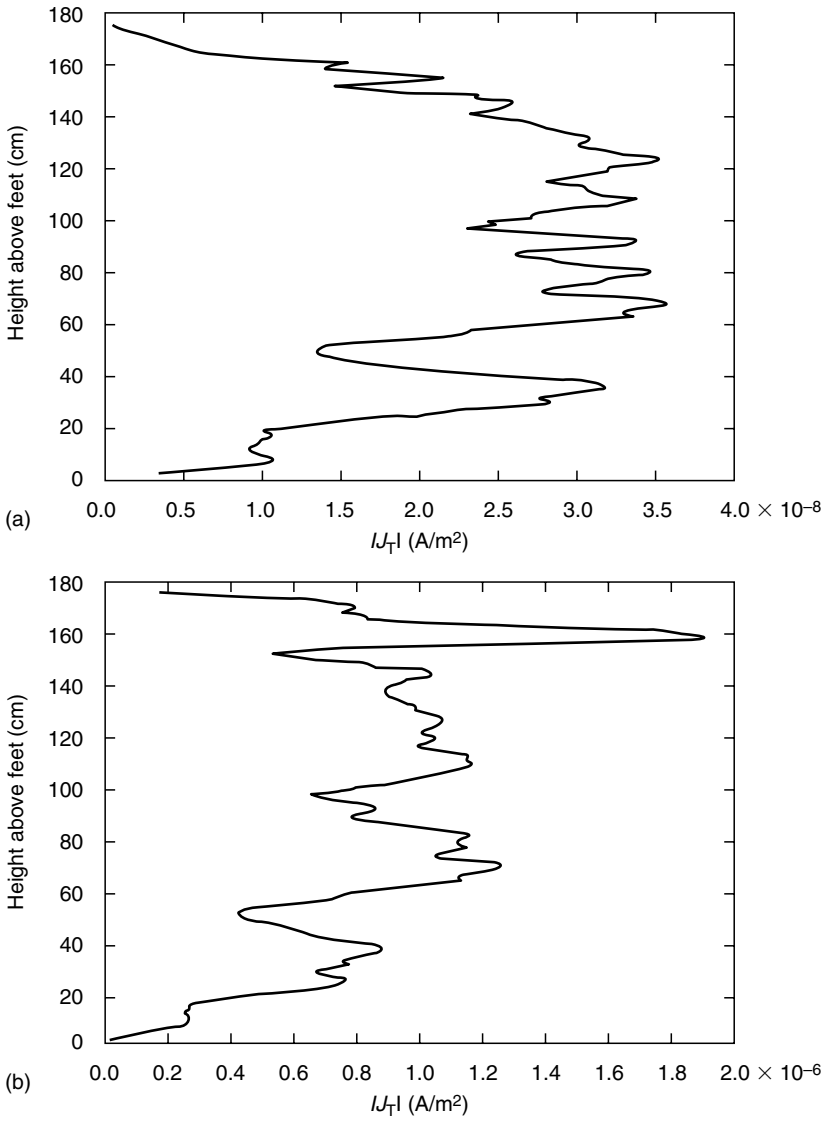

FIGURE 10.13
Section-averaged magnitudes of total current densities for the various sections of the body for magnetic fields of the blankets. Nearly identical current densities were obtained also for a grounding plate at distances of 0.25, 0.5, and 1.0 m underneath the body. Input current = 1 A.

note that the induced current densities are larger by a factor of about 500 for the conventional blanket vis-a-vis those for the low-magnetic-field blanket.

The calculated section-averaged magnitudes of the total current densities due to electric fields of both the blankets in the absence of a grounded plane are shown in Figure 10.14a and b, respectively. It should be noted that while the current densities induced by the electric fields of a low-magnetic-field blanket (Figure 10.14a) are considerably higher than those due to magnetic fields (Figure 10.25a), the converse is true for a conventional blanket. For this blanket, the current densities induced by the magnetic fields (Figure 10.13b) are higher than those due to electric fields (Figure 10.14b). In fact, while the current densities due to magnetic fields are fairly small for a low-magnetic-field blanket

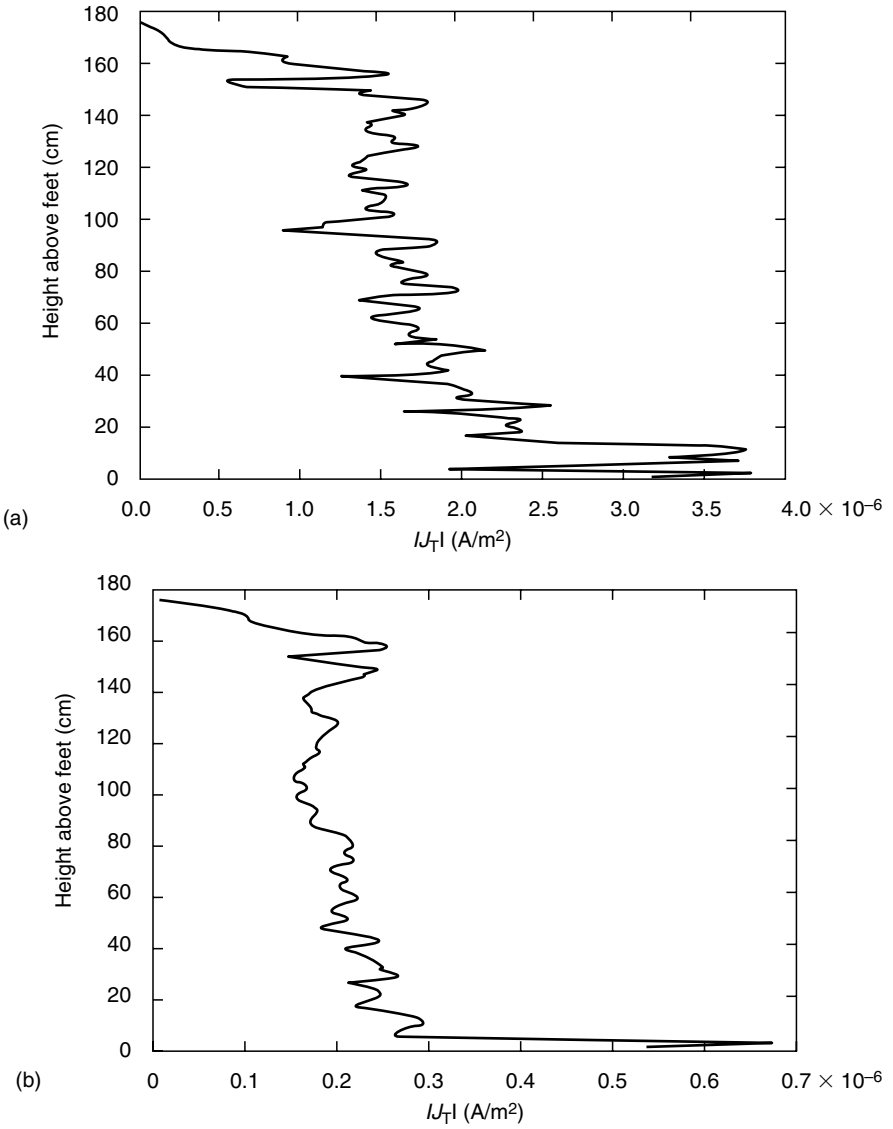

FIGURE 10.14
Section-averaged magnitudes of total current densities for the various sections of the body for electric fields of the blankets. No ground plane underneath the body.

as compared to those for a conventional blanket, the current densities due to electric fields of a low-magnetic-field blanket are even higher than those for a conventional blanket (see Figure 10.14a and b). The reasons for these observations can be seen from the values of magnetic and electric fields given in Table 10.4 for the two types of blankets, respectively. While fairly small magnetic fields are calculated for the low-magnetic-field blanket as compared to those for the conventional blanket, the converse is true for the electric fields created by these blankets. As seen in Table 10.5, somewhat higher electric fields are created by the low-magnetic-field blanket as compared to those for the conventional blanket. This is likely due to the higher potential difference between the twin-lead conductors that are used for the low-magnetic-field blankets.

TABLE 10.4

Comparison of the Calculated and Measured Magnetic Field (μT) and Electric Field (V/m) Close to a Flat Blanket [2]

	Grid Size (cm)	Calculated	Measured
Low-magnetic-field blanket[a]

	10.5 × 10.5	70.1	95.4
Peak	—	176.1	167.2

[a]For this blanket, the magnetic-field results are normalized for a blanket input current of 1.227 A, that is, a power input of 135 W.
[b]For this blanket, an input current of 1 A is assumed.

10.4.2.2.2 Power Transmission Lines

The FDTD method has been used for calculations of internal **E** and **H** fields and induced current densities for exposure to electric, magnetic, or combined electric and magnetic fields at power-line frequencies [37]. While recognizing that the conductivities of many biological tissues (skeletal muscle, bone, etc.) are highly anisotropic for power-line frequencies, however, the effect of anisotropy is neglected for the sake of simplicity. They could be included in more complex models by separately identifying these tissues.

Both sinusoidal and prescribed time-varying incident fields can be used with the FDTD procedure—hence the method is well suited also for transient exposures that are often of interest at power-line-related frequencies. For sinusoidally varying fields, the solution is completed when a sinusoidal steady-state behavior for **E** and **H** fields is observed for each of the cells. For lossy biological bodies this typically takes a time step on the order of three to four time periods of oscillation. Since Δt is fixed for a given cell size, a larger number of iterations are therefore needed at lower frequencies. Because of the large number of iterations, the FDTD procedure would be clearly inapplicable for calculations at power-line frequencies were it not for the quasi-static nature of the coupling at low-frequencies [16,88,89]. Thus, the field outside the body does not depend on the internal tissue properties, but it depends only on the shape of the body so long as the quasi-static approximation holds, that is, the size of the body is a factor of 10 or more smaller than the wavelength, and $| \sigma + j\omega\varepsilon | \gg \varepsilon_0$, where σ and ε are the conductivity and the permittivity of the tissues, respectively; $\omega = 2\pi f$ is the radian frequency; and ε_0 is the permittivity of the free space outside the body. Under these conditions, the electric fields in air are normal to the body surface, and the internal tissue electric fields can be obtained from the boundary conditions in terms of fields outside:

2000				0.055	0.060	

[a]The frequency considered is 120 MHz.
[b]The frequency considered is 210 MHz.

$$j\omega\varepsilon_0 E_0 = (\sigma + j\omega\varepsilon)E_{\text{tissue}} \tag{10.19}$$

A higher quasi-static frequency f', at 5 to 20 MHz, may therefore be used for irradiation of the E model, and the internal fields E thus calculated may be scaled back to frequency f of interest, for example, 60 Hz. Since in the FDTD method, one needs to calculate in the time domain until convergence is obtained, this frequency scaling to 5 to 20 MHz for f reduces the required number of iterations by over five orders of magnitude. From Equation 10.19 we can write

$$\omega'(\sigma + j\omega\varepsilon)E_{\text{tissue}}(f) = \omega(\sigma' + j\omega\varepsilon')E'_{\text{tissue}}(f') \tag{10.20}$$

or

$$E_{\text{tissue}}(f) = (f\sigma'/f'\sigma)E'_{\text{tissue}}(f') \tag{10.21}$$

assuming that $\sigma + j\omega\varepsilon \sim \sigma'$ at both f' and f [2,90]. To validate the use of a higher frequency f to obtain induced E fields at ELF frequencies, test cases involving homogenous and layered spheres have been used. Excellent agreement between the numerical and analytical results lends support to the validity of the FDTD method for calculating internal E fields and current densities at power-line-related frequencies. It should be noted that incident E and H fields of any orientation and relative magnitudes can be prescribed in the FDTD method, allowing the possibility of calculations for realistic

exposure conditions. Also, the choice of a considerably higher frequency such as 5 to 20 MHz reduces the number of iterations needed to obtain converged results by five to six orders of magnitude as compared to those that would be needed at ELF frequencies of 10 Hz to 1 kHz.

Some calculated results using a 16-tissue, 1.31-cm resolution, anatomically based model of the human body are given in Figure 10.15. A frequency f' of 5 to 10 MHz was used to reduce the computation time. At the higher irradiation frequency f', $\sigma' = \sigma$ was assumed, that is, conductivities of the various tissues at 60 Hz. Furthermore, the incident **E** field, $\mathbf{E}_i(f') = 60\mathbf{E}_i(f)/f'$, was used to obtain $\mathbf{E}_{\text{tissue}}(f)$ at, say, $\mathbf{E}_i(f) = 10\,\text{kV/m}$. The incident magnetic field $\mathbf{H}_i(f')$ has similarly been taken to be considerably lower ($= 60\mathbf{H}_i(f)/f'$) to account for the fact that the induced current densities and internal electric fields are proportional to the frequency of the incident fields and would therefore be higher at the assumed frequency f'. Recognizing the anisotropy in the conductivity of skeletal muscles, two different values of muscle conductivities are taken for curves (1) and (2). For these curves a higher conductivity of 0.52 S/m is taken for the skeletal muscle, and an average value of 0.11 S/m is taken for the muscle in the interior of the body. For curves (3) and (4), however, a lower conductivity of 0.11 S/m is taken for all of the muscle, interior or skeletal. The results shown in Figure 10.15, curves (1), (3), and (4) are for $E_{\text{inc}} = 10\,\text{kV/m}$ (vertical) and $H_{\text{inc}} = 26.5\,\text{A/m}$ ($B_{\text{inc}} = 33.3\,\mu\text{T}$) from side to side of the model. To point out the preponderance of the induced currents due to incident electric field, $H_{\text{inc}} = 0$ is assumed for the calculations shown in curve (2). It is interesting to note that the layer currents due to *E*-field exposure alone are almost 98% to 99% of the currents calculated for the combined electric and magnetic fields. It is also interesting to note that the calculated foot currents of 155 to 160 μA are in excellent agreement with 165 μA that would be projected from the measurements of Deno [91] for the human body. The variations of the induced currents calculated along the height of the body have been checked against the results by DiPlacido et al. [92]. The agreement with the results of these two authors who had

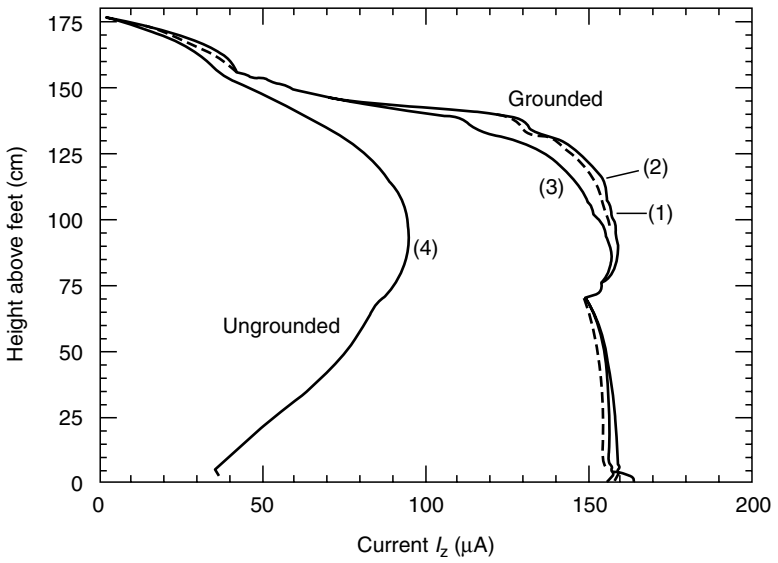

FIGURE 10.15
Calculated layer currents for anatomically based grounded and ungrounded models exposed to EMFs at 60 Hz. For curves (1) and (2), $s = 0.52\,\text{S/m}$ for skeletal muscle, and $s = 0.11\,\text{S/m}$ for the interior muscle. For curves (3) and (4), $s = 0.11\,\text{S/m}$ for all of the muscle. $E = 10\,\text{kV/m}$ (vertical), $H = 26.5\,\text{A/m}$ from side to side for all of the curves except for curve (2), for which only **E**-field exposure is assumed.

used a vertical electric field such as that under a high-voltage power line was found to be very good [37].

10.4.2.3 Absorption in Human Bodies Exposed to Far Field of RF Sources

As noted, the configuration and frequency of the electromagnetic source and the geometry and composition of the biological body will influence the induced field and power absorption and distribution inside the body. Moreover, the field emitted from a source is dictated by the frequency, size, and configuration of the source. Near an antenna, the radiated energy is in the form of a spherical wave in which the wave fronts are concentric shells. The spheroidal wave front expands as the wave propagates outward from the source. At distances far from the source, the radius of curvature of the spherical shells becomes so large that the wave front would essentially appear as a plane. They are therefore referred to as plane waves. Plane waves are important since their behavior is well quantified; the fields are uniform in planes normal to the direction of propagation, and the power density varies only in the direction of propagation. In this case, both electric and magnetic fields of the propagating wave are orthogonal in space and lie in the plane of the wave front, and are related through the intrinsic impedance of the medium. In other words, in the far or radiation zone, the electric and magnetic fields have only transverse components.

In this section, we shall briefly summarize some of the efforts devoted to field computation using various models of the human body, which consists of large quantities of numerical cells, and present some results obtained for plane wave exposures. Note that some, especially the simpler, models are of interest primarily for whole-body SAR and can provide quite adequate results for frequencies lower than 30 MHz. To achieve more accurate structural representation of the human body, anatomically based models are needed.

10.4.2.3.1 SAR Induced in Cubic-Cell Models

The VMoM for field computation has been used for models of the human body consisting of 200 to 1000 cubic cells. These models account for the gross anatomic and biometric characteristics of human bodies and have been used by several investigators [24–28]. The models are 1.75 m tall and can be made either homogenous or inhomogenous by choosing an equivalent or a volume-weighted complex permittivity for each cell. The cubic-cell model has been employed, successfully, to calculate whole-body averaged absorption. It is important to note that for subdivision with less than three cells per wavelength, the magnitude and phase resolutions would be such that even with convergence the reliability of the MoM computed SAR would be questionable.

According to the MoM, the body may be partitioned into N cubic subvolumes or cells that are sufficiently small for the electric field and dielectric permittivity to be constant within each cell. The integral equation is then transformed into a system of $3N$ simultaneous linear equations for the three orthogonal components of the electric field at the center of each cell. The simultaneous equations may be written in matrix form as

$$[G][E] = -[E^i] \tag{10.22}$$

where $[G]$ is a $3N \times 3N$ matrix and $[E^i]$ and $[E]$ are column matrices representing incident and induced electric fields at the center of each cell. The elements of $[G]$ can be evaluated as shown in Liversy and Chen [24]. In particular, the diagonal elements of the $[G]$ matrix may be evaluated exactly by approximating each subvolume with a sphere of equal volume centered at the position of an interior point. If the actual shape of the cell differs

appreciably from that of a sphere, this approximation may lead to unsatisfactory numerical results [36]. In such cases, a small cylindrical volume may be created around an interior point. It may also be necessary to evaluate these terms by numerical integration throughout the cubic subvolume for increased accuracy. The evaluation of off-diagonal elements of the [G] matrix is considerably simplified since it does not involve principal value operations. Therefore, for a given applied field configuration, the induced electric fields inside the body are obtained by matrix inversion. That is,

$$[E] - [G]^{-1}[E^i] \tag{10.23}$$

Factors that influence the computational accuracy include frequency, body size, cell dimensions, and computer memory. It has been found that reliable numerical results can be obtained if the linear dimensions of the cell do not exceed a quarter free-space wavelength [24]. For a computer with sufficient capacity to invert a 120 $\times$ 120 matrix, the maximum number of cells is limited to 40. If we assume, for simplicity, symmetries between the right and the left half and the front and the back of a 1.7-m-tall adult human body, this computer would handle approximately a cell size around 10^{-5} m^3. Once the 10^{-5}-m^3 cell size is adopted, 750 MHz would be the highest frequency that can be considered for field intensity calculation without violating the criterion that the linear dimension of the cell not exceed a quarter free-space wavelength.

The computational resources necessary to obtain even a regional SAR using this MoM approach are quite extensive. A relatively full complex matrix, $3N \times 3N$ in dimensions, is required for a model with N cells. The computation time required for a noniterative solution of the matrix equation is therefore proportional to a value between N^2 and N^3, which increases rapidly as N increases. The faithfulness with which a cubic-cell model approximates the detailed structure of a biological body and the maximum usable frequency increases with the number of cells. In fact, substantial errors will occur if

$$N \leq (2\pi L)/(\lambda' 6^{1/2}) \tag{10.24}$$

where L/λ' is the ratio between the linear dimension of the body and the wavelength in the body.

The accuracy of the numerical method can be verified by comparison with known results from exact analytic solutions based on well-characterized geometric bodies, such as spheres. It should be noted that perfect agreement between the exact solution, based on Mie theory, and the numerical method, based on the volume integral equation, is not expected unless a large number of cubic cells are used to simulate the sphere. Figure 10.16 shows one eighth of a sphere approximated by one eighth of a ''cubic model of a sphere,'' which is constructed from 73 cubic cells. Clearly, a better approximation can be achieved by a larger number of smaller cubic cells. Nevertheless, for a brain sphere constructed from 40 cubic cells at a frequency of 918 MHz, the computed maximum field intensity deviated from the exact solution by less than 9% [93].

A model of a human body consisting of 180 cubic cells that accounts for the anatomic and biometric characteristics of human beings is shown in Figure 10.17. The model is 1.75 m tall and can be made either homogenous or inhomogenous by using an equivalent or a volume-weighted complex permittivity for each cell [94]. The average absorption or whole-body SAR for the model of the human body shown in Figure 10.17 as a function of frequency is illustrated in Figure 10.18. The electric field vector is along the height of the body, and the plane wave propagates from front to back of the model with an incident power density of 10 W/m^2. A homogenous complex permittivity approximately two thirds of that for muscle is used in the calculations. Note that the whole-body SAR

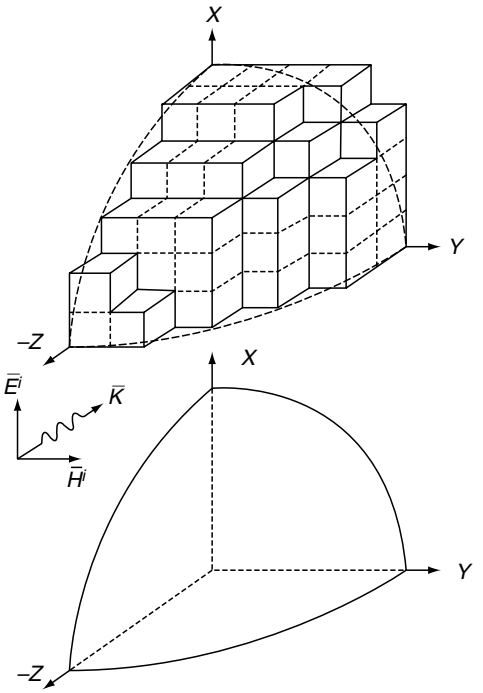

FIGURE 10.16
Approximation of one eighth of a sphere by an equivalent cubic-cell-formed structure.

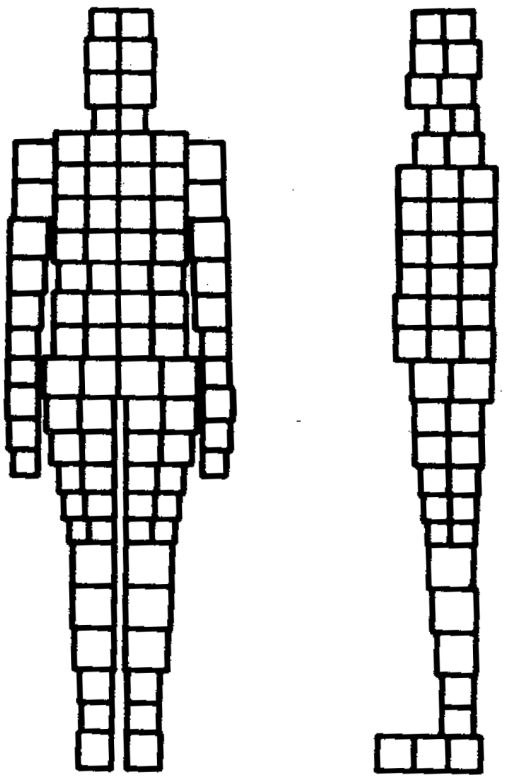

FIGURE 10.17
A cubic-cell representation of the human body.

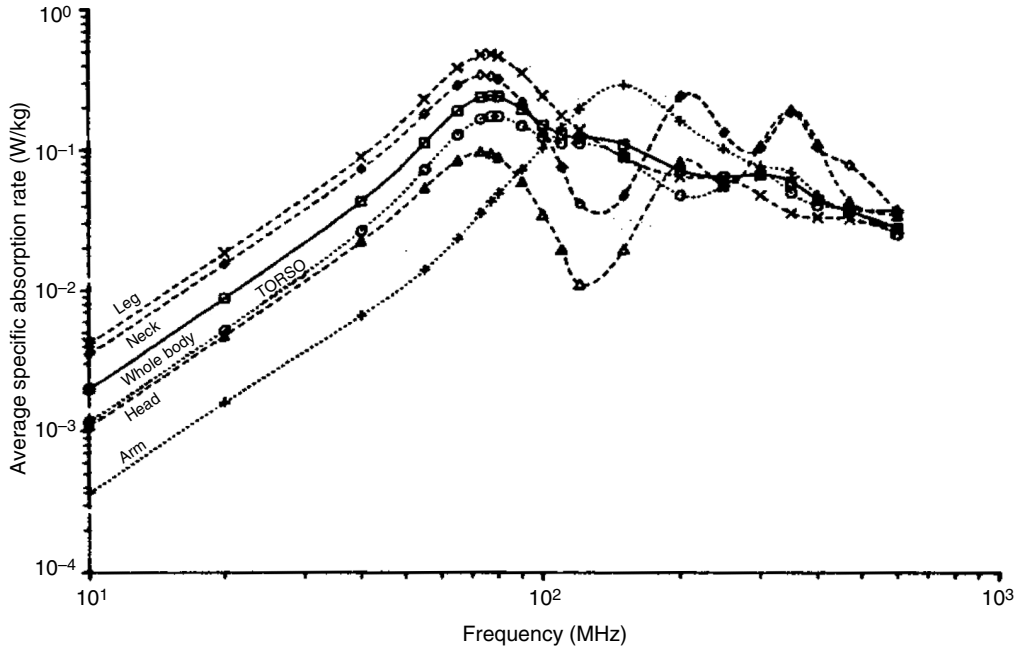

FIGURE 10.18
Average SARs for a homogenous 180-cell model of the human body exposed to a vertically polarized, 80-MHz plane wave. The incident power density is 10 W/m^2.

increases with frequency until it reaches a maximum of about 0.23 W/kg at 77 MHz (resonance frequency), and it then decreases as 1/frequency. The experimental data shown in Figure 10.19 are obtained from a saline-filled scale model of the human body. It can be seen that the calculated absorption is in good agreement with that found experimentally [27,95], except for the resonant frequency, which is somewhat lower (70 MHz) in the experimental case. It should be mentioned that whole-body SAR, given in Figure 10.18, is typically within 10% of that estimated from prolate spheroidal models of the same height and dielectric property. Further, when inhomogenous complex permittivities are used with the model, the whole-body SAR changes less than 2% from that depicted in Figure 10.18. Thus, if one is primarily concerned with average absorption over the body, a homogenous prolate spheroidal model may be quite adequate.

While the MoM based on the volume integral equation has been a useful numerical procedure for computation of average SAR and SAR distribution in complex tissue geometries, the requirement of a full $3N \times 3N$ matrix presents severe limitations. The computation times required to provide even regional SAR distribution of sufficient resolution to delineate the resonant frequency for the head region are enormous. A minimum of 340 cells was needed, increasing the computation time by a factor of 4 over the 180-cell models [95,96].

Matrix inversion operations consume the largest block of time in moment method solutions for the cubic-cell models. The computer time required is proportional to the cube of the number of cells. However, the matrix generated is usually diagonally dominant and well-conditioned. For a human-size body, iterative procedures for matrix inversion are practical at frequencies below about 60 MHz. The convergence rate decreases with increasing frequency and fails above 90 MHz. This is most likely caused by the decrease in the degree of diagonal dominance with increasing frequency. A number of approaches have been investigated to alleviate this difficulty. A semi-iterative procedure

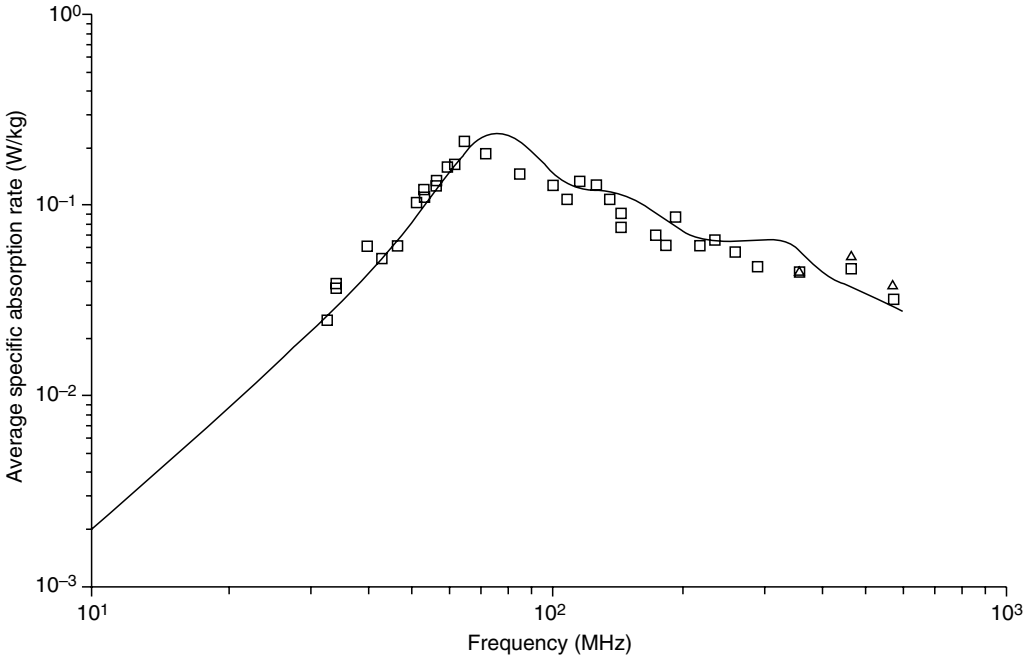

FIGURE 10.19
Whole-body averaged absorption for a homogenous cubic-cell model of humans exposed to vertically polarized plane in free space. The incident power density is 10 W/m^2.

called band approximation method appears to be an efficient algorithm that can be profitably used to invert large matrices generated by the number of cells for human models at arbitrarily high frequencies, and converges significantly faster than standard iterative algorithms [96].

10.4.2.3.2 SAR Induced in Fine Resolution Anatomical Models

To accurately evaluate the SAR induced in the human body, the FDTD method was introduced during the late 1980s, when the limitations of the MoM due to its memory requirements were reached. The capability of FDTD to take into account heterogeneities in models of the human body was first demonstrated using a model of the isolated human torso [69]. Later, a complete model of the human body was considered [97], and results for an isolated homogenous man model standing in free space were compared with results for an inhomogenous man model, under both isolated and grounded conditions [97]. The incident field was a plane wave propagating parallel to the ground plane and with the electric field vertically polarized (parallel to the long axis of the human body), at frequencies of 100 and 350 MHz. The human body model was obtained from cross-sectional diagrams and had a resolution of 2.62 cm at 100 MHz. The total occupied volume was $23 \times 12 \times 68$ cubic cells. At 350 MHz, the resolution was 1.31 cm for a total volume of $45 \times 24 \times 135$ cubic cells. The result, depicted as layer-averaged SAR or organ-averaged SAR, demonstrated the importance of considering inhomogenous models of the human body. For example, the homogenous model was not able to predict the peak SAR obtained in the eyes at 350 MHz, or the difference in absorption among the different organs.

Since these first works on power absorption, several papers have been published using anatomical models of the human body with finer resolutions.

The VH body model has been used to evaluate power absorption and temperature increase as a function of frequency of the incident plane wave, by considering a grounded male, either barefoot or with shoes [98]. The model had a resolution of 5 mm, a total height of 180 cm, and weight of about 103 kg. The large mass was due to the use of the VH model, which is far from the so-called ''reference man,'' as defined by International Commission on Radiological Protection (ICRP). The reference man weighs 73 kg and has a height of 176 cm [99]. In the referenced paper [98], for the frequency range between 10 and 900 MHz, SARs averaged over the whole body (SAR_{WB}) and locally, that is, averaged over 1.0 g (SAR_{1g}) and 10 g (SAR_{10g}), were evaluated. In particular, it has been found [98] that when the incident power density is equal to the reference levels set in the exposure standards, the basic restrictions on SAR_{WB} and on local SARs are never exceeded. Moreover, it has been shown [98] that the ratio, SAR_{10g}/SAR_{WB} was about the same (either 25 or 50 according to the body part considered) as the value used in the safety guidelines to convert basic restrictions on SAR_{WB} to basic restriction on local peak SAR [100]. On the other hand, the SAR_{1g}/SAR_{WB} ratio was found to be always higher than the value of 20 adopted in the safety guideline [101].

Figure 10.20 gives the SAR_{WB} as a function of frequency in a grounded male for an incident plane wave with a power density of 10 W/m^2 for two different human body models [98,102]. The SARs are slightly different because the two body models were different in height, weight, and tissue composition. The influence of the human body model on electromagnetic power absorption is further illustrated in Figure 10.21, where a comparison among the SAR_{WB} values obtained with the heterogenous VH model and a homogenous VH model consisting either of muscle or fat is reported. The frequencies considered are from 10 to 200 MHz to highlight the differences in power absorption at resonance.

It can be seen from the figures that a higher peak appeared at resonance in the homogenous muscle model, and lower absorptions were obtained in the homogenous fat model. Moreover, data from a lighter model (65.8 kg) obtained by reducing the cell dimension on the horizontal plane suggested that the lighter body absorbed more elec-

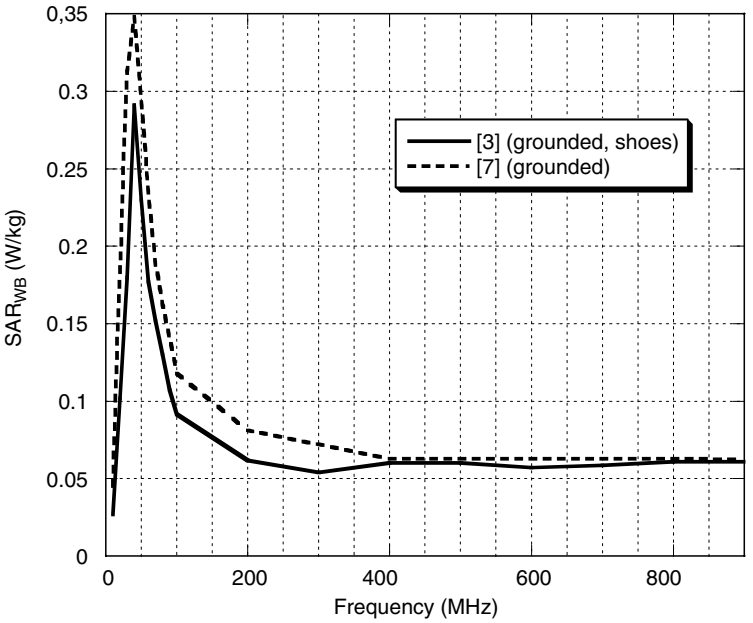

FIGURE 10.20
SAR as averaged over the whole body as a function of the frequency.

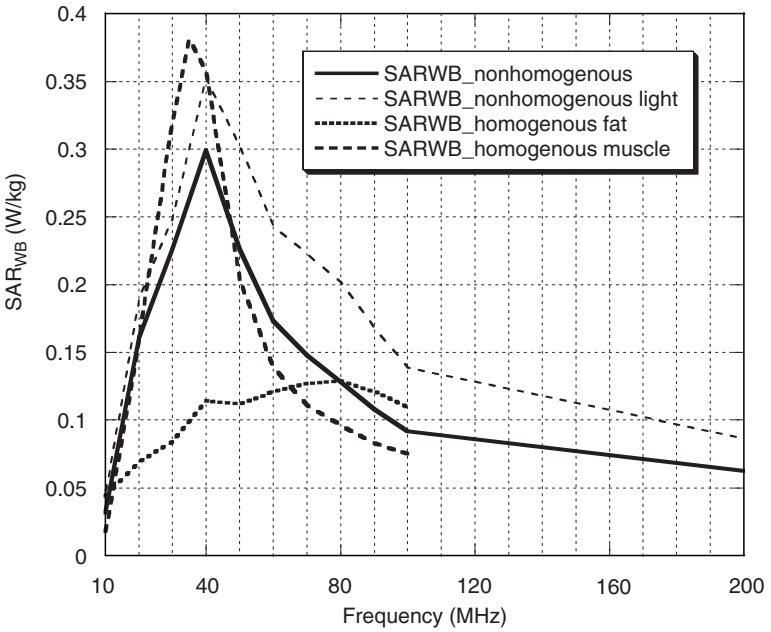

FIGURE 10.21
SAR as averaged over the whole body as a function of the frequency for different VH body models: nonhomogenous, nonhomogenous with a lighter weight (65.8 vs. 103 kg), homogenous fat, and homogenous muscle.

tromagnetic power than the heavier one. The frequency dependence of power absorption is clearly evidenced by Figure 10.20 and Figure 10.21. Indeed, this frequency dependence was the basis of the different limits imposed on the reference levels for different frequencies in the safety guidelines [100,101].

In Table 10.5 some literature data are summarized for the SAR_{WB} as a function of frequency (10 MHz to 2 GHz) for a grounded and isolated man model exposed to an incident power density of 1.0 mW/cm^2.

The first two columns refer to data in Figure 10.20, while the successive columns report data from published literature. Note the resonant frequencies of 40 vs. 70 MHz for grounded or isolated bodies. Moreover, the data in Table 10.5 show nonsignificant differences in SAR averaged over the whole body by changing the model resolution from 3 to 5 mm [103]. For the same reason the cubic-cell model described in the previous section had been employed, successfully, to calculate whole-body averaged absorption. The SAR_{WB} has a weak dependence on model resolution.

Likewise, a study on the SAR dependence on permittivity values [104] showed that uncertainty in permittivity values does not substantially affect the SAR as averaged over the whole body, while the same uncertainties have a greater effect on local SAR. In particular, considerations of different frequencies and orientations of the incident plane wave, or higher or lower permittivity values, showed that the maximum difference in SAR_{WB} was within $\pm 20\%$ [103]. Larger differences were found in local SAR, particularly when the permittivity of muscle, representing about 42% of the whole-body mass, was changed [103].

The data in the last column of Table 10.5 were obtained from a human body model [105] that was developed by using a new, semiautomatic procedure to construct numerically a frequency-dependent, dielectric anatomy model, starting from MRI images. The main difference between this human body model and the models usually considered in FDTD calculations is that in this model permittivity and conductivity can vary, even for the

same tissue, thus reflecting the realistic spatial inhomogeneity of such parameters. The semiautomatic procedure requires a short time to construct the model; thus, it could be used for dosimetry studies based on the model of specific persons.

A high-resolution human body model ($1.974 \times 1.974 \times 3.0$ mm) and a coarser one ($5.922 \times 5.922 \times 6.0$ mm), both for isolated and grounded conditions, were employed to determine the power absorption in the head and neck region and to evaluate the frequencies at which the absorption may be maximized [106]. It was observed that under isolated conditions two resonant frequencies occurred for the head and neck, one associated with the whole-body resonance and the other with a local resonance of the head and neck. Under grounded conditions, three resonances were observed; the additional resonance was attributed to a torso resonance.

Some studies were conducted to evaluate power absorption in models of women and children. Specifically, a 10-year-old child and a 5-year-old child were considered by scaling the adult human body model [106]. It should be noted that simply scaling the adult human body model to the children's dimensions does not produce an accurate model since the different organs scale differently; however, the general features in terms of height and weight are fulfilled, thus allowing for the determination of general properties of electromagnetic power absorption. In this way, resonant frequencies of 104 MHz for the isolated model and 65 MHz for the grounded 10-year-old child were obtained, while for the 5-year-old model, they were 126 and 73 MHz, respectively.

In a different study, power absorption in scaled versions of the adult human body model representing 10-, 5-, and 1-year-old children was evaluated for both grounded and isolated conditions [102]. Figure 10.22 gives the SAR_{WB} obtained for the three child models under isolated conditions and an incident power density of $1\,mW/cm^2$. A shift in the resonant frequency with the height of the model—the taller the model, the lower

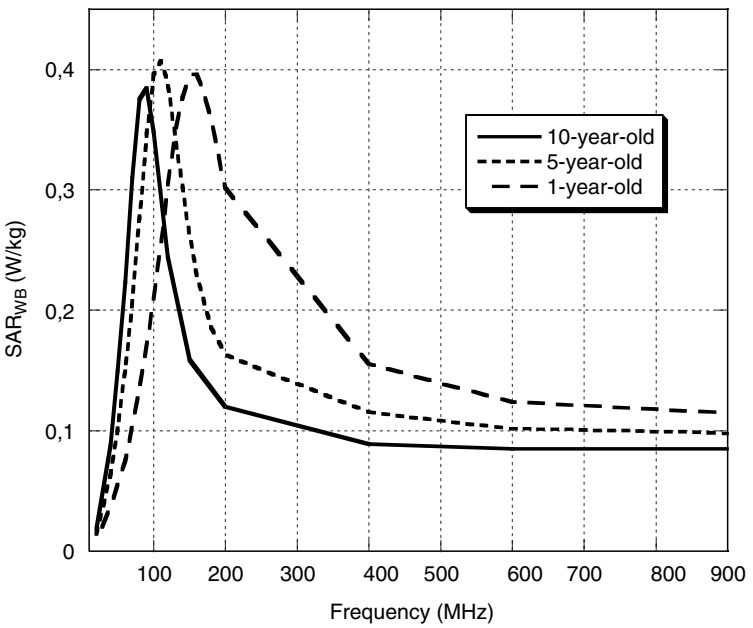

FIGURE 10.22
SAR as averaged over the whole body as a function of the frequency for different child body models: 10, 5, and 1 year old. Incident power: $1\,mW/cm^2$. (Data from Dimbylow, P.J., *Phys. Med. Biol.*, 47, 2835, 2002.)

the resonance frequency—can be observed from the figure; note also the higher absorption in the smaller child body model [102].

The potential differences between SAR induced in man and woman have been explored using slightly different models [107,108]. In one study, 2-mm resolution models were developed for evaluating power absorption in Japanese males and females. Note that the use of the 2-mm resolution body models had led to an overestimation of the skin weight by 50% or more than the average value for the Japanese reference body [107]. The computed results showed that the difference in SAR_{WB} between male and female models was small, within 1.1 dB. The authors concluded that gender does not affect SAR_{WB}. Similarly, they obtained no significant differences between the male and female models with regard to local SARs. However, the overestimation of skin weight, and perhaps other tissues, in the 2-mm resolution body models could have influenced their results and conclusions.

In contrast, a clear difference in power absorption was reported [108] between Caucasian male and female models. The two Caucasian body models were developed using the semiautomated procedure previously cited [105]. In particular, considerably greater SAR_{WB} was obtained in the female model than in the male one (about 40% higher in the frequency range between 500 MHz and 2.0 GHz and 25% higher in the frequency range between 2.0 and 4.0 GHz). The difference in local SARs (both SAR_{1g} and SAR_{10g}) were insignificant between genders for up to 3.0 GHz, while above this frequency, say up to 4 GHz, the SAR_{1g} and SAR_{10g} in the female model became larger than those in the male model. The authors observed that this result could be explained by the difference in subcutaneous fat between man and woman. It was noted that a better identification and modeling of the skin layer could influence the results. Clearly, further studies are needed to assess the similarities and differences in power absorption between male and female body models exposed to EMFs of radiating sources.

In summary, available data on electromagnetic power absorption in human body models exposed to plane wave fields show that the choice of the human body model affects the results obtained. The observed differences among the published data are usually more pronounced in local SARs than in SARs averaged over the whole body. The body height, mass, tissue distribution and composition, including fat and muscle, are important factors in power absorption and can explain some differences among the published data. Another fundamental aspect is the value assigned to the dielectric properties of different tissues or organs identified in the body model. In the case of children, the variation in tissue dielectric properties with age also may influence the computed results. It is noteworthy that the above publications have used dielectric properties from the same sources [109,110].

10.4.2.4 Human Exposure to the Field Radiated by Transceiver Base-Station Antennas

The enormous growth in the number of subscribers of mobile telecommunication systems during the past few years has pushed upward the system's capacity. As a result, more and more base stations have been installed on the rooftop of existing buildings in densely populated areas, and many more are expected to be set up as the next-generation mobile networks (UMTS, IMT2000, etc.) are deployed. These installations are giving rise to widespread concerns among the population about possible deleterious effects on human health from exposure to the EMFs radiated by the base-station antennas. Recently, increasing attention has been paid to the topic of numerical exposure and compliance assessment for base-station installations.

A great deal of work has been done in the area of field intensity prediction in the vicinity of base-station antennas to determine the so-called free-space compliance boundary. The studies were aimed toward a direct comparison with reference levels suggested

by international exposure guidelines [100,101]. They generally have neglected both the influence of the environment in which the antennas operate and the dosimetric problem of SAR evaluation inside an exposed subject. In particular, considerable efforts have been spent on determining simplified and efficient analytical [111,112] and numerical [113,114] models to evaluate field levels near base-station antennas. Starting from the theory of collinear dipole arrays, typically employed in base transceiver station (BTS) antennas, practical analytical formulas have been derived to predict average power density falloff as a function of distance from the antenna. The space surrounding the antenna is often divided into a cylindrical-wave region, closest to the antenna, and a spherical-wave region, further away [111]. A complementary formulation also has been proposed, on the basis of an exact asymptotic solution for the radiated field, to derive approximate analytical formulas that allow a conservative prediction of equivalent peak power density as a function of the distance from the antenna [112].

Besides the aforementioned practical analytical formulations, simplified numerical models are often used, by subdividing the antenna into elementary radiators [113,114]. Under the hypothesis of weak coupling between the subelements, the near field can be quickly computed through a superposition of the fields independently radiated by the different elements. Once the radiation pattern of the subelements is known, the field is derived using the antenna gain-based formula [113,114]. For better accuracies in the vicinity of the antenna, an MoM simulation of the subelement can be invoked [114]. These simplified approaches represent extremely fast tools for field intensity prediction, but they are limited by a minimum distance from the antenna where they can be applied in order to maintain an acceptable computational accuracy. On the other hand, when field computations within a distance of a few wavelengths from the antenna have to be done, full-wave numerical techniques, such as FDTD, must be adopted. The accuracy of FDTD models for evaluating the near field of base-station antennas has been investigated and validated through a comparison with measurements carried out in a fully anechoic chamber [115].

Full-wave approaches require knowledge of the internal structure of the antenna, which is not always available. Cylindrical- and spherical-wave expansion techniques have been proposed to evaluate the near field, starting from measurements performed on a surface enclosing the antenna [116–118]. The basic approach consists of performing field measurements on a spherical surface surrounding the antenna and describing the measured field as a superposition of spherical modes [115]. Once the spherical-wave expansion coefficients have been determined, the near field can be extrapolated for all points lying outside the minimum sphere enclosing the antenna. This technique also has been improved to allow extrapolation of the field inside the minimum sphere [117]. To this end, the spherical-wave expansion coefficients are derived for each of the antenna subelements. This approach extends the range of applicability of the formulation to all points outside the minimum sphere of a single subelement, which is much closer to the antenna than the minimum sphere of the overall array. Recently, an alternative solution to extend field extrapolation close to the antenna was proposed, which consists of spherical-wave expansion outside the minimum sphere of the antenna and cylindrical-wave expansion for the region close to the antenna, with an appropriate matching of the two expansions [118].

The effect of the surrounding environment must be taken into account to some extent in dealing with the problem of evaluating induced SAR in a subject exposed to the field radiated by BTS antennas, since the antenna is not operating in a free-space condition. A very interesting approach, applicable to on-site evaluations, consists of using mixed experimental and numerical procedures [119–121]. One procedure is based on on-site measurement of the amplitude and phase of the exposure field distribution over a surface

surrounding the antenna. The measurement is then used to numerically evaluate induced SAR distributions inside a phantom. The measured fields are used to excite the FDTD domain via the equivalence principle [119]. A much faster and efficient procedure uses previously stored FDTD-computed **E**-field distributions inside a phantom exposed to spatially impulsive electric fields, the equivalent spatial impulsive responses of the phantom or Green's functions. The on-site measurement of amplitude and phase of the exposure field is made over an equally spaced grid of points placed on an appropriately chosen surface [120]. The procedure has recently been enhanced and made faster by substituting the spatial impulse response with responses to spatial harmonic components [121]. In this way, good accuracy is achieved using only six to ten spatial harmonic components, as opposed to the 54 spatial impulse responses needed previously.

The aforementioned hybrid experimental–numerical procedures have the great advantage of allowing easy characterization of environmental perturbations to the exposure field by directly including them in the measured field. On the other hand, they require the antenna to be already installed and operating at the time of measurement. The last point makes such procedures not suitable for *a priori* compliance assessment evaluations during the planning stage of a cellular network. For such evaluations, a thorough numerical dosimetric analysis is required. Once again, a possible approach, when the environment can be neglected and the antenna can be supposed to operate under free-space conditions, consists of performing full-wave FDTD simulations and modeling both the BTS antenna and a numerical phantom of the exposed subject. The applicability of such an approach has also been demonstrated, through a comparison with SAR measurements, for exposure locations in close proximity to the antenna [122]. The main drawback of full-wave FDTD analysis is the large amount of memory required to discretize the simulation space for phantom locations not in the close proximity of the antenna. This problem can be faced by exploiting parallel computer architectures with parallelized versions of the FDTD code [123]. Parallel FDTD also has the potential to allow SAR computations for large antenna–phantom distances.

More efficient techniques have been developed that combine two different techniques, one to model BTS antenna and propagation in free space and the other, SAR inside the phantom [124,125]. In particular, if the antenna–phantom distance is such that mutual coupling can be neglected, a hybrid ray-tracing (RT)–FDTD approach can be used [124]. RT is used to model field propagation from the BTS antenna to an equivalent surface surrounding the phantom, and FDTD is employed to study absorption inside the phantom, using RT-derived exposure fields for excitation. For closer antenna–phantom distances, where the mutual coupling cannot be neglected, a hybrid FEM–MoM technique has been proposed [125]. In this case, MoM is used to model the BTS antenna, while FEM is used to study absorption inside the phantom. The MoM and FEM formulations are coupled together and are solved iteratively. These hybrid approaches allow very efficient SAR computation for different antenna–phantom distances and are well suited for evaluating free-space compliance distances, on the basis of SAR restrictions. They do not require the use of derived exposure field reference levels. For example, the RT–FDTD technique has been applied to a common 14-dBi-gain GSM900 antenna using the VH phantom. It was shown that for a total radiated power of 30 W, typical for urban area installations, SAR basic restrictions for the general population may be exceeded at distances of 2 m or less. Note that, at these distances, only occupational personnel are allowed [124].

The RT–FDTD hybrid technique also has been successfully employed to study human exposure to the field radiated by a BTS antenna in an urban scenario, including the effect of environmental perturbations to the exposure field [126]. In this case, image sources have been introduced to represent corner-reflector-like urban scenarios. Three different exposure conditions have been considered for a rooftop-mounted 14-dBi-gain BTS

TABLE 10.6

Spatial Maximum (E_{iMAX}) and Spatial Average (E_{iAVE}) of the Incident Field (rms Value); Maximum SAR Values Averaged over 1 g (SAR_{1g}) and over 10 g (SAR_{10g}), and SAR Value Averaged over the Whole Body (SAR_{WB}) for Three Exposure Conditions

	E_{iMAX} (V/m)	E_{iAVE} (V/m)	SAR_{1g} (mW/kg)	SAR_{10g} (mW/kg)	SAR_{WB} (mW/kg)
Rooftop	4.2	2.8	5.3	3.0	0.12
Balcony	8.1	5.5	13.2	8.5	0.46
Street	1.3	1.1	0.26	0.17	0.01

antenna, radiating 30 W in the GSM900 frequency band: (1) a subject standing on the rooftop, near the antenna mast; (2) a subject standing on a balcony of a building facing the antenna at a distance of 30 m, within the antenna main beam; and (3) a subject standing in the street below the 30-m tall building on which the BTS antenna was mounted. The computed results for the incident electric field and SARs, under these exposure conditions, are given in Table 10.6.

From Table 10.6, because of the high directivity over the vertical plane of base-station antennas, it appears that the highest field levels are not obtained on the rooftop of the building where the antenna is located. Instead, they are on the nearby building, in the direction of the maximum antenna radiation. As expected, the lowest field levels are experienced by a subject standing in the street, as a result of the large distance from the antenna and the off-axis position with respect to the antenna pointing direction. In all cases, the computed SARs are at least two orders of magnitude lower than the basic restrictions, confirming the expected low exposure levels for people living near a BTS installation in urban areas.

More recently, some hybrid techniques have been developed, with enhanced capabilities in modeling complex urban environments, by taking into account diffraction phenomena [127–129]. One such technique uses FEM to model the BTS antenna, the uniform theory of diffraction (UTD) to model the effects of the environment on field propagation, and FDTD to study power absorption in the exposed subject [127]. The technique has been employed to study exposure of a subject standing inside a room with a microcell BTS antenna mounted on the external wall. Another possible hybrid solution exploits time domain physical optics, instead of UTD, to model field scattering from the environment and FDTD to study absorption inside the exposed subject [128].

Finally, a hybrid UTD–FDTD technique has been developed to highlight some key points related to compliance assessment procedures for cellular base-station antennas, in a realistic urban environment [129]. The scenario analyzed consists of a room in one building where the field, radiated by a GSM900 or a UMTS BTS antenna installed on a facing building, penetrates through the room's external wall and window. The relation between SAR in an exposed subject and ambient field in the absence of the subject has been investigated for the complex scenario. As expected, the ambient field showed a highly nonuniform distribution resulting from the many reflections and diffractions that took place. The results showed that whole-body averaged SARs (SAR_{WB}) are closely correlated with the exposure field value averaged over the volume that would be occupied by the exposed subject. In particular, it has been estimated that assessing SAR_{WB} on the basis of volume-averaged field values yields an average error of approximately 6%. Peak 1-g and 10-g averaged SARs, instead, show a rather complex and difficult-to-predict relation with reference to the exposure field. Analysis of the results has revealed that the use of the volume-averaged exposure field value, in the absence of the subject, can lead to

an underestimation of the peak local SARs, up to 36%. On the contrary, using the maximum volumetric value yields an overestimation of peak local SAR (up to approximately four times). The conclusion was that peak local SAR showed a good correlation (15% average error) with the maximum average exposure field value obtained by varying the position of a vertical averaging plane, having a surface equivalent to the projected human body area, inside the volume occupied by the subject.

10.4.2.4.1 *Human Exposure to the Fields Produced by Coexisting Wireless Communication Systems*

The discussions thus far have dealt with the problem of human exposure to fields radiated by a single base-station antenna from the cellular mobile communication systems (i.e., GSM, UMTS, etc.). However, as the development of communication systems making use of wireless technology expands, new exposure scenarios are encountered in everyday life. Following the enormous growth in the number of base stations in densely populated areas, one of the most promising systems in the near future may be the so-called Wi-Fi system, namely, wireless LAN adopting the IEEE 802.11b communication standard. Wi-Fi is characterized by completely different coverage ranges. Unlike base-station antennas of cellular systems, which are installed almost entirely in outdoor locations, access points (APs) of Wi-Fi systems would operate essentially inside buildings. Nonetheless, the EMFs radiated by the two systems will coexist in indoor environments, particularly if buildings located in front of a rooftop-mounted base-station antenna are considered. This poses new questions about human exposure in such environments. It becomes important to assess typical exposure levels attributable to each system.

The problem has been recently addressed by considering exposure of a subject standing inside a room with a Wi-Fi AP and facing a dual-band GSM900/GSM1800 BTS antenna mounted on the rooftop of a nearby building [130]. The AP radiates a power of 100 mW at 2.44 GHz, while the GSM BTS employs an antenna with a 18-dBi gain, radiating a total power of 30 and 20 W in the GSM900 and GSM1800 frequency bands, respectively. The computed results for exposure field values and SAR levels are summarized in Table 10.7 and Table 10.8. Specifically, the first two columns of Table 10.7 show the peak ($E_{\text{vol peak}}$) and average ($E_{\text{vol ave}}$) root mean square (rms) exposure field values over the entire parallelepiped volume where the subject will be placed, while the third column reports the average ($E_{\text{sup ave}}$) rms exposure field values over vertical sections of the parallelepiped volume. In particular, the minimum and maximum field values are given because the averages depend on where exactly the surface is placed. Table 10.8 presents whole-body, peak 1-g and 10-g averaged SARs inside the exposed subject.

It can be seen from Table 10.7 that the highest contribution to the total field level inside the room is not due to the indoor source but to the outdoor one. In particular, the average **E**-field

TABLE 10.7

Exposure Field (rms Values) for the Indoor Scenario (Coexisting Outdoor GSM BTS and Indoor Wi-Fi AP)

	$E_{\text{vol peak}}$ (V/m)	$E_{\text{vol ave}}$ (V/m)	$E_{\text{sup ave}}$, min.–max. (V/m)
GSM900	5.57	3.13	2.73–3.44
GSM1800	3.61	1.70	1.62–1.91
Total GSM	6.18	3.56	3.19–3.93
Wi-Fi	2.51	1.13	1.05–1.19
Total	6.30	3.74	3.40–4.09

TABLE 10.8
SAR Values for the Indoor Scenario (Coexisting Outdoor GSM BTS and Indoor Wi-Fi AP)

	SAR_{WB} (mW/kg)	SAR_{1g} (mW/kg)	SAR_{10g} (mW/kg)
GSM900	0.109	2.41	1.08
GSM1800	0.027	1.31	0.58
Total GSM	0.136	3.07	1.46
Wi-Fi	0.014	0.79	0.35
Total	0.150	3.66	1.60

value attributable to the Wi-Fi system is as low as 1 V/m. The computed data also demonstrate that coexistence of the two systems (GSM and Wi-Fi) is possible without exceeding the reference levels for the exposure field, as averaged over the volume occupied by the body or over an equivalent surface, even if the particularly stringent limits issued by some national regulations (e.g., 6 V/m) are considered. Finally, the SARs presented in Table 10.8 suggest that a typical exposure scenario results in RF absorption that is two orders of magnitude below the basic restrictions, both for whole-body and for locally averaged SAR.

10.4. 2.5 Coupling of Transien t EM Pulses into the Hum an Body

Electromagnetic transient radiations are widely used for studying the susceptibility of test objects to broadband EMPs, and increasingly, pulsed fields are being explored for telecommunication purposes. The main characteristics of these pulse fields are waveforms that include high peak powers, fast rise times, and a narrow pulse width. Earlier investigations on their interaction with biological systems relied on mathematical analyses of canonical shapes of dielectric equivalent bodies, such models as planar tissue layers and bodies of revolution [131–134]. The well-known effect of microwave hearing from pulse-induced thermoelastic pressure in the human head have been investigated both analytically [135–140] and numerically [141–143]. More recently, major strides have been made in the development of UWB systems for wireless telecommunications [144,145]. It promises a powerful combination of low power, high throughput, greater range, and better inherent security, using nanosecond pulses. This section presents predictions of fields and power depositions, which have been obtained from the frequency-dependent FDTD formulations described in Section 10.4.1.5, for models of the biological body.

10.4.2.5.1 Modeling of Tissue Properties with the Debye Equation

For UWB calculations using the $(FD)^2TD$ method, the measured properties for the various tissues may be fitted to the Debye equation (Equation 10.14) with two relaxation constants [77–79]. For the results shown here, the measured properties of biological tissues (muscle, fat, bone, blood, intestine, cartilage, lung, kidney, pancreas, spleen, lung, heart, brain/nerve, skin, and eye) were obtained from the literature. Optimized values for ε_{s1}, ε_{s2}, ε_{∞}, τ_1, and τ_2 in Equation 10.14 were obtained by nonlinear least squares matching to the measured data for fat and muscle (Table 10.9), with τ_1 and τ_2 being the average of the optimized values for fat and muscle. All other tissues have properties falling roughly between these two types of tissues. This was done to facilitate volume averaging of the tissue properties in cells of the heterogenous human model. Having τ_1 and τ_2 constant for all tissues, allowed linear (volume) averaging of the ε values for each tissue in a given cell to calculate ε values for that cell.

TABLE 10.9

Debye Constants for Tissues, $\tau_1 = 46.2 \times 10^{-9}$ s and $\tau_2 = 0.91 \times 10^{-10}$ s (Average of Optimum for Fat And Muscle)

Tissue	ε_∞	ε_{s1}	ε_{s2}

10.4.2.5.2 Induced Currents and SAs

The $(FD)^2TD$ formulation has been used to calculate coupling of an ultrashort pulse to the heterogenous model of the human body. From the calculated internal fields, the vertical currents passing through the various layers of the body are calculated by using the following equation:

$$I_z(t) = \delta^2 \sum_{i,j} \frac{\partial D_z}{\partial t} \tag{10.25}$$

where δ is the cell size ($=1.31$ cm), and the summation is carried out for all cells in a given layer. The layer-averaged absorbed energy density or SA and the total energy W absorbed by the whole body can be calculated using the following relationships:

$$\mathrm{SA}|_{\text{layer } k} = \frac{\delta t}{N_k} \sum_{i,j,t} \frac{E(i,j,k,t)}{\rho(i,j,k)} \frac{\partial D(i,j,k,t)}{\partial t} \tag{10.26}$$

$$W = \delta t \delta^3 \sum_{i,j,k,t} E(i,j,k,t) \frac{\partial D(i,j,k,t)}{\partial t} \tag{10.27}$$

In Equation 10.26 and Equation 10.27, δt is the time step ($=\delta/2c = 0.02813$ nsec) used for the time domain calculations, N_k is the number of cells in layer k of the body, and $\rho\,(i,j,k)$ is the mass density (in kg/m^3) for each of the cells in the corresponding layers.

A typical time domain, UWB pulse with a peak amplitude of 1.1 V/m is shown in Figure 10.23. It is interesting to note that the pulse has a rise time of about 0.2 nsec and a total time duration of about 7 to 8 nsec. The Fourier spectrum of the pulse is shown in Figure 10.24. Most of the energy in the pulse is concentrated in the 200- to 900-MHz band with the peak of the energy being at about 500 MHz.

For purposes of illustration, the results that follow assume the incident fields to be vertically polarized, since this polarization is known to result in the strongest coupling for standing individuals [146]. Also, a uniform plane wave illumination of the whole body is assumed by the incident fields. The $(FD)^2TD$ procedure is used to calculate the temporal

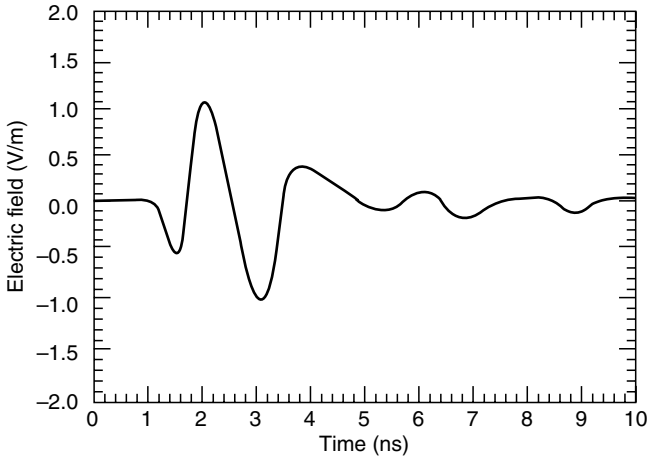

FIGURE 10.23

variations of total vertical currents for the various sections of the body for both the shoe-wearing grounded and ungrounded exposure conditions of the model. The current variations for a couple of representative sections such as those through the eyes and the bladder are given in Figure 10.25a and b, respectively. The calculated peak currents for the various sections are on the order of 1.1 to 3.2 mA/(V/m). It is interesting to note that there is very little difference in the induced currents, whether the model is grounded or not. This is due to the fact that most of the energy in the pulse is at frequencies in excess of 300 MHz, where the effect of the ground plane on the induced currents or the SARs is minimal.

In Figure 10.26, the peak current for each section of the body is plotted with a section resolution of 1.31 cm. The maximum peak sectional current of 3.5 mA, which is equal to 3.2 mA/(V/m), occurs at a height of 96.3 cm above the bottom of the feet. A very similar result also had been observed for calculations using isolated and grounded models of the human body for plane wave exposures at frequencies of 350 to 700 MHz, where the highest induced currents on the order of 3.0 to 3.2 mA/(V/m) were calculated for sections of the body that are at heights of 85 to 100 cm relative to the feet.

The SA and the total absorbed energy for exposure to the UWB pulse can be calculated using Equation 10.26 and Equation 10.27. The total energy absorbed by the body exposed

to a single pulse of the type shown in Figure 10.23 is 2.0 and 1.91 pJ for isolated and shoe-wearing grounded conditions, respectively.

10.4.2.6 Absorption in the Head of Cellular Phone Users

The widespread use of cellular mobile telephone systems has brought about an increased concern for possible adverse health effects from the RF field emitted by the handset. Indeed, exposure standards have been mandated by various national bodies to limit human exposure to cell phone radiations. These RF exposure standards provide specifications in terms of power deposition per unit mass, that is, SAR induced in the user's head, with which cell phones must comply [100,101].

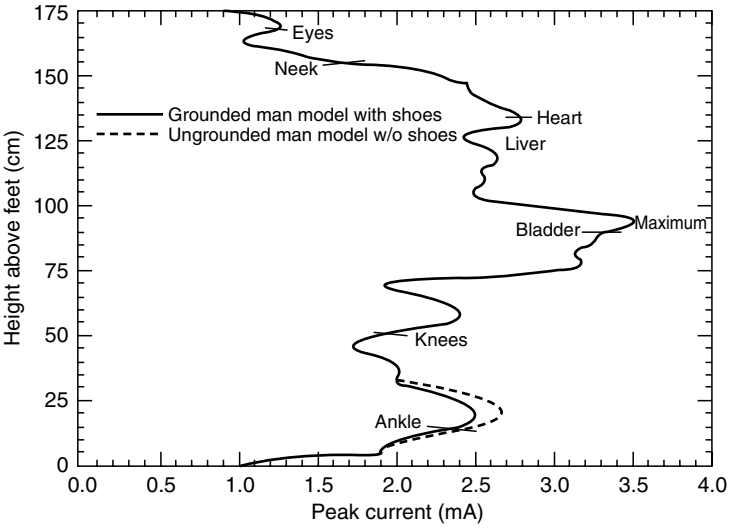

FIGURE 10.26
Peak currents induced for the various sections of the body for shoe-wearing grounded and ungrounded conditions of the model. $E_{\text{peak}} = 1.1$ V/m.

Laboratory procedures for compliance testing of mobile phones are based on experimental measurements, performed according to published protocols [147,148]. In these tests, real phones and phantom head models, shells filled with a material with dielectric properties equivalent to those of the brain tissue at the frequencies of interest, are used. Clearly, the phantom is a simplified model of the human head and is specifically designed for compliance testing. Consequently, it is not suited for an accurate analysis of the SAR distribution in various tissues and organs of the head. A detailed analysis of the distribution of the power absorption would be required to obtain a better understanding of SARs inside the head. Such information is needed for the necessary extrapolation of results from *in vivo* and *in vitro* experimental studies devoted to investigating the effects of RF radiation on humans. They would provide the exposure data needed in epidemiological studies aimed at evaluating any possible dose–effect relations.

Increasingly, advances in computational bioelectromagnetics have made detailed evaluation of SAR distribution inside the human head possible through the use of accurate and realistic models of the human head and the source, that is, the mobile phone, and the use of suitable numerical methods such as the FDTD technique.

The first numerical studies were performed by simulating the phone radiating element as a half-wavelength dipole or a quarter-wavelength monopole mounted on a box [149–154]. These antenna models, and the last in particular, can only be used as a rough model of the retractable antenna, which at the beginning was in nearly all cell phone handsets. However, at present, the need for more and more compact terminals and for dual-band operation has given rise to new antenna types. In particular, two types of antennas have been developed: planar integrated antennas and helical antennas. While half-wavelength dipoles and monopoles can be easily implemented inside an FDTD code, modeling of helix or planar antennas can become a rather difficult task.

The difficulties in modeling helical structures with the FDTD method were revealed in some recent studies. For example, only rather large structures have been studied employing a pure FDTD scheme [155,156]. For smaller structures, published reports had either employed equivalent sources [157] or a hybrid MoM–FDTD technique [158,159]. While these reports show some problems and drawbacks, investigations using FDTD, properly

modified through the use of a graded mesh, have obtained good agreement with MoM and experimental results [160,161]. In these studies, both near-field and radiation patterns of dual-band cell phones equipped with a helical antenna have been reproduced. Moreover, the SAR distributions inside the VH model of the head have been computed, showing a higher penetration depth at 900 MHz and higher superficial SARs at 1800 MHz. Moreover, approximately 80% and 50% of the radiated power was absorbed inside the head at 900 and 1800 MHz, respectively. For a phone in contact with the ear and tilted to bring its axis along the ear–mouth direction (the so-called cheek position), radiating an average power of 250 mW at 900 MHz and 125 mW at 1800 MHz, peak 1-g SARs of 1.65 and 1.08 W/kg were obtained in the head at 900 and 1800 MHz, respectively. In the same examples, the peak 1-g SARs in the brain were 0.13 and 0.06 W/kg at the two considered frequencies, respectively.

Planar antennas can be mounted on the top, lateral, or back sides of the phone [162–165]. Shorted patch antennas typically have a 10-dB bandwidth between 5% and 10% that can be increased to about 12% by parasitically coupling another printed radiator in the vertical direction (stacked patch). For comparison, the bandwidth is about 30% for the monopole antenna [163]. In this case, an important consideration is the influence of the hand wrapped around the handset. For a cell phone equipped with a planar antenna, the hand has a detuning effect on the antenna resonant frequency and causes a reduction of the bandwidth; both are evident where the hand masks the antenna. About 30% of the radiated power was absorbed by the hand, while for the monopole the hand absorption was only 15% [162]. For a radiated power of 250 mW at the frequency of 900 MHz and a head–handset separation of 2 cm, the computed peak 1-g SAR was 0.95 W/kg for a laterally mounted planar inverted F antenna (PIFA), and the result was 0.49 W/kg for a monopole antenna [162]. When a phone equipped with a side-mounted PIFA was kept in contact with the ear, the peak 1-g SAR increased to 1.4 W/kg [164]. Note that the back-mounting configuration gave rise to a substantial (up to three times) reduction in the peak SAR [162].

Another important task for an accurate evaluation of the power absorption in the head is the model adopted for the phone case. The typical approach, followed in the literature, consists of representing the case as a box, that is, a plastic-coated metal parallelepiped [149–165]. In order to model the correct shape of cell phones, both CAD files [166] and topometric sensors [167] have been used. However, in most previous studies, the internal structures of the phone have been modeled simply as a homogenous perfect conductor. Recently, CAD files have been used also to model the internal structures (printed circuit board, battery, keypad and buttons, etc.) of the phone [168]. An alternate approach to a suitable numerical model of the mobile phone was proposed by Pisa et al. [169]. It starts with a simplified model, which includes only the main phone parts (antenna, keyboard, internal box, plastic coating, etc.) having ''realistic'' dimensions and electric properties. The realistic parameters are then tuned by using an optimization procedure, which minimizes a functional that depends on the differences between the measured and simulated electric and magnetic fields in front of the phone and on the SAR inside a cubic phantom. As an example for the applicability of the proposed optimization method, a numerical model of a commercial phone, operating at 900 MHz, was implemented, and the power deposition in the VH model of the human head was computed for various phone–head distances. The results in terms of peak SAR in various head organs and tissues and for various phone–head distances are presented in Table 10.10. The SAR_{1g} and SAR_{10g} show a monotonic decrease when the phone–head distance increases, while the peak SARs inside the head tissues reach their maxima when the phone is kept at specific distances from the head. This behavior is due to the fact that with the telephone pressed against the head, the power absorption is confined to a limited region in front of the

antenna feed point, whereas by moving the handset away from the head, a greater portion of the head is exposed. When the distance was further increased, the SAR decreased monotonically as a result of the decay in field intensity. This study also showed that the use of inaccurate phone models (last row in Table 10.10) could give rise to SARs, averaged over 1 g, up to three times higher than those computed for the optimized model [169].

Faced with a rapid saturation of the cellular phone market, many cell phone manufacturers and service providers are turning their attention toward youths in promoting handsets that are cheap, with inexpensive service plans, or both [170]. An issue of particular interest is the possible difference in power absorption between children and adults. To answer this question, the first problem to be addressed is the realization of an accurate numerical model of a child's head. Because of ethical concerns, the availability of anatomical models of children has been limited. The common approach for obtaining a model of the child has been the reduction of the dimensions of the voxel size of adult models. Sometimes, this reduction was performed by employing different scaling factors for the different parts of the head. It appears that dielectric constants for children may be considerably higher than adults [171]. However, since the detailed data for the dielectric properties of tissues in children are scarce, they are usually assumed to be equal to those of adults or generically increased by a constant factor in most models. Nevertheless, using these models, some papers have reported increases of up to 50% in the peak 1-g SARs in the child head, compared to an adult head, for exposure to cell phones operating at frequencies around 835 and 1900 MHz [151,172]. A similar increase has been observed in the peak 1-g SARs obtained in the brain. A possible explanation of these results is the larger depth of penetration of power in the child models as compared to the adult one [151,172]. Other papers devoted to the investigation of differences between child and adult exposure to cellular phones have shown no significant difference in peak 1-g SAR between adults and children [173,174]. There are several possible explanations for the discrepancy. It has been suggested that the contradictory results may be due to the different phone excitation schemes used by different authors [175]. The disparity in distances of separation between the antenna and the head also was suggested as a pivotal factor in determining the reported discrepancies [170].

In an effort to help resolve the discrepancies, the SAR distributions induced in two child's head models, an isotropic scaling of the VH head (child size, CS) and an

	CL	0.27	0.91	0.30	0.06	0.15	0.10

tanisotropic scaling of the VH head (childlike, CL), have been computed and compared with SAR distributions induced in the VH by a mobile phone equipped with a back-mounted dual-band patch antenna [176]. Some of the results are presented in Table 10.11. It can be seen that the peak SAR_{10g} showed an increase of about 50% and a reduction of about 25% for the child models compared to the adult model at 900 and 1800 MHz, respectively. Moreover, as the brain is closer to the mobile phone in the case of CS and CL heads, the SAR_{1g} in the brain of children is slightly more significant than that for the adult.

Other exposure scenarios also have been investigated, including head exposure inside a car and cell phones not placed in contact with the ear. In some studies, the influence of the metallic and dielectric structures of a car on SAR induced by a cellular phone inside an adult head was analyzed [155,177–179]. Studies performed by modeling the whole car have shown that the main influence on SAR distribution was due to structures that were very close to the head [178,179]. In particular, the presence of a vertical glass wall in parallel with the antenna axis did not significantly influence the SAR distribution, while a metallic wall can cause up to an 80% increase in the peak 1-g SAR [155,177]. The presence of a reflecting wall placed horizontally over the head, simulating the roof of a car, rendered the SAR distribution more uniform, increasing the lower values and reducing the higher ones [155].

Cellular phones commonly are used in contact with the ear. However, when they are used with a headset, they can be positioned at different body locations. Moreover, unintentional exposures also might occur for a subject standing close to someone using a cellular phone, for example, in a crowded environment. The peak SAR produced by a phone placed slightly above the navel of the VH model has been calculated by using the FDTD method, and the results have been compared to those of a flat phantom—modeled as a multilayered transmission line—whose thickness was varied statistically [180]. The exposure of a human subject to a half-wavelength dipole placed at various positions at a distance of 9 mm from the body surface also has been investigated [181]. In particular, 11 different locations have been considered, that is, in front of the right ear and left ear, the nose, eye, heart, lung, shoulder, stomach, hip, lower back, and the groin. The computed results showed that the maximum values of SAR_{1g} and SAR_{10g} occurred, in all cases, when the phone is close to the ear. For all other positions, corresponding to possible locations of the phone when used in conjunction with a headset, peak 1-g SAR values were at least 30% lower than those obtained in the common ear position.

10.5 Temperature Elevations Induced in Biological Tissues by EM Power Absorption

10.5.1 Introduction

EM energy impinging on the human body induces currents and fields inside the body. A major biological response from absorption of EM energy in the RF and microwave frequency range is the elevation of tissue temperature. Consequently, most internationally recognized guidelines for limiting human exposure to EMFs in the RF and microwave range use SAR as the basic dosimetric metric [100,101]. Likewise, the vast majority of studies available in the literature, addressing the topic of human exposure to EMFs, focus their attention on the dosimetric problem of quantifying induced power absorption inside the exposed subject. A central premise of these exposure guidelines is to protect exposed subjects against temperature increases exceeding the threshold for induction of adverse thermal effects. Therefore, an increasing number of investigators are beginning to address the problem of human exposure to EMFs with a thermal analysis to estimate the temperature increment induced inside the exposed subject.

Another domain in which a thermal analysis can be very useful, or even essential, is that of therapeutic applications where EMFs are deliberately used to cause predefined temperature increases in specific target tissues in the body. Some of the applications include hyperthermia cancer treatment and microwave tissue ablation. In such cases, performing a numerical electromagnetic and thermal study of the applicator in its intended operating environment, inside the body, can be a valuable aid in designing the applicator, in establishing the clinical protocol (i.e., power to be delivered, time of application, etc.), and for treatment planning purposes.

In the following, an overview of the available analytical formulations to characterize heating induced by EMFs is presented. Some numerical implementations, suitable to study the thermal problem in realistic situations, are summarized with specific examples.

10.5.2 Bio-Heat Equation

The bio-heat equation (BHE) was originally proposed by Pennes in 1948 to analyze temperature distributions in a resting forearm [182]. Subsequently, it has been modified to study phenomena of heat transport and exchange for the whole body [183,184]. It is an analytical model that describes the temperature distribution $T = T(\mathbf{r},t)$ inside the body. One of the more general formulations of the BHE is given here for temperature rises associated with exposures to EMFs:

$$\nabla \cdot (K(\mathbf{r})\nabla T) + A(\mathbf{r},T) + Q_{\mathrm{v}}(\mathbf{r}) - R_{\mathrm{L}}(\mathbf{r}) - B(\mathbf{r},T)(T - T_{\mathrm{B}}) = C(\mathbf{r})\rho(\mathbf{r})\frac{\partial T}{\partial t}\,(\mathrm{W/m^3}) \qquad (10.28)$$

The five terms on the left side of Equation 10.28 represent heat accumulation (or loss) per unit time and per unit volume at a point inside the body. Specifically, the various ways through which heat is transferred, produced, or removed from the tissue are:

- Heat transfer through internal conduction, where K (W/(m°C)) is the tissue thermal conductivity
- Metabolic heat production (A [W/m^3])
- Electromagnetic power deposition (Q_{v} [W/m^3])

- Respiratory heat losses in the lungs (R_L [W/m^3])
- Heat exchange due to capillary blood perfusion, which is proportional to blood flow and is represented by the parameter B (W/(°C m^3)), and the difference between blood and tissue temperature ($T_B - T$); note that T_B is a function of time (i.e., $T_B = T_B(t)$)

The right side of Equation 10.28 denotes the temperature increase (or decrease) per unit time. The thermal capacitance per unit volume is given by the product between the tissue specific heat, C (J/(kg°C)) and density, ρ (kg/m^3).

It should be mentioned that the BHE assumes that heat exchange with blood takes place exclusively via capillary perfusion. In reality, heat exchange also occurs with large blood vessels. This mechanism does not take the form of a distributed exchange throughout the tissue volume, like the $B(T - T_B)$ term in the BHE, but instead, the form of a localized exchange at the blood vessel walls. To account for it would require the introduction of an additional term in the BHE [185,186]. Moreover, it would require precise knowledge of the structure of the vasculature inside the biological body, which is not always available. However, this mechanism only alters temperature distribution near large blood vessels and does not significantly affect the overall temperature distribution, especially the maximum temperature increases elsewhere in an exposed body [187]. Therefore, this mechanism can generally be neglected without significant loss of accuracy, if the principal purpose is to assess safety compliance of a given exposure situation, from the thermal point of view. On the other hand, proper inclusion of large blood vessels may be important when planning hyperthermia or ablation treatments. The presence of a large blood vessel in the target region may cause temperature elevations to remain below the minimum threshold required for effective treatment.

A first step in using the BHE to compute the temperature increases induced by exposure to EMFs is the evaluation of SAR or local power deposition. In fact, $Q_v = \rho$ SAR is the exogenous heat source responsible for the alteration in temperature profiles inside the exposed subject. Once the Q_v term is determined, the BHE would provide the time evolution of temperature, provided that appropriate initial and boundary conditions are imposed, as discussed later. In this manner, the BHE allows assessment of both the transient response and steady-state temperature increases.

An implicit assumption in the above discussion is that the electromagnetic and thermal problems are independent and can be investigated sequentially. This is equivalent to assuming that electromagnetic transients are irrelevant and therefore the steady-state SAR distributions can be used as the input for the thermal analysis, and that changes in tissue temperature do not alter the field distribution inside the tissue. Concerning the first assumption, the time constants of the electromagnetic and thermal processes are of orders of magnitude different, with the EMF reaching steady state at most after a few microseconds, while thermal constants inside living biological tissues are of the order of a few minutes under usual circumstances. This means that electromagnetic transients can indeed be neglected for the thermal analysis. The second assumption, instead, deserves some more attention. In fact, dielectric constants of biological tissues are temperature dependent, and therefore, the EMF distribution could change as heating proceeds and temperature increases. However, this effect may be neglected so long as the temperature elevation is small, that is, on the order of a few degree Celsius, as is expected for common EMF exposures. If temperature increase is large and the induced variation in dielectric constants is no longer negligible, for example, when heating food in a microwave oven, the electromagnetic and thermal problems must be solved in a coupled manner, iteratively updating the electromagnetic solution as heating progresses [188–190].

10.5.2.1 Initial Conditions

The BHE is a partial differential equation in time and space; its solution requires the specification of both initial and boundary conditions. For studies involving RF- and microwave-induced heating inside the human body, the initial temperature distribution typically is set to the physiological norm, computed as the steady-state solution of Equation 10.28 in the absence of external power deposition ($Q_v = 0$). Thus, the resulting equation is

$$\nabla \cdot (K(\mathbf{r})\nabla T) + A_0(\mathbf{r}) - R_L(\mathbf{r}) - B_0(\mathbf{r})(T - T_{B0}) = 0 \ (\mathrm{W/m^3}) \tag{10.29}$$

In this case, thermal parameters do not depend on temperature and are set to their physiological values at approximately 37°C. Similarly, the physiological value at rest is used for blood temperature. Note that Equation 10.29 does not contain time derivatives and, therefore, does not require any initial condition to be solved.

10.5.2.2 Boundary Conditions

Boundary conditions are needed to account for the heat exchange between the body surface, namely, the skin, and the external environment, in both the general and the steady-state formulations of the BHE as represented by Equation 10.28 and Equation 10.29, respectively. The simplest boundary conditions that can be applied are the adiabatic condition, that is, a thermally insulated surface, or the Dirichelet boundary condition, that is, an enforced surface temperature. Adiabatic conditions can be used to model tissue surfaces in close contact with highly insulating materials, such as the catheters used to insert antennas employed in hyperthermia or ablation treatment. In contrast, Dirichelet boundary conditions can be used for surfaces in close contact with a circulating fluid kept at a constant temperature (forced convection).

Adiabatic and Dirichelet boundary conditions are rather simple but they are not suitable for representing the general heat exchanges that take place at the skin. A general boundary condition, obtained by imposing the continuity of the heat flow perpendicular to the surface of the body, can be expressed as [191]:

$$-K(\mathbf{r})(\nabla T \cdot \mathbf{n}_0)_S = H(T_s - T_A) + \mathrm{SW}(T)(\mathrm{W/m^2}) \tag{10.30}$$

where S is the skin surface and $\mathbf{n}_0$ is the outward unit vector normal to S. The terms on the right side of Equation 10.30 represent the two ways in which heat is exchanged with the environment. In particular, the first term describes heat loss due to convection, and it is proportional to the difference between skin temperature (T_S) and ambient air temperature (T_A) through the convection coefficient H (W/(m^2°C)). The last term represents heat loss due to sweating (SW).

A few words are needed about radiative heat exchange. If one assumes the body surface is surrounded by objects that are all at the same ambient temperature T_A, the expression for heat exchange through radiation from the body surface to the environment, per unit area, is given by [192,193]:

$$Q_r = e\sigma(T_s^4 - T_A^4)(\mathrm{W/m^2}) \tag{10.31}$$

where e is the surface emissivity, σ is Stefan–Boltzmann's constant, and the temperatures are expressed in degrees Kelvin (K). Under normal conditions, T_S and T_A do not differ significantly from about 300 K, and Equation 10.31 can be approximated as [193]:

$$Q_r = H_r(T_s - T_A)(W/m^2) \tag{10.32}$$

where H_r is an equivalent convection coefficient. Therefore, the convective term in Equation 10.32 can effectively model both convective and radiative heat exchanges, by using an overall convection coefficient that also takes into account the equivalent convection parameter H_r in Equation 10.32. There are cases, however, in which the surrounding objects are at different temperatures. In such circumstances, the problem becomes very complex and a possible solution, based on the use of an RT method to connect mutually visible surfaces and consider radiant heat transfer between them, has been proposed [194]. However, the simple approach of an equivalent convection is generally sufficient for an accurate analysis of the thermal problem.

It is worthy of mention that the convective boundary condition also can be used to represent an adiabatic condition by simply setting the convective coefficient to zero. It can also represent an approximate Dirichelet boundary condition, by using a very high convective coefficient and setting T_A equal to the imposed surface temperature.

10.5.3 Thermoregulatory Responses

The temperature of the human body is regulated to within a narrow range of about 37°C, in its core. Under normal circumstances, this is accomplished through an exquisite thermoregulatory mechanism involving sweating and vasodilatation (see Chapter 5 by Black for more details on thermoregulation [285]). The thermoregulatory mechanism is activated whenever the temperature $T(\mathbf{r})$ in specific parts of the body, where thermal sensors are placed, shifts from its basal value $T_0(\mathbf{r})$. In particular, the basal temperature distribution $T_0(\mathbf{r})$, which corresponds to a state of ''thermal comfort,'' is the one obtained in a naked subject when the external air temperature T_A is about 30°C (in a dry environment) [184,195].

Since a part or all of the absorbed electromagnetic energy is converted into heat inside the human body, computations of tissue temperature must take into account the thermoregulatory mechanisms in response to the heat input from RF and microwave absorption, starting from a state of thermal comfort [195]. Specifically, the presence of thermoregulatory mechanisms causes some of the terms in Equation 10.28 and Equation 10.30 to vary with body temperature. The first term that shows a dependence on temperature in Equation 10.28 is metabolic heat production, which may be characterized by the following equation [196]:

$$A(\mathbf{r},T(\mathbf{r})) = A_0(\mathbf{r})(1.1)^{(T(\mathbf{r})-T_0(\mathbf{r}))} \tag{10.33}$$

where A_0 is the basal metabolic rate in the tissue. Equation 10.33 shows that metabolic heat production depends only on local tissue temperature. It must be noted that this dependence is not related to thermoregulation but rather to the fact that metabolic processes are slightly accelerated when the temperature increases.

With regard to the variation of blood flow, there are two different, but essential, phenomena: one for internal tissue perfusion and the other for peripheral (skin) perfusion. For blood perfusion to the internal tissues, the regulation depends only on local tissue temperature [196,197]. Thus, in a simple model, blood perfusion could be assumed to be at its basal value B_0 until the local temperature reaches 39°C. When the local temperature exceeds 39°C, the blood perfusion starts to increase linearly with temperature in order to enhance the local heat removal process, until the local temperature rises to above a value of about 44°C. At this point, the increasing rate of blood perfusion arrives at a maximum. Accordingly, the internal blood perfusions are modeled by the following expressions:

$$B(\mathbf{r},T(\mathbf{r})) = B_0(\mathbf{r})\ T(\mathbf{r}) \leq 39^{\circ}\mathrm{C} \tag{10.34}$$

$$B(\mathbf{r},T(\mathbf{r})) = B_0(\mathbf{r})[1 + S_B(T(\mathbf{r}) - 39)]\ 39^{\circ}\mathrm{C} < T(\mathbf{r}) < 44^{\circ}\mathrm{C} \tag{10.35}$$

$$B(\mathbf{r},T(\mathbf{r})) = B_0(\mathbf{r})(1 + 5S_B)\ T(\mathbf{r}) \geq 44^{\circ}C \tag{10.36}$$

The above model of the internal temperature regulation mechanism is rather simple. A more complex temperature control model, instead, would include regulation of blood perfusion in the skin through vasodilatation. In particular, two different signals are used as feedback to regulate vasodilatation: one is the hypothalamic temperature increase ($T_H - T_{H0}$), used as an indicator of the elevation of the body core temperature, and the other is the average skin temperature increase $\overline{\Delta T}_s$, defined as follows:

$$\overline{\Delta T}_s = \frac{\int_S (T(\mathbf{r}) - T_0(\mathbf{r}))\,dS}{S} \tag{10.37}$$

where S is the skin surface of the body. The two feedback signals are assigned different weights, with a greater importance given to the hypothalamic temperature, and then used, together with local skin temperature, to regulate skin blood flow according to [183,184]:

$$B(\mathbf{r},T(\mathbf{r})) = \left[B_0(\mathbf{r}) + F_{HB}(T_H - T_{H0}) + F_{SB}\overline{\Delta T_S}\right]2^{(T(\mathbf{r})-T_0(\mathbf{r}))/6} \tag{10.38}$$

where F_{HB} and F_{SB} are the weights of the hypothalamic and skin temperature signals, respectively.

From the above discussion, it can be noted that blood acts as a heat transfer agent, taking heat away from the inner body parts, whose temperature is higher than that of the blood, and bringing this heat to the body periphery. There, heat is passed to the skin layers, whose temperature is lower than that of the blood, and dissipated through sweating and evaporation. During microwave irradiation, the net heat exchange, between blood and the various body tissues, is different from zero, and consequently the blood temperature T_B varies according to the following equation:

$$Q_{BTOT} = C_B\rho_B V_B \frac{\partial T_B}{\partial t}(\mathrm{W}) \tag{10.39}$$

where Q_{BTOT} is the net rate of heat acquisition of the blood from the body tissues, C_B and ρ_B are the blood specific heat and mass density, respectively, and V_B is the total blood volume, assumed equal to about 5 L [198]. When the thermal equilibrium is reached, the net heat exchange is null, and therefore blood temperature stays at a constant value, slightly higher than the basal one.

The feedback mechanism that regulates sweating (SW in Equation 10.30) is very similar to that regulating peripheral blood flow and can be described as follows [183,184]:

$$\mathrm{SW}(\mathbf{r},T(\mathbf{r})) = \left[\mathrm{PI} + F_{HS}(T_H - T_{H0}) + F_{SS}\overline{\Delta T_S}\right]2^{(T(\mathbf{r})-T_0(\mathbf{r}))/10} \tag{10.40}$$

where PI represents *perspiratio insensibilis* (insensible perspiration), that is the basal evaporative heat loss from the skin.

In fact, this model still represents a simplification of the thermoregulatory system of the human body, which is very complex. For example, the skin from different parts of the body does not have the same sweating behavior, as implied by Equation 10.40, and there exist other internal temperature sensors, besides the hypothalamus. Notwithstanding these limitations and the great variability in thermoregulatory behavior among different subjects, the model can be considered a good starting point to assess thermal responses in a human subject exposed to an EMF. It must also be observed that in most practical situations, induced thermal elevations are very small and thermoregulatory responses may not be invoked, so that basal physiological values for thermal parameters may be assumed for the BHE.

10.5.4 Numerical Methods for Solving the Thermal Problem

The combination of the BHE and the thermal boundary condition represent a complicated problem, which can become nonlinear if thermoregulatory mechanisms are considered. Analytical solutions of this problem, neglecting thermoregulation, can be obtained only for simplified body geometries and exposure conditions, which allow an analytical determination of the SAR distribution. For example, an analytical solution in stratified media may be obtained as an expansion in eigenfunctions, which are applicable to planar, cylindrical, and spherical multilayer geometries [199,200]. Also, an analytical solution for the case of a multilayer slab has been investigated in terms of Green's functions [201]. More complicated solutions, able to take into account thermoregulatory mechanisms, have also been developed, based on a simplified cylindrical segment approximation of the human body [183,184,202,203]. In particular, the thermal behavior of the human body is simulated by means of two systems: a controlling system and a controlled one. The controlled system, modeled by the BHE, determines the temperature distribution inside the body, while the controlling system provides feedback signals able to modify the thermal parameters of the controlled one in order to maintain a constant body core temperature (thermoregulation). The principal limitation of this approach stems from modeling the body as a few homogenous cylindrical segments, each having a uniform SAR and temperature distribution.

When studying more realistic and detailed geometries, like an anatomically based body model, analytical or cylindrical segment solutions are no longer feasible, and a numerical approach becomes necessary. One possibility is the development of a finite element solution of the BHE [204,205]. However, the most common approach is to use a finite difference scheme, which will be discussed in some detail in the following. One of the main reasons for preferring a finite difference solution, besides its computational efficiency, is that it allows a very simple link with the FDTD method, which is the most popular numerical method for SAR computations. Earlier finite difference solutions of the BHE, used in conjunction with cubic-cell models of the human body, comprised only a few hundred voxels. They used an implicit formulation to avoid the restrictions on the size of the time step. Since these solutions required matrix inversions, they were computationally intensive [16]. As more detailed body models, comprising thousands of voxels, became available, new finite difference solutions were developed. These techniques, based either on explicit or on alternate direction implicit (ADI) formulations, are discussed in the following.

10.5.4.1 Explicit Finite Difference Formulation

One approach to obtain a finite difference explicit formulation of the BHE is based on the thermal balance approach [98]. The body under consideration is divided into cubic cells of

side δ, and the temperature is evaluated at the center of each cell. Temperatures are computed at equal-time steps, δt. In the following, the expression $T^n(i,j,k)$ represents temperature computed at time $n\delta t$ in the (i,j,k) cell. The finite difference formulation is derived by imposing the thermal balance to each cell [192], such that

$$Q_{\text{tot}}^{n,n+1}(i,j,k) = \Gamma(T^{n+1}(i,j,k) - T^n(i,j,k))(\text{J}) \tag{10.41}$$

where $Q_{\text{tot}}^{n,n+1}$ is the total heat accumulated (positive) or lost (negative) in the cell during the time interval $[n\delta t - (n+1)\delta t]$, $(T^{n+1} - T^n)$ is the variation of the cell temperature in the same time interval, and $\Gamma = C\rho\delta^3$ is the thermal capacitance of the cell. The heat $Q_{\text{tot}}^{n,n+1}$ is accumulated (or lost) in the cell through the five mechanisms present in the BHE, and, for boundary cells, also through convection to external air and sweating (Equation 10.30).

Heat transfer through internal conduction is governed by Fourier's law. For the (i,j,k) cell, the heat $Q_{\text{K}}^{n,n+1}$ entering the cell through conduction from the $(i-1,j,k)$ cell in the time interval $[n\delta t - (n+1)\delta t]$ can be derived by exploiting the well-known analogy between heat conduction and electrical current conduction [185,192]. In particular, if K_1 and K_2 are the thermal conductivities of the two cells under examination, heat flows through the series connection of two thermal conductances, equaling $K_1\delta^2/(\delta/2)$ and $K_2\delta^2/(\delta/2)$, respectively. Therefore, heat flowing from the center of the $(i-1,j,k)$ cell to the center of the (i,j,k) cell, through the boundary face, experiences an overall thermal conductance equal to $2K_1K_2\delta^2/((K_1+K_2)\delta)$. As a result, we obtain:

$$Q_K^{n,n+1}(i,j,k) = \frac{2K_1K_2}{K_1+K_2}\delta^2\frac{T^n(i-1,j,k) - T^n(i,j,k)}{\delta}\delta t \tag{10.42}$$

An expression similar to Equation 10.42 holds for heat exchanged with the other neighboring cells.

The contributions of metabolic heat production and electromagnetic power deposition are volumetric heat sources, and therefore the contribution they give to $Q_{\text{tot}}^{n,n+1}$ can be immediately derived and is expressed by Equation 10.43 and Equation 10.44, respectively:

$$Q_A^{n,n+1}(i,j,k) = A(i,j,k)\delta^3\delta t \tag{10.43}$$

$$Q_{Q_v}^{n,n+1}(i,j,k) = Q_v(i,j,k)\delta^3\delta t \tag{10.44}$$

Respiratory losses in the lungs are taken into account by subtracting the volumetric loss R_L from the metabolic heat production A in the corresponding cells for the lung.

Finally, the contribution to $Q_{\text{tot}}^{n,n+1}$ due to capillary blood perfusion takes the form of a volumetric term and can be represented, as in metabolic heat production and exogenous heat deposition, as:

$$Q_B^{n,n+1}(i,j,k) = B(i,j,k)((T_B - T^n(i,j,k))\delta^3\delta t \tag{10.45}$$

For boundary cells in contact with air, heat flow through the face is governed by convection rather than conduction. For a generic cell (i,j,k), considering a face in direct contact with air, the heat $Q_{\text{H}}^{n,n+1}$ entering the cell through convection in the time interval $[n\delta t - (n+1)\delta t]$ is:

$$Q_H^{n,n+1}(i,j,k) = H(T_A - T^n(i,j,k))\delta^2\delta t \tag{10.46}$$

Heat losses due to sweating at the skin surface (SW) are converted to a volumetric heat loss term and are directly subtracted from the metabolic heat production term A in the skin cells.

Note that in Equation 10.42, Equation 10.45, and Equation 10.46, the temperature has been referred to the time instant $n\delta t$ in order to obtain, at the end, an explicit formulation. Starting from the equations given above, general explicit formulations that hold for each cell can be derived. (See the paper by Bernardi et al. [98] for additional details)

10.5.4.1.1 Stability Criterion

Explicit finite difference formulations are straightforward to implement and are computationally efficient, but they have a limitation on the maximum time step δt that can be used without incurring numerical instability.

The stability criterion for the previously mentioned finite difference scheme can be obtained through Fourier's analysis, which yields the following restriction on δt, derived for internal cells (no convective contributions) [206]:

$$\delta t \leq \frac{1}{6(K/C\rho\delta^2) + (B_0/2C\rho)} \tag{10.47}$$

Because of the typical values of thermal parameters and convection coefficients for the human body, the stability criterion for the peripheral voxels, where some of the faces exchange heat through convection rather than conduction, is less stringent than that of Equation 10.47. Consequently, Equation 10.47 may be safely assumed as the stability criterion for the overall scheme.

10.5.4.2 ADI Formulation

While the explicit finite difference formulation of the BHE has been applied to many simulations, it becomes computationally unaffordable when very small cell sizes are used or when high thermal conductivity materials are present in the domain under study. This stems from the extremely small time steps δt that would be required according to Equation 10.47. In such cases, the ADI formulations can be used [207]. ADI is a general method, developed for numerical solution of parabolic equations. It combines unconditional stability, typical of implicit methods, with the computational efficiency due to the tri-diagonal nature of the resulting matrices [208–210]. Note that the Fourier heat conduction equation is a typical parabolic equation. While the BHE is no longer parabolic, because of the presence of the term related to blood flow, ADI can still be applied, but it loses its unconditional stability. In any case, for time steps on the order of a few seconds, the scheme has proved to be stable in typical applications. It can yield reductions on the order of tenfold or more [207] in execution time, over the classical explicit formulation.

The basic idea behind the ADI technique is to extend to the 3-D case the 1-D Crank–Nicolson's scheme, which averages the outcome from the explicit and the implicit formulations to obtain second-order accuracy both in space and in time variables [192]. In particular, Crank–Nicolson's scheme can be extended to the full 3-D case, by using a sequence of approximate Crank–Nicolson solutions along the three axes, indicated as $T^*(i,j,k)$, $T^{**}(i,j,k)$, and $T^{***}(i,j,k)$, the last one being used as the final estimate for $T^{n+1}(i,j,k)$.

The first approximate solution is obtained using Crank–Nicolson's scheme along the x axis only, while backward differencing is used along y and z:

$$\frac{K}{\rho C}\frac{1}{2}\left(\frac{T^*(i-1,j,k)-2T^*(i,j,k)+T^*(i+1,j,k)}{(\delta x)^2}+\frac{T^n(i-1,j,k)-2T^n(i,j,k)+T^n(i+1,j,k)}{(\delta x)^2}\right)$$
$$+\frac{K}{\rho C}\frac{T^n(i,j-1,k)-2T^n(i,j,k)+T^n(i,j+1,k)}{(\delta y)^2}$$
$$+\frac{K}{\rho C}\frac{T^n(i,j,k-1)-2T^n(i,j,k)+T^n(i,j,k+1)}{(\delta z)^2}$$
$$=\frac{T^*(i,j,k)-T^n(i,j,k)}{\delta t}-\frac{A_0+Q_v+B_0T_B}{\rho C}$$
$$+\frac{B_0}{\rho C}\frac{T^*(i,j,k)+T^n(i,j,k)}{2} \tag{10.48}$$

Extending subsequently Crank–Nicolson's solution along the y axis and the z axis, the following expressions are obtained for the second and third estimates:

$$\frac{K}{\rho C}\frac{1}{2}\left(\frac{T^*(i-1,j,k)-2T^*(i,j,k)+T^*(i+1,j,k)}{(\delta x)^2}+\frac{T^n(i-1,j,k)-2T^n(i,j,k)+T^n(i+1,j,k)}{(\delta x)^2}\right)$$
$$+\frac{K}{\rho C}\frac{1}{2}\left(\frac{T^{**}(i,j-1,k)-2T^{**}(i,j,k)+T^{**}(i,j+1,k)}{(\delta y)^2}+\frac{T^n(i,j-1,k)-2T^n(i,j,k)+T^n(i,j+1,k)}{(\delta y)^2}\right)$$
$$+\frac{K}{\rho C}\frac{T^n(i,j,k-1)-2T^n(i,j,k)+T^n(i,j,k+1)}{(\delta z)^2}$$
$$=\frac{T^{**}(i,j,k)-T^n(i,j,k)}{\delta t}-\frac{A_0+Q_v+B_0T_B}{\rho C}$$
$$+\frac{B}{\rho C}\frac{T^{**}(i,j,k)+T^n(i,j,k)}{2} \tag{10.49}$$

$$\frac{K}{\rho C}\frac{1}{2}\left(\frac{T^*(i-1,j,k)-2T^*(i,j,k)+T^*(i+1,j,k)}{(\delta x)^2}+\frac{T^n(i-1,j,k)-2T^n(i,j,k)+T^n(i+1,j,k)}{(\delta x)^2}\right)$$
$$+\frac{K}{\rho C}\frac{1}{2}\left(\frac{T^{**}(i,j-1,k)-2T^{**}(i,j,k)+T^{**}(i,j+1,k)}{(\delta y)^2}+\frac{T^n(i,j-1,k)-2T^n(i,j,k)+T^n(i,j+1,k)}{(\delta y)^2}\right)$$
$$+\frac{K}{\rho C}\frac{1}{2}\left(\frac{T^{n+1}(i,j,k-1)-2T^{n+1}(i,j,k)+T^{n+1}(i,j,k+1)}{(\delta z)^2}+\frac{T^n(i,j,k-1)-2T^n(i,j,k)+T^n(i,j,k+1)}{(\delta z)^2}\right)$$
$$=\frac{T^{n+1}(i,j,k)-T^n(i,j,k)}{\delta t}-\frac{A_0+Q_v+B_0T_B}{\rho C}$$
$$+\frac{B_0}{\rho C}\frac{T^{n+1}(i,j,k)+T^n(i,j,k)}{2} \tag{10.50}$$

Starting from the above expressions, it is possible to derive the general ADI formulation that holds for each internal cell. (See the paper by Pisa et al. [207] for additional details.) The formulation can also be adapted to boundary cells, where convective heat exchange must be considered, by introducing a fictitious external node.

10.5.5 Temperature Elevations in Subjects Exposed to EM Fields

When an EM field impinges on the biological body, a fraction of the incident power is absorbed by the body and is converted into heat in the body tissue. Thus, the absorbed energy can cause temperature increases in various body organs and tissues. If the temperature increase is small, it has little effect and is controlled by the thermoregulatory mechanisms of the body. However, if the temperature increment is large, it can produce irreversible biological damage. For example, a temperature increase of about 4.5°C for more than 30 min would produce neuronal damage [211]. Experiments performed on the rabbit eye indicated that a threshold increase of 3°C to 5°C in the lens can induce cataract formation [212,213]. The temperature increase necessary to induce thermal damage to the skin is about 10°C [214,215], while it is 8°C for muscle tissues [216]. Also, experiments performed using laboratory animals have shown various physiological and behavioral effects when the body core temperature rises more than 1°C to 2°C [100]. (See also Chapter 5 by Black [285].)

Moreover, most RF protection standards have adopted basic restrictions in order to keep the thermal increments below some agreed upon level. In particular, the value of 4 W/kg averaged over the whole body (SAR_{WB}) had been adopted by exposure guidelines as the threshold for the induction of adverse thermal effects associated with an increase of the body core temperature of about 1°C in animal experiments. Restrictions on local SAR were introduced in order to limit local temperature increments, since the ratio of the local peak to whole-body averaged SAR can be as high as 20:1 for exposure to a uniform plane wave [217]. However, it is important to note that tissue heating during EM exposure is strongly influenced not only by the power dissipated in the local tissue volume, but also by the way in which absorption is distributed in the surrounding area, by the thermal characteristics of the tissue and its neighbors, and, finally, by the heat exchange with the external environment. The correlation between local SAR values and temperature increases and between SAR and temperature distributions is not straightforward. There have been many studies dealing with thermal increments due to exposures both to the far field of radiating sources and to the near field of cellular phones. In the following some of these studies will be summarized and discussed.

10.5.5.1 Temperature Increments in the Human Body Exposed to the Far Field of Radiating RF Sources

In the past, temperature elevations due to EM power absorption in the human body have been evaluated using several models. The earlier studies were based on a simplified cylindrical segment approximation of the human body [183,184,202,203]. In these studies, the thermal behavior of the human body was simulated by means of two systems: a controlling system and a controlled one. The controlled system, modeled by the BHE, determines the temperature distribution inside the body, while the controlling system provides feedback signals able to modify the thermal parameters of the controlled one in order to maintain a constant body core temperature (thermoregulation). These studies are limited to modeling the body as few homogenous cylindrical segments, each one having a uniform SAR and temperature distribution. A subsequent study [197] used a cubic-cell model with tissue inhomogeneity and took into account the thermoregulatory mechanisms in the BHE. In this case, the BHE was solved using an implicit formulation, which

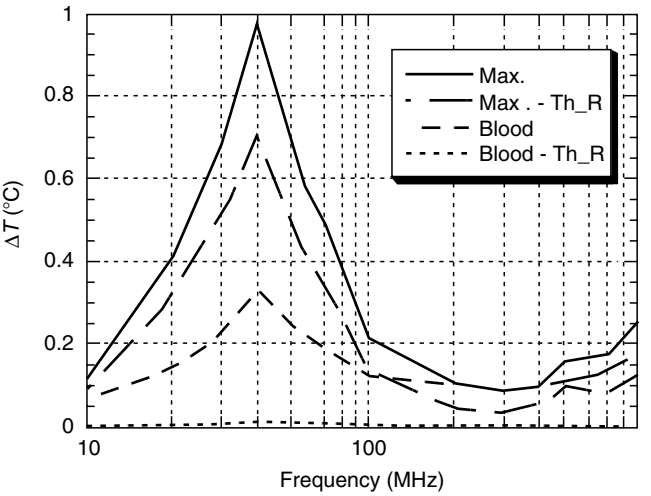

FIGURE 10.27
Maximum temperature increases (ΔT) in the body and blood of a subject wearing shoes, as a function of frequency, with or without thermoregulation (Th_R) for a P_{inc} equal to the limits set by ICNIRP [101].

avoided the restriction in the size of the time step. The explicit formulation requires a computationally intensive matrix inversion. Lately, explicit formulations of the BHE have been developed to study thermal responses in anatomically accurate body models [196,218,219]. In most of these studies, only limited body regions were considered, and thermoregulation mechanisms were neglected.

More recently, the electromagnetic and thermal problems have been combined in a detailed anatomical model of the human body (5-mm resolution) [98]. The FDTD method was used to compute the EMF distribution inside the exposed body, while an explicit finite difference formulation of the BHE, together with an accurate model of the human thermoregulatory system, were developed to compute the corresponding temperature increase.

For an incident power density equal to the maximum permissible value in the International Commission on Non-Ionizing Radiation Protection (ICNIRP) exposure guidelines for the general public [101], Figure 10.27 shows the maximum temperature increase ΔT_{max} obtained inside the body and in the blood as a function of frequency for a subject wearing shoes, both with and without thermoregulation [98]. It can be seen that the highest ΔT values are obtained at 40 MHz. It is also interesting to note that when thermoregulation is considered, the increase in blood temperature is practically zero, while the maximum temperature rise in the body can reach 0.72°C. This happens since blood temperature is very close to the body core temperature, which thermoregulation tends to keep as constant, while the maximum temperature increments are usually found in the superficial tissue layers.

It is worth noting that at 40 MHz, the maximum temperature increase (i.e., 0.72°C in the presence of thermoregulation) is found in the muscle tissues of the ankle. The threshold for the induction of thermal damage in muscle is about 45°C [216], which corresponds to a temperature increase of about 8°C. This temperature differential coincides with the safety factor of 10 promulgated by ICNIRP [100] for occupational exposure in limiting the power density from inducing a thermal effect. Moreover, a safety factor of 50 can be deduced from the temperature increase obtained at 10 MHz and in the frequency range between 100 and 900 MHz, where the maximum temperature increases are less than 0.16°C.

Figure 10.28 shows the distribution of the maximum temperature increase for each horizontal layer of the body at 40 MHz (a) and 900 MHz (b), for an incident power density of 1 mW/cm.^{2} At 40 MHz, the maximum temperature increases are obtained at the level

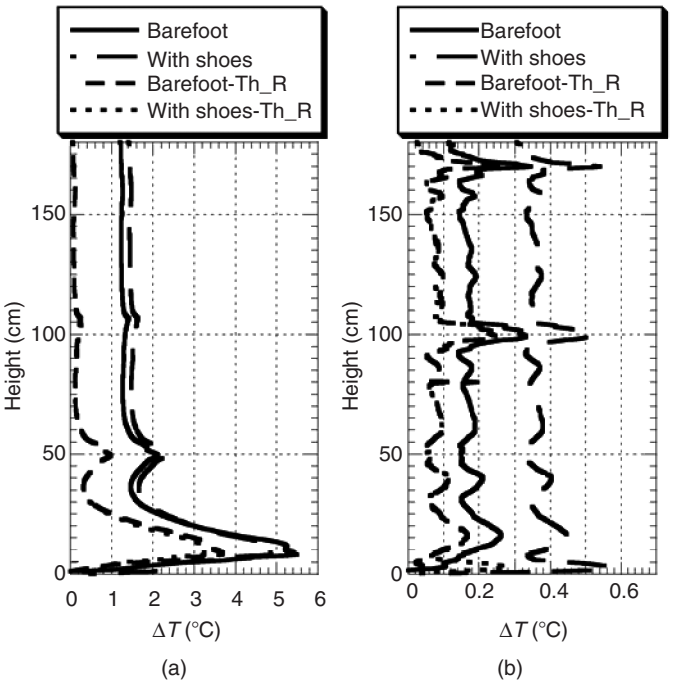

FIGURE 10.28
Layer peak temperature increase (ΔT) in the absence or presence of thermoregulation (Th_R) for a grounded subject barefoot or with shoes ($P_{inc} = 1\,mW/cm^2$). (a) $f = 40\,MHz$ and (b) $f = 900\,MHz$.

of the ankles, where the maximum local SARs also are located. The result showed that the presence of the shoes could influence temperature change. Since shoes are isolators from the thermal point of view, they prevent heat flow from going to the ground through them and provoking higher heating within the body. The only exception is in the ankle section, where heating was higher in the barefoot model because of the higher SAR values, at 40 MHz.

Also, the presence of the thermoregulatory mechanisms reduced the temperature increase almost uniformly along the body. Figure 10.28 illustrates clearly the role of blood convection in heat exchanges. In fact, even without active thermoregulation, heat could be spread from the point where its deposition is relatively high (e.g., the ankle at 40 MHz) to the rest of the body, by an increase in the temperature of the circulating blood. Therefore, even if power absorption is limited to one body region, temperature elevations may occur throughout the body. This is clearly visible at 40 MHz, where, although power absorption is mainly confined to the ankle region, in the absence of thermoregulation significant temperature elevations (about 1.4°C, $P_{inc} = 1.0\,mW/cm^2$—see Figure 10.28a) can be observed in the brain. The corresponding elevation in blood temperature elevation is about 1.46°C. It is interesting to note that at 900 MHz, in the absence of active thermoregulation, the brain temperature elevation (0.5°C, $P_{inc} = 1.0\,mW/cm^2$—see Figure 10.28b) is higher than blood temperature elevation (0.35°C), as a result of power deposition inside the brain.

10.5.5.2 Temperature Increments in the Head of a Cellular Telephone User

One consequence of RF power absorption in the human head exposed to the field emitted by a cellular phone is temperature increase in the head. In practical situations, in addition to RF power deposition, there are two other causes for temperature increase. The first one is the contact between the phone case and the user's head (ear and cheek, in particular), which blocks the convective heat exchange between the skin layers and the air. It causes

the temperature to rise in tissues around the contact zone. Obviously, this heating is independent of the radiated power, and indeed it was observed also for a wired phone. The second cause for temperature increase is the heating of the phone itself, because of the power dissipated in the internal circuitry, especially the power amplifier. This heating is transferred to the head tissues via thermal conduction.

Studies on temperature rises in the human head, associated with the field emitted by the cell phone, are usually conducted by using anatomically based head models, a numerical solution of the electromagnetic problem, and finite difference formulations of the BHE [161,164,172,187,220–223]. For example, the dissipation in the power amplifier was simulated by adding a power deposition of 250 mW at 900 MHz and 125 mW at 1800 MHz, uniformly distributed inside the upper part of the phone with a 50% efficiency [161]. The heating effects due to SAR, phone contact, and power dissipation in the amplifier were considered separately and were subsequently added together in order to obtain the temperature elevation. The maximum temperature elevations obtained in the ear and in the brain of a user's head are given in Table 10.12 for 900 and 1800 MHz. The ambient air temperature was assumed to be 24°C and a time interval of 15 min, approximating the duration of a long phone call. Although a steady state would not have been reached, the temperature elevation after 15 min is expected to be very close to the steady-state value [164].

The data shown in Table 10.12 reveal some interesting aspects. First, the temperature elevation induced inside the brain by SAR alone was less than 0.1°C, especially when the phone was kept in the ''cheek'' position. This configuration resulted in a marked reduction in power deposition inside the brain. Table 10.12 also shows that the mere contact of the cellular phone with the ear and cheek, even in a standby mode, in which no RF power is radiated, can cause a temperature elevation in the ear reaching as high as 1.5°C. This is due to the highly insulating properties assumed for the phone plastic shell. A negligible maximum temperature elevation of about 0.01°C, instead, is obtained in the external brain region. If the contribution from power dissipation in the amplifier is included, the induced temperature elevations are not significantly altered. It must be noted, however, that this result arises from consideration of power dissipation in the power amplifier alone. In the real situation, additional power dissipation is present in the internal circuitry of the handset, besides the power amplifier, and hence slightly higher temperature elevations may be observed [221].

Note: Results are for visible human (VH) adult, isotropically reduced child size (CS), and anisotropically reduced child-like (CL) numerical phantoms.

TABLE 10.12

Temperature Elevations Induced in the User's Head, after 15 min, by a Phone Equipped with a Dual-Band Monopole-Helix Antenna (Average Radiated Power: 250 mW at 900 MHz and 125 mW at 1800 MHz)

Frequency (MHz)	Position	Heating Cause	ΔT_{max} (°C)	$\Delta T_{maxbrain}$ (°C)
900	Vertical	SAR	0.221	0.061
	Cheek	SAR	0.136	0.023[a]
		Contact	1.543	0.012[b]
		Contact + power dissipation	1.544	0.012[b]
		Contact + power dissipation + SAR	1.581	0.023[a]
1800	Vertical	SAR	0.155	0.036
	Cheek	SAR	0.085	0.011[a]
		Contact	1.543	0.012[b]
		Contact + power dissipation	1.543	0.012[b]
		Contact + power dissipation	1.549	0.012[b]

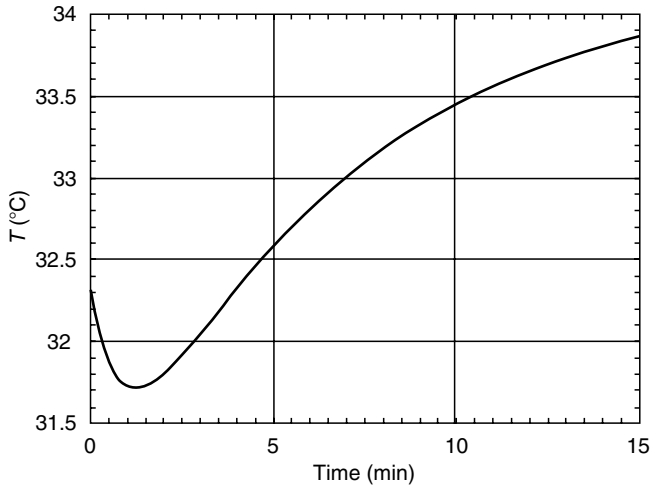

FIGURE 10.29
Time evolution of the temperature at a point on the ear in direct contact with a nonradiating phone.

The effect of the phone contact on the temperature evolution in the ear region is shown in Figure 10.29. It can be seen that when the phone was put in contact with the ear, the ear temperature experienced a quick decrease. This is because the phone was initially at ambient temperature (24°C), which was lower than the ear temperature. However, soon afterward, the heat supplied by the blood and conducted from the neighboring tissues stopped the decrease. Indeed, the temperature started to elevate, going beyond the initial value, because of the suppressed convective exchange with air.

When all heating sources are considered simultaneously, the results indicate that the maximum temperature elevation in the ear was almost entirely due to the contact effect, with only a very slight contribution due to SAR deposition in the ear region. However, the situation was completely different in the brain region. In fact, the heating effects due to SAR and phone contact tend to heat different parts of the brain. The contact-effect heating occurred in the lower external brain region, and the SAR-induced heating appeared mostly in the upper external brain region. Therefore, these two heating effects are not additive in the brain, and when they are simultaneously present, as opposed to the case when only one is considered, the result is that the portion of the brain affected by heating becomes larger. The peak temperature increase in the brain is therefore governed by the more significant of the two heating causes. At 900 MHz, SAR is more dominant, while at 1800 MHz, because of the lower radiated power, the two heating effects are comparable. Note that the ANSI/IEEE safety guidelines, which restrict the 1-g averaged spatial peak SAR to 1.6 W/kg, are associated with maximum temperature rises in the brain between 0.03°C and 0.09°C. These values are about 50 times lower than the threshold for thermal damage. The ICNIRP safety guideline of a 10-g averaged spatial peak SAR equal to 2 W/kg, results in maximum temperature rises in the brain between 0.1°C and 0.2°C, which is about 25 times lower than the threshold value.

10.6 Thermal Therapeutic Applications of Microwave Energy

Recent advances in technological development and in the understanding of EMF interaction with biological materials and systems have launched a broad range of biomedical applications. The following is a brief overview of computational techniques involved in

the development of ablative and hyperthermia therapies, including microwave cardiac ablation, endometrial ablation, and hyperthermia treatment of cancer. All of these therapeutic applications involve the use of microwave technologies to produce localized depositions of electromagnetic energy and, as a result, a rise of the local temperature in biological tissues. The target tissue temperature for the ablative treatments is about 65°C [224,225], whereas for the hyperthermia treatments, it is about 43°C [226]. The ablation treatments include the treatment for cardiac arrhythmias and for endometrial disorders such as menorrhagia. In all cases, the distribution of temperature increase must be carefully controlled in order to avoid excessive temperature increase in the surrounding healthy tissue. (See also Chapter 12 by Chou [284].)

10.6.1 Ablation for Cardiac Arrhythmias

Cardiac arrhythmias are mainly due to the presence of abnormal electrical sources or current paths in the cardiac tissues and are usually treated by destroying the tissue substrate where the electrical anomaly is localized [227–230]. This was performed by surgical resection initially, and later on by delivering a high-intensity DC shock with a defibrillator [227,230]. However, the high voltages and currents associated with the DC shock resulted in uncontrollable cardiac damages and severe complications. Subsequently, the use of RF EMFs to heat and destroy the arrhythmic tissue was proposed [230], and the advantages of microwave technology were demonstrated [228,229].

The RF ablation of cardiac tissue is usually performed using a unipolar arrangement, in which a catheter electrode placed into the heart delivers RF current to a large dispersive ground electrode on the skin surface of the patient. The RF current that flows from the catheter to the ground electrode following radial paths generates heat. While flowing from the catheter, the RF current density decreases as the second power of distance; consequently, the heat generation decreases according to the fourth-power law with the distance from the electrode. With this arrangement, the lesion (ablated tissue) is restricted to a small region (usually about 2 to 3 mm in diameter) contiguous to the catheter electrode, and the lesion dimensions cannot be extended by increasing the delivered power [225,227,229–231]. In microwave ablation, a catheter antenna is inserted into the cardiac chamber and is used to deliver MW power [225,228]. Since MW power deposition inside tissue decays with distance by following a second-power law, deeper lesions can be obtained compared to RF ablation [229,232–234].

In cardiac ablation treatments the lesion is usually defined as the region where temperature exceeds 65°C, which represents the threshold for irreversible damage of this tissue. This region must be large enough to ablate all the abnormal tissue responsible for the arrhythmia. Catheter antennas used for MW ablation have included monopoles [235,236], dipoles [229,237,238], and helices [232,239]. The design of a MW catheter antenna is a crucial point in MW ablation treatments and requires a complete study of the performance of the antenna imbedded in blood and in contact with the cardiac tissue. Performance parameters usually analyzed include the radiation pattern in the tissue; antenna impedance, which governs the bandwidth of the antenna; surface current suppression, in order to prevent heating of tissue along the catheter feeding cable; and dimensions of the induced lesion [240,241].

The design and performance evaluation of the microwave ablation antennas can be conducted by using computational tools and tested through *in vitro* or *in vivo* experimental studies [229,233,238,242]. Numerical tools allow the analysis of antenna performances under different operating conditions, and the evaluation of both electromagnetic power deposition and temperature increase in the tissue. In particular, the numerical evaluation of temperature increase induced inside the cardiac tissue allows the evaluation of blood flow influence on the induced lesion. This evaluation is of fundamental importance since the

The cap-choke microwave catheter antenna.

presence of high blood flow rates inside the heart chambers provides a very effective heat removal process at the heart tissue surface so that the blood flow strongly limits the efficiency of both RF and MW ablation systems. Several numerical studies of SAR and temperature increase have been performed with the FEM [236,243–245] as well as the FDTD [246].

Figure 10.30 shows a cap-choke antenna mounted on an RG/178BU flexible coaxial cable operating at 2450 MHz [238]. The structure was realized by connecting an annular cap to the inner conductor of the cable, and a cylindrical coaxial choke to the outer conductor. A junction, filled with high-temperature epoxy resin, was used to separate the cap from the choke. Figure 10.31 shows the same antenna inserted in a two-layer cylindrical model of the heart. The heart model was used to study the influence of antenna position (touching or pressed into the cardiac muscle) and of blood flow (high or low) on the induced lesion. As an example, some computed results are presented in Table 10.13 for the amount of power to be delivered to the cardiac tissue to obtain lesions of different depths, under four operating conditions for an exposure duration of 60 sec [246].

10.6.2 Ablation for Endometrial Disorders

While still in the beginning stage, microwave and RF thermal ablation of the endometrium have been suggested recently as efficient and cost-effective alternatives to surgical resection as a treatment for dysfunctional uterine bleeding [247–251]. Techniques presently in

use include electrosurgery resection and Nd:YAG laser coagulation under direct hysteroscopic visualization [247,248,252–256]. The reported rates of complete amenorrhea are between 25% and 70% [253,256]. The variability arises principally from the unpredictable nature of induced thermal injury and perforation of the uterine wall [253]. Quantitative measures and patients' subjective reports of microwave endometrial ablation suggest a higher rate of satisfaction, acceptability, and life quality improvement [257,258].

In endometrial ablation, as in cardiac ablation, the design of the catheter antenna should be carefully tested to ensure the desired temperature increase (up to an increase of about 40°C in this case) in the tissue of interest. A sleeved-slot antenna designed for endometrial ablation operation at 915 MHz is depicted in Figure 10.32. The antenna configuration is similar to that of the catheter antenna for cardiac ablation, and is mounted on an RG8U coaxial cable. Figure 10.33 shows a comparison of the axial SAR distribution obtained from an FDTD analysis and from temperature measurements made in a cylindrical phantom filled with a muscle-equivalent material [259]. Two radial distances from the antenna axis, 2.5 and 7.5 mm, are shown. The SAR data obtained experimentally were normalized to the ones obtained from the FDTD simulation with 1.0 W of radiated power.

Figure 10.34 presents the lesion depth, defined as the region around the antenna where the temperature increase was greater or equal to 38°C (final temperature 75°C), as a function of the time of the exposure at different radiated powers. The curves were obtained by considering an antenna inserted in a cylindrical phantom filled with muscle-equivalent material. They simulate an antenna touching the endometrial tissue to be ablated. The lesion dimensions were evaluated as the depth from the antenna outer conductor. These curves can serve as guides in clinical trials where the antenna feeding power and time of exposure are key parameters to be chosen for a desired lesion dimension.

10.6.3 Microwave Interstitial Hyperthermia for Cancer Treatment

Hyperthermia cancer therapy is a treatment procedure in which tumor temperatures are elevated to above 43°C [226]. Investigations performed on cell cultures, tumor-bearing animals, and human patients have clearly shown that hyperthermia affords preferential

killing of malignant cells, enhances the cytotoxic effects of many anticancer drugs, and potentiates the cell-killing ability of ionizing irradiation [260–266].

An important aspect of the development of applicators for microwave hyperthermia is the production of required temperature distributions in superficial and deep-seated tumors, that is, to produce temperatures in excess of 43°C in the tumor tissue, in order to guarantee the destruction of the malignant cells, while maintaining the temperature in the healthy tissue below 42°C to avoid thermal damage. In microwave hyperthermia, the antenna must provide efficient power delivery, good impedance matching at the frequency of operation, and a uniform SAR distribution in the tumor region. However, if the region to be treated is large compared to the field penetration depth, the required SAR uniformity cannot be achieved with a single microwave antenna, and the use of antenna

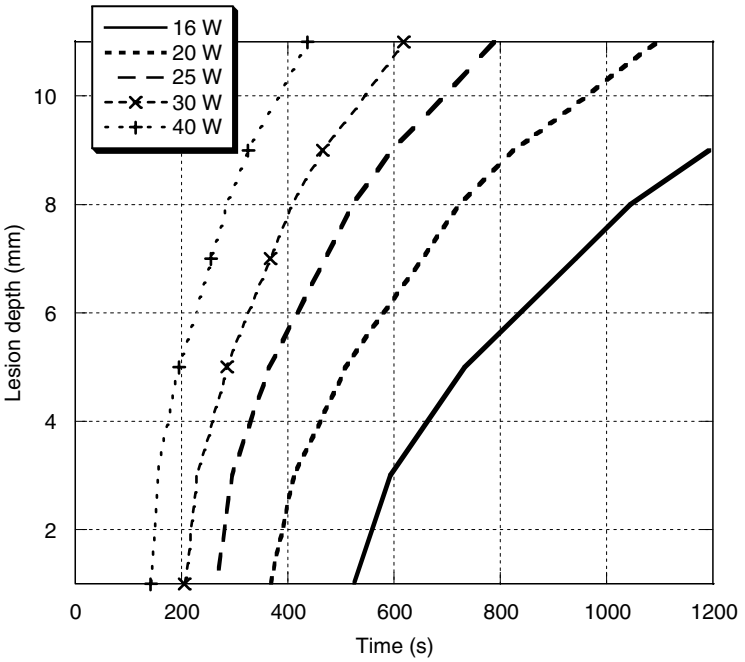

FIGURE 10.34
Endometrial lesion depth as a function of exposure duration for different radiated powers.

arrays becomes necessary. The following paragraphs present some computational results for thin catheter antennas designed for interstitial hyperthermia treatment of brain tumors.

Many investigations have been conducted on electromagnetic power deposition with regard to hyperthermia treatment for cancer. Most earlier studies were conducted analytically, modeling the catheter dipole antenna and surrounding tissue with a lossy transmission line [267–270]. Later, numerical and experimental studies were conducted on several antenna types, with the aim of optimizing antenna performances [270–274]. Considerable attention was devoted to arrays of antennas that have been studied both experimentally [275–277], by measuring the rate of temperature change caused by the radiated power, and theoretically, using antenna theory approaches [275,276,278] or approximate numerical procedures [277,279]. Indeed, antenna arrays have proved to be more suitable for increasing the region of uniform SAR deposition. More recent studies calculated, besides the electromagnetic power deposition, also the corresponding temperature increase. In fact, thermal analysis is a fundamental step in evaluating the effectiveness of the microwave applicator since it allows the assessment of the region where the temperature is above the threshold, and estimation of the required input power. Temperature distributions produced by interstitial antennas in tumor tissues have been experimentally evaluated by using microwave radiometry [277] and computed by using finite difference explicit solutions of the BHE [280,281]. A numerical solution of the BHE allows the analysis of the influence of different parameters such as blood flow on the temperature increase [280] and the development of clinical protocols [281].

Recently, an ADI solution of the BHE has been developed to study a 3-D array of catheter antennas inserted into a brain-equivalent phantom [282]. The antenna considered (Figure 10.35) was a sleeved-slot antenna mounted on a UT-34 coaxial cable [259,283]. An equilateral triangular array of the sleeved-slot antennas was studied in a phantom of brain-equivalent tissue in order to assess its capability in heating tumor regions of various dimensions [282]. Figure 10.36a shows the SAR distribution for 15-mm spacing among the antennas in the array; while in Figure 10.36b, contour plots at $\Delta T = 6^{\circ}\mathrm{C}$ for various radiated powers and for a 15-mm spacing are presented. The graphs shown in Figure 10.36a and b are for a horizontal plane passing through the antenna slot [282].

Results such as those in Figure 10.36 can provide guidance to clinical protocols regarding the input power and optimal geometry (array spacing) for achieving an efficient tumor heating. For example, there is a minimum input power below which three separated regions around the three interstitial antennas constitute the region with temperatures above 43°C. Once this power is exceeded, a simply connected domain is obtained.

It is interesting to note that blood flow is remarkably low in the necrotic core of tumor tissues compared to normal tissue. Moreover, the rate of blood flow in normal tissue increases during hyperthermia. These phenomena may be investigated by varying the blood perfusion parameter in the BHE. Computer simulations, performed by varying the blood perfusion parameter from 5% to 200% of the nominal value, showed that the heat removal mechanism becomes less efficient as the blood flow is decreased, and the effective region of hyperthermia therapy is enlarged [282]. Consequently, the reduced blood flow in the necrotic tumor core and the increase in blood flow in normal tissue can serve to facilitate hyperthermia therapy.

10.7 Concluding Remarks

Knowledge of internal electric and magnetic fields, induced current densities, and SARs is fundamental in the study of biological responses, health effects, and medical applications

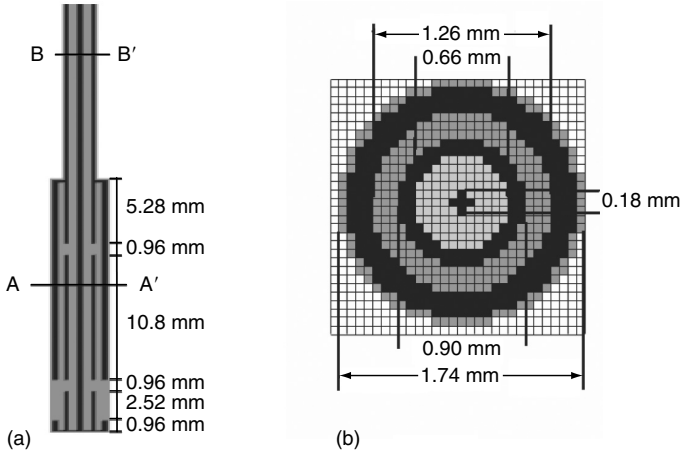

FIGURE 10.35
Longitudinal (a) and horizontal AA′ (b) sections of the sleeved-slot antenna.

of EMFs. Complexities of biological tissues and of the incident fields make closed-form analytical solutions impractical, and computer methods are needed to predict the internal fields and their distributions. Great strides have been made during the past decade in the area of numerical dosimetry using anatomically based models of the human body. Among the most valuable of the numerical methods for predicting field intensities and SAR calculations are the impedance method for use at lower frequencies, where quasi-static approximations may be made ($<\sim$40 MHz for the human body), and the FEM and FDTD methods, which may be used at any frequency of interest. For numerical calculations, the FDTD method requires a computer memory and computation time that is proportional to N. This is a considerable advantage over the computing methods, such as MoM or MoM–FFT. This chapter described the salient features of these methods and the many bioelectromagnetic exposure conditions for which they have been applied. Because of the limitations on the length of the chapter, only a few of the important recent applications of some of these methods were presented in some detail.

Note that numerical methods have matured to a level that they are being increasingly used by researchers in many laboratories for dosimetric calculations for important and

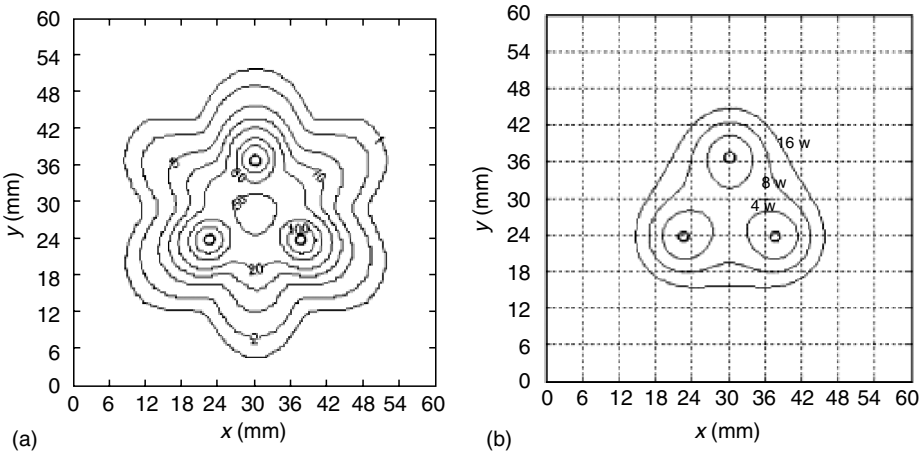

FIGURE 10.36

meaningful bioelectromagnetic problems. Some of the future developments will involve improving the efficiencies of the various codes by techniques such as use of the expanding grid rather than the regular grid, elimination of the relatively shielded interior regions of the modeled space at higher frequencies, and use of truncated models of the body at microwave frequencies where there is a lack of coupling between the various regions of the body. Because of accurate modeling of the tissue heterogeneities and shapes, these models have and will continue to play an important role in emerging technologies with bioelectromagnetic concerns. Some of the likely applications are personal wireless and mobile communications systems, automotive devices such as electric automobiles and collision avoidance systems, medical devices such as MRIs, implantable pacemakers and defibrillators, applicators for hyperthermia, and other minimally invasive therapeutic and surgical procedures.

Experimental EMF Exposure Assessment

Sven Kühn and Niels Kuster

CONTENTS

11.1 Objectives and Limitations

Experimental electromagnetic field (EMF) exposure assessments can be divided into two categories: (1) densitometry, that is, quantification of the incident EMF or the field characteristics at the location of exposed bodies but without their presence, and (2)

dosimetry, that is, quantification of the EMF induced in biological tissues or bodies. In most cases of compliance evaluation, verification that the actual exposure is below a certain value is paramount to accurate determination of the individual exposure. However, highly accurate predictions are needed for some medical applications, for instance, hyperthermia. The focus of this chapter is on dosimetry for frequencies above 10 MHz, often referred to as radio frequency (RF) dosimetry. At lower frequencies, experimental dosimetry is usually limited to measurement of the incident magnetic fields.

11.1.1 Dosimetry

Dosimetry is the science of quantifying the three-dimensional (3–D) distribution of EMF inside tissues and organs of biological bodies. The term is also applied with media having dielectric characteristics similar to biological bodies, for example, cell cultures, tissue-simulating liquids, etc. The induced field is the only field parameter that can interact with biological processes and therefore is referred to as the primary quantity.

Dosimetry usually refers to the assessment of the induced fields on a macro level, that is, the averaged induced fields across cells. Microdosimetry refers to the evaluation of fields across membranes, proteins, etc. This is a new field facing various basic problems such as material models and transitions between classical and quantum electrodynamics. Since the field of microdosimetry has not yet matured and since microdosimetry can be directly developed from locally averaged induced fields in the frequency range considered (<300 MHz), the term dosimetry in this chapter refers to marcodosimetry only.

The distribution of induced fields, particularly at RF, is a complex function of numerous parameters such as frequency, incident field strength, incident angle, field impedance, incident field distribution, polarization, size and shape (posture) of the biological body, tissue distribution, dielectric characteristics of the tissues, etc. In general, the dynamics of the induced field strength range over several orders of magnitude. In other words, the strength and distributions of the fields induced by the same incident exposure greatly vary with anatomy and body orientation with respect to the field and posture.

It is practically impossible to measure the fields noninvasively or *in vivo*; thus, measurements can only be obtained postmortem. The limitations [1] associated with postmortem evaluations include (1) accessibility to only certain tissues, (2) dielectric changes (e.g., lower tissue temperature and decreased blood content), (3) field distortions by the invasively introduced probe, and (4) large uncertainties associated with obtaining accurate measurements near and across tissue boundaries [2,3]. Only the integrated, totally absorbed power can be determined relatively easily by the calorimeter method (see Section 11.3.2.4).

Progress in computational electromagnetics along with the exponential growth of computational power and memory have facilitated determination of the field distributions in full anatomical human bodies with resolutions much smaller than 1 mm^3 (see Chapter 10 on RF modeling by Lin). The lossy and low-resonance properties of complex anatomical structures pose no special challenges for numerical methods (Figure 11.1). Limitations are only due to inadequate phantoms providing insufficient spatial resolution, for example, to accurately represent the scull [3].

Nevertheless, experimental dosimetry is often superior to numerical approaches for the compliance testing of commercial devices. Sources usually consist of highly resonant structures tightly assembled with other electronic and metallic structures. It is difficult to predict with reasonable and known uncertainty whether and how distortion of resonances and excitations of secondary structures might occur through simulations, especially when also considering the scattered fields of biological bodies. Small differences can

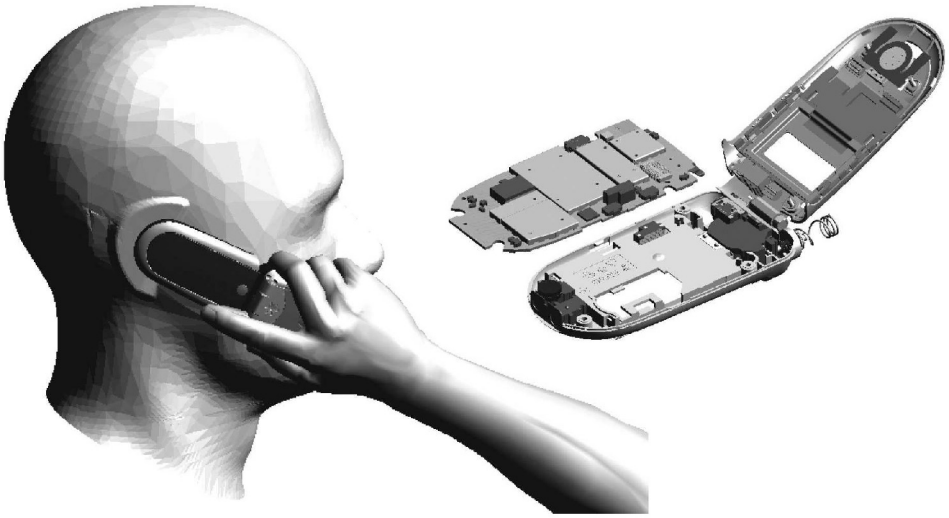

FIGURE 11.1
The latest advances in numerical techniques enable the computation of realistic scenarios without restrictions regarding spatial resolution and material description. The remaining difficulties are material parameters and manufacturing tolerances.

easily result in deviations of more than a factor of 2 from reality. Only when the structure is electromagnetically well-defined can good correspondence between simulations and measurement generally be achieved, that is, with an uncertainty smaller than 20% [4]. On the other hand, experimental techniques allow testing of the physical device under test (DUT) and do not require verification of the computational model.

The detailed information of the field distributions inside anatomical bodies obtainable by numerical methods is often irrelevant, since it cannot be generalized. For safety considerations, the upper boundary of exposure for the entire population rather than individual exposure is relevant. Hence, worst-case phantoms are often applied to assess the upper exposure boundary for specific exposure conditions, for example, from mobile transmitters. Since the degree of freedom for these phantoms is relatively large, they can be chosen homogenously (see Section 11.4.1). Recent evaluation of the procedures for mobile phone compliance testing has confirmed that conservative assessments are possible with a simplified experimental technique using homogenous phantoms [4–6].

During the past decade, considerable progress has been achieved in experimental dosimetric assessment. Since the late 1990s, experimental techniques have been routinely applied for evaluating transmitters operating in the closest vicinity of the body. They have proven to be more reliable, cheaper, and faster. A summary of these techniques and procedures is provided in this chapter. However, dosimetric assessments are limited to homogenous phantoms or to a few tissues in biological bodies. These assessments are normally applied for testing compliance with the basic restrictions or for the validation of results obtained by computational techniques.

11.1.2 Densitometry or Incident Exposure Assessment

Experimental dosimetry requires sophisticated instrumentation, significant expertise, and time. It is impractical for *in situ* exposure assessments. Therefore, easy to apply techniques and methods using a worst-case approach have been developed to determine compliance

with potentially hazardous induced fields by determining the incident fields. The worst-case concept derives the conditions for maximum induced fields inside the human body for an incident field strength in terms of the polarization, field distribution (plane wave), field impedance (plane wave), size, and posture of the human body and its dielectric properties. The induced fields are lower than a value X if the local maximum incident field strength of the E field and H field is below the value Y. Attempts to alter this conservative approach have yielded alternatives with an insufficient scientific and engineering basis (see Section 11.5).

Assessment of the incident exposure is simple for plane wave or far-field conditions. Under these conditions, the E field vector is perpendicular to the H field vector, and both are orthogonal to the direction of propagation. The ratio of the E and H fields is equal to the wave impedance Z at any location:

$$Z = \frac{E}{H} \tag{11.1}$$

and in free space

$$Z_0 = 377\,\Omega \tag{11.2}$$

Furthermore, the amplitude is constant over the entire volume of the absent exposed body. In these cases, it is necessary to measure only one component (E or H field) at one location in space. Unfortunately, far-field conditions rarely occur. However, far-field conditions are approximately met locally by changing the amplitude in space at distances larger than the extension of the reactive near-field zone:

$$r > \frac{2D^2}{\lambda}, \quad D \sim \frac{\lambda}{2} \tag{11.3}$$

$$r > \frac{\lambda}{2\pi}, \quad D \ll \frac{\lambda}{2} \tag{11.4}$$

where r is the radius or distance from the transmitting antenna/structure, λ the wavelength, and D the largest antenna dimension.

In other words, for distances meeting the requirements of Equation 11.3 and Equation 11.4, only the maximum of the field components must be determined to demonstrate compliance.

For any distance smaller than the requirements of Equation 11.3 and Equation 11.4, the maximum of both components must be spatially scanned to reliably predict that the maximal induced fields are below a certain limit. Fine volume scanning of transmitter antennas in the very near field yields greater uncertainty and is more time-consuming than dosimetric measurement in homogenous phantoms. Since such near-field assessments are more conservative than specific absorption rate (SAR) evaluations, they are rarely conducted in the context of exposure assessments.

11.2 Fundamental Quantities of EMF

The basic quantities necessary for electromagnetic exposure assessment are summarized in Table 11.1.

TABLE 11.1

Quantities, Symbols, and Units Used in Experimental Exposure Assessment

Symbol	Quantity	Unit
$\vec{E}$	E field (vector)	V/m
$\vec{H}$	E field (vector)	A/m
S	Power density (scalar)	W/m^2
$\vec{S}$	Pointing vector, $\vec{S} = \vec{E} \times \vec{H}$	W/m^2
W	Energy density	W/m^3
SAR	Specific absorption rate	W/kg
ΔT	Temperature increase	K
J	Current density	A/m^2
$\bar{\varepsilon}$	Complex permittivity, $\bar{\varepsilon} = \varepsilon_0 \cdot \bar{\varepsilon}_r$	F/m
ε_0	Permittivity of free space, $\varepsilon_0 = 8.854 \times 10^{-12}$	F/m
$\overline{\varepsilon_r}$	Complex relative permittivity, $\overline{\varepsilon_r} = \varepsilon_r' - j\varepsilon_r''$	
σ	Conductivity	S/m
μ	Permeability, $\mu = \mu_r \cdot \mu_0$	H/m
μ_0	Permeability of free space, $\mu_0 = 4\pi \times 10^{-7}$	H/m
μ_r	Relative permeability	
c	Specific heat capacity	J/(kg K)
ρ	Mass density	kg/m^3

11.2.1 Primary Quantities: Basic Restrictions

Restrictions on exposure to time-varying electric fields, magnetic fields, and EMF that are based directly on established health effects are termed basic restrictions (see Chapter 8 on standards by Van Deventer et al. [68]). Depending on the frequency of the field, the physical quantities used to specify these restrictions are either the current density (J) or the SAR. The dosimetric quantities used in current guidelines [7–10] are J for frequencies up to 10 MHz and the SAR for the frequency range from 100 kHz to 10 GHz. J is related to the internal electric field by Ohm's law:

$$J = \sigma E \tag{11.5}$$

E is the internal electric field, and σ is the complex conductivity of the tissue.

SAR is the ratio of the average rate of the absorbed power to the absorbing mass. It is defined as follows:

$$\mathrm{SAR} = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\mathrm{d}W}{\mathrm{d}m}\right) = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\mathrm{d}W}{\rho \mathrm{d}V}\right) \tag{11.6}$$

where dW is the incremental energy dissipated in an incremental mass dm included in an incremental volume dV and ρ is the mass density. SAR can also be calculated directly from the electrical loss, which is proportional to the mean square of the locally induced electric field strength E:

$$\mathrm{SAR} = \frac{\sigma E^2}{\rho} = \frac{J^2}{\sigma \rho} \tag{11.7}$$

and to a temperature increase by:

$$\mathrm{SAR} = c\frac{\mathrm{d}T}{\mathrm{d}t} \tag{11.8}$$

where c is the local specific heat capacity of the tissue. Equation 11.8 is valid only if the exposed body is in thermal equilibrium or in a steady thermal state at the beginning of the exposure, and either heat exchange processes can be neglected during the measurement interval or the processes are known to correct dT correspondingly. Current safety standards [7–10] for limiting EMF exposure provide maximum limits for basic restrictions for the uncontrolled/general public as well as for controlled/occupational exposure over the whole considered frequency range. The standards are ambivalent with respect to the quantity SAR. The debate among experts is whether SAR is a dosimetric quantity only relevant as a surrogate for thermally based models of EMF interaction or whether it can describe effects in addition to those related to temperature. SAR is directly related to the induced internal E fields as well as to the current density (Equation 11.7) but only directly related to the induced H fields for special cases.

11.2.2 Derived Quantities: Reference Levels or Maximum Permissible Exposure

The derived quantities are the electric field strength (E), magnetic field strength (H), magnetic flux density (B), and power density (S). As discussed in the previous sections, these quantities were derived from the basic restrictions using experimental or computational methods and represent conservative limits for worst-case exposure scenarios. Derived limits are called reference [7] or maximum permissible exposure levels [8,9]. Compliance with these quantities implies compliance with the basic restrictions. However, if the reference quantities exceed the derived limits, the relevant basic restrictions are not necessarily exceeded. In such cases, compliance can be demonstrated by dosimetric means.

In summary, reference levels are easy to assess if the plane wave or far-field conditions are met (see Section 11.1.2) and the resulting SAR and induced current densities are below the corresponding basic restrictions under all circumstances. Typical reference limits for occupational/controlled and general public/uncontrolled exposure are given in Refs. [7–10].

11.3 Experimental Techniques

11.3.1 Field Probes

E field probes have been used for microwave measurement since the early 1970s. The first power meters were developed by Aslan [11] and Rudge [12]. Aslan used a thermocoupling model consisting of two pairs of thin-film, vacuum-evaporated electrothermic elements that functioned as both an antenna and a detector. Rudge employed two small diode-loaded dipoles as sensor elements. The first prototype of an isotropic, miniature field probe was introduced by Bassen et al. [13] in 1975. Additionally, fiber optic field probes had already been proposed in the 1970s [14]. Comprehensive overviews of field probes are reported in Refs. [2,15].

11.3.1.1 Broadband E *Field Probes*

Diode-based field probes are well established and commonly used for dosimetric assessment. These probes consist of an appropriate field sensor, a detector, transmission lines, and read-out electronics (Figure 11.2). Three mutually orthogonal diode-loaded dipoles with an isotropic receiving pattern constitute the probe. To achieve good spatial resolution and broadband performance, electrically short dipoles are employed:

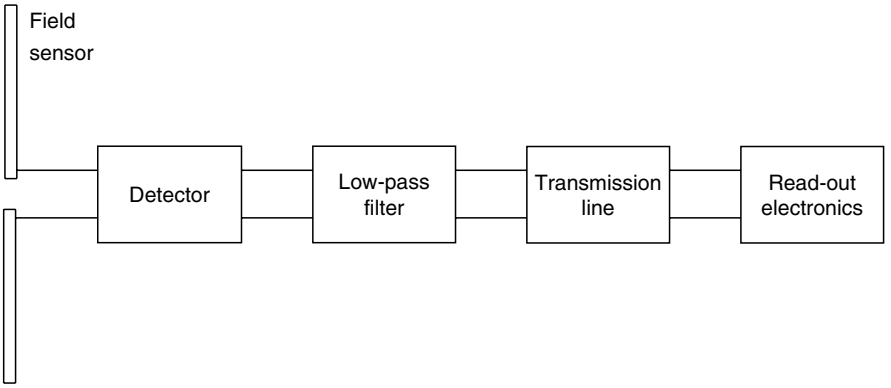

FIGURE 11.2
Simplified schematic of a broadband field probe.

$$\beta h = \frac{2\pi h}{\lambda} \ll 1 \tag{11.9}$$

where h is the length of a dipole arm, β the propagation constant, and λ the wavelength [15]. A flat frequency dependence cannot be achieved if the length of the probe is larger than a fraction of the wavelength ($< 0.05\lambda$). However, this limitation can be overcome by gradually resistive dipoles [16].

Typical isotropic E field probe sensors are shown in Figure 11.3. An RF detector diode (usually Schottky type) is located in the center of the dipole arms. If the detector diode is operated in the square-root law region, the diode current is proportional to the RF power delivered over the dipole to the detector diode. The detector diode is connected with a highly resistive line to the data acquisition electronics. The transmission lines must be designed precisely to eliminate distortions, such as parasitic sensor elements and scattering, which cause degradation of the pattern and unwanted polarization characteristics of the actual receiving antenna. High-resistive transmission lines are ideal for minimizing field perturbation and pickup effects. A detailed investigation of transmission line design

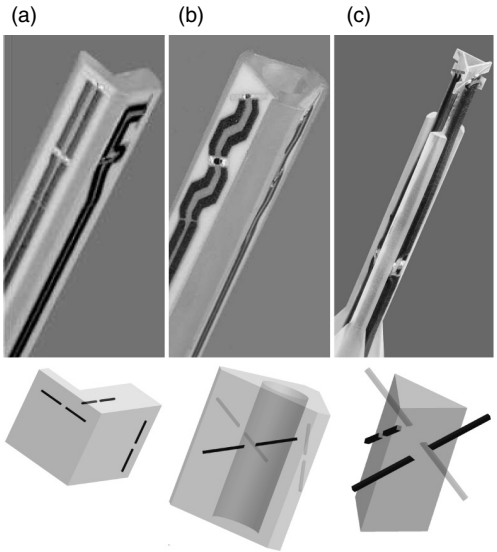

FIGURE 11.3
E field probe configurations: (a) E field probe for measurements in air with one sensor aligned to the probe axis and two orthogonally, (b) dosimetric probe for E field measurements in tissue-simulating liquids allowing integration of an optical proximity sensor in its center, and (c) miniature dosimetric probe with interleaved dipoles. (From IT'IS Foundation. With permission.)

can be found in Smith [17]. Current probe designs apply either thin-film ($R \sim 10\ \mathrm{M\Omega/m}$) [14] or thick-film ($R \sim 500\ \mathrm{M\Omega/m}$) [18] techniques.

The induced fields are recorded by the read-out electronics. The electronics typically consist of a measurement amplifier and an analog digital converter. The read-out field values are then optically forwarded. The optical transmission provides a galvanic decoupling and reduction of field-perturbing conductive parts near the DUT.

In addition to *E* field probes, *H* field probes are also available, the basic theory of which can be found in Whiteside and King [19]. *H* field probes and *E* field probes are basically similar, except for the field sensor element, that is, *H* field probes employ a small loop element instead of a dipole sensor. The disadvantages of loop-based sensors include a strong frequency dependence and currents induced by both *H* and *E* fields. Different methods for flattening the frequency dependence of loop probes have been proposed in Refs. [2,20]. The ratio of the voltage induced in a circular loop with diameter *d* by the *E* field and the *H* field is [19]:

$$\frac{V_E}{V_H} \simeq -\mathrm{j}2\pi\frac{d}{\pi} \tag{11.10}$$

Therefore, for electrically small loops only, that is, $d/\lambda \ll 0.01$, the current will mainly be determined by the magnetic field. In Poković [2], lossy covers were proposed to suppress the *E* field sensitivity of the loop.

In contrast to dipole-based sensors, thermocouple probes are true square-root law [a1]detectors. Such sensors are, for example, used in free space field probes by Narda [21]. These sensors are, however, impractical for dosimetric and near-field applications because of their generally lower sensitivity and dynamic range.

Thermistors are also true square-root law detectors and also small. They can have higher resolution than thermocouples but need more frequent calibration.

Based on the setup of these isotropic field probes, the measured field magnitude is yielded from the root sum square of the three orthogonal components:

$$|X| = \sqrt{|X_1|^2 + |X_2|^2 + |X_3|^2}\ X \in \{E,H\} \tag{11.11}$$

This summation is carried out regardless of any phase differences between the respective components. Hence, if maximum hold peak detectors are applied, the field reading represents the upper bound of the field magnitude.

The output signal of the probes just described is dependent on the following parameters:

- Frequency, modulation, and field strength
- Polarization, direction, and field gradients
- Material boundaries near the probe sensors
- Sources of interference (noise, static and low-frequency fields, vibration, temperature, etc.).

Therefore, it is necessary to quantify the influence of these parameters. Calibration under well-defined conditions is carried out to characterize the most crucial parameters for each probe individually. A detailed summary of different calibration methods for field probes and characterization of the parameters contributing to the measurement uncertainty is given in Poković [2]. All possible influences must be included in the resulting uncertainty assessment, since the conditions during the actual application of the probes differ

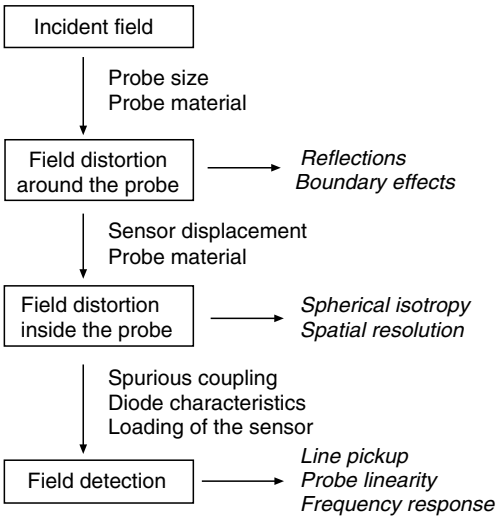

FIGURE 11.4
Impact of the constructional details on the probe characteristics.

considerably from the calibration scenario. Figure 11.4 provides an overview of different probe construction parameters that contribute to the probe characteristics.

Modern dosimetric field probes are available in the frequency range from 10 MHz up to 6 GHz. They have an isotropy error lower than ± 0.5 dB and sensitivities in the range of 1–10 $\mu W/g$ [22]. Modern probes have very small sensor tip dimensions (2.5 mm) and high spatial resolution, allowing measurements very close to material boundaries. A probe with reduced size (tip diameter 1.0 mm) was introduced by Poković et al. [23] and enables accurate dosimetric measurements for frequencies exceeding 10 GHz. Although this probe consists of only a single sensor element, isotropy is obtained by 120° rotation around the probe axis and an appropriately aligned sensor element. Probes for determining both the electrical and the magnetic field vector information are presented by Poković et al. [24]. This technique is based on measurements of five or more field components in space and reconstruction of the ellipse parameters by a combination of a downhill simplex and a Givens updating algorithm.

11.3.1.2 Electro-Optical Sensors

In contrast to RMS sensors, it is possible to measure fields over a broad frequency band in the time domain by exploiting electro-optic methods. Recent advances in semiconductor and photonic crystal research have provided the foundation for the next generation of near-field measurement equipment based on electro-optical methods. The basic concept of electro-optic probes is shown in Figure 11.5.

The most important electro-optic effects for measuring EMF are the Pockels effect and the quantum confined Stark effect (QCSE). The Pockels effect describes the refraction index dependence on the induced E field of anisotropic dielectric crystals such as cadmium telluride (CdTe) [25] or lithium nobiat ($LiNbO_3$) [26,27]. H field-sensitive crystals have also been determined, for example, cadmium manganese telluride (CdMnTe) [25]. The QCSE is based on the change of the absorption spectrum of a semiconductor structure under the influence of the electric field. Sensors exploiting the Pockels effect are reported in Refs. [25–27]. A detailed summary of electro-optic phenomena, materials, and applications can be found in Agullo-Lopez et al. [28]. Alternatively, the signal from the field sensor can modulate a small laser diode rather than the external electro-optical modulation.

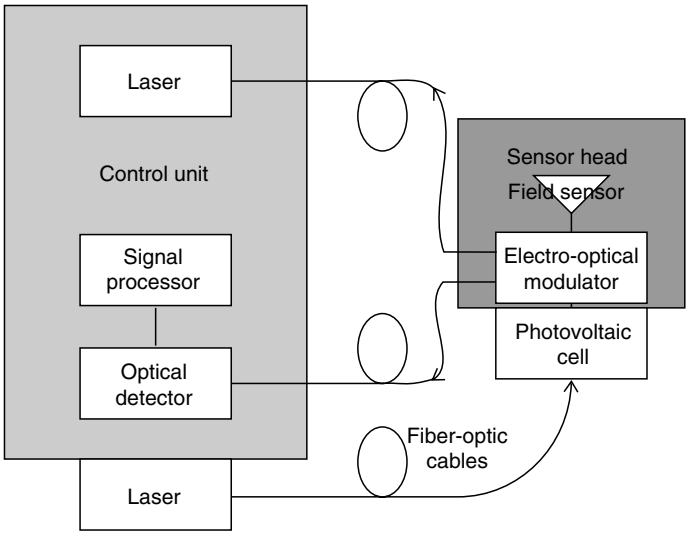

FIGURE 11.5
Principle of an electro-optic probe for EMF measurements.

The most common modulators are the Mach–Zehnder interferometer (MZI) as well as the already mentioned method of the direct modulation of the laser-diode current. The MZI (Figure 11.6) splits the light of a single-mode fiber into two parallel branches of $LiNbO_3$ waveguides. The feedpoints of the dipole are connected to electrodes that are located between the parallel branches, resulting in the antipodal modulation of the phase of the light. For recombined light, the phase modulation results in an intensity modulation. Sensitivities of 1–10 mV/(m Hz) can be reached. The upper cutoff frequency of these sensors is primarily determined by the length of the branches. For high sensitivity, the transit time through the interferometer must be much lower than the periodic time of the signal being measured. In Refs. [26,27], interferometers with a 3-dB bandwidth of 10 GHz were realized. A possibility to overcome this limitation could be the application of traveling wave modulation [29].

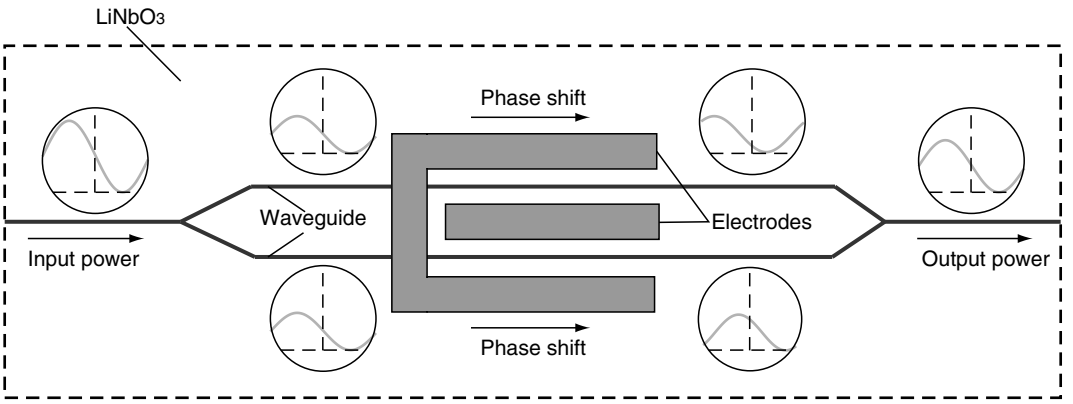

FIGURE 11.6
Schematic of an MZI. The light through the waveguide is modulated antipodally by the electrodes by changing the refractive index of the $LiNbO_3$ substrate.

Another approach reported in Ref. [25] uses only nonconductive parts in the sensor tip. Different types of crystals that are sensitive to electric and magnetic fields are used. Linear polarized light passing through the electro-optic crystal is reflected on a dielectric mirror and passes through the crystal again, where the polarization is changed. A beam-split polarizer transduces the ellipticity change into a change of the optical intensity. Sensors with a sensitivity of 10–400 V/m and 0.1–0.8 A/m in the frequency range from DC to 2 GHz were realized.

For modulation using QCSE, semiconductors with pn- or pin-junction structures are used. A varying reverse bias over the junction modulates the electric field and consequently the absorption and reflection spectra of the semiconductor as well. If the modulator is operated at a constant frequency, different reflection and transmission characteristics of the light and an intensity modulation result.

In addition to passive modulation (QCSE), direct modulation of a vertical cavity surface emitting laser (VCSEL) [30–32] has recently been applied. The current through the laser is directly modulated by the measurement signal. The VCSEL is especially suitable for modulation because of its high bandwidth, low threshold current, and low noise.

The MZI is the most popular modulation method among the three mentioned, and several commercial products are available based on this technology. Disadvantages include the limited ability to reduce its size as well as the bandwidth limitations. Passive modulators are relatively simple to manufacture as integrated circuits. Although passive modulators are inferior to MZI regarding sensitivity, the development of miniature field probes applying the VSCEL technology is currently the most promising approach.

11.3.2 Temperature Instrumentations

11.3.2.1 Temperature Probes

The locally induced SAR can also be assessed by temperature measurements, as summarized in Equation 11.8. A typical temperature rise curve as applied for SAR measurements is shown in Figure 11.7. Two types of temperature probes exist: those based on thermistors and those based on optical effects. The requirements for temperature probes for SAR assessments are:

- *Small size:* The probe must be small to resolve high temperature gradients, without disturbing the temperature distribution as well as the RF field.
- *Nonconductive materials:* Only electrically nonconductive materials prevent heating of the probe by induced currents and are transparent to EMF.
- *Low noise level:* Especially for dynamic temperature measurements, for example, SAR, small differences must be detected accurately. Therefore, the noise level should be much smaller than 10 mK.
- *Short reaction time:* A short reaction time is essential for SAR measurements, since the temperature rise (dT/dt) is only proportional to the SAR if heat diffusion does not occur. An appropriate probe must have reaction times much lower than 100 msec [33].

Temperature probes for SAR measurement using thermistors were first described by Bowman [34]. These probes utilize high-resistance thermistors that are connected through high-resistance lines to the read-out electronics. In Burkhardt et al. [35], a temperature probe based on a VITEK thermistor (BSD Medical Devices, U.S.A.) is presented. This probe has a noise level of 5 mK, a sensitivity of 5 mK/sec, and a tip diameter of

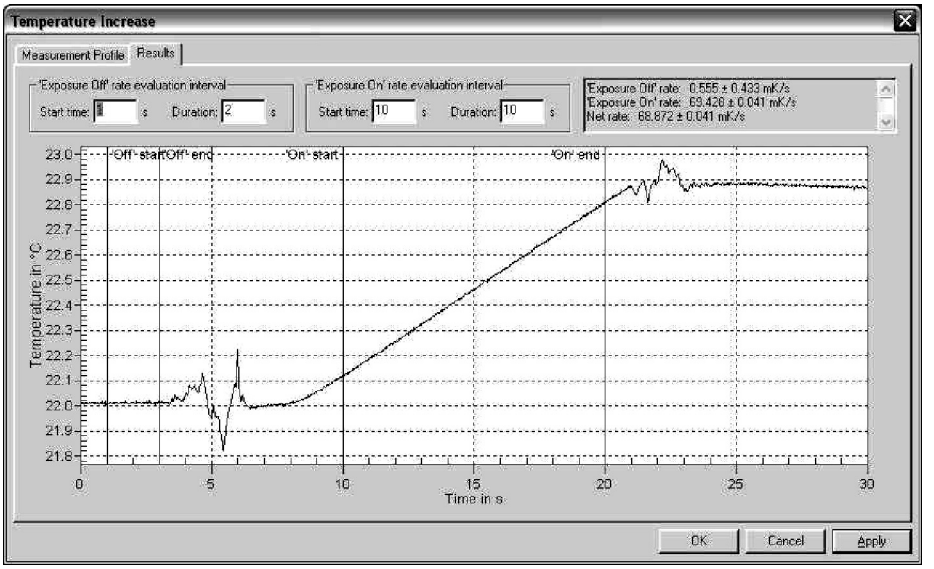

FIGURE 11.7
Typical temperature rise curve for SAR assessment. The linear part of the rise curve is applied for the calculation of the SAR. (Acquired using DASY4 from SPEAG, Switzerland.)

1 mm; however, it has a relatively slow response time of 240 msec. In Schuderer et al. [36], a novel temperature probe design for dosimetric assessments was introduced. The probe provides a spatial resolution of 0.02 mm^3, noise level of 4 mK, a sensitivity of 0.5 mK/sec, as well as a response time of only 10 msec.

In addition to the thermistor concept, temperature probes based on thermo-optical effects are also available. These probes are applied in high-voltage transformers, industrial microwave ovens, and hyperthermia treatment. One of the exploited effects is the decay rate of a phosphorescent layer at the tip of a fiber optic cable [37]. These modern commercially available probes have a noise level of 0.1 K and reaction times of 250 msec. Another exploited effect is the interferometric application of a cavity that is filled with materials that have highly temperature-dependent refraction indices. These probes reach sensitivities of 2–3 mK/sec [35].

11.3.2.2 Infrared Photography

The measurement of temperature by black body-equivalent radiation (infrared photography) is an alternative to invasive measurements using temperature probes. The resolution of infrared thermographs can be very high (<1 mm), and the sensitivity of affordable systems has continuously improved over the years. This was also one of the first methods to measure SAR [38], since the surface radiation can be recorded quickly using infrared cameras without perturbation of the incident field. Infrared cameras were also used to measure the temperature of Global System for Mobile Communications (GSM) mobile phones [39]. The technique has several disadvantages:

- It has limited sensitivity compared to temperature or dosimetric probes.
- It is limited to surfaces.

- The thermal radiation characteristics of the materials must be determined accurately.
- The background radiation must be homogenous.
- Evaporation and convection can cause substantial errors and must be controlled.
- Different aspect angles of the camera can cause different results.

11.3.2.3 Microcapsulated Thermo-Chromic Liquid Crystals

A novel idea to assess 3-D temperature distributions optically and in quasi real time was proposed by Suzuki et al. [40]. Microcapsulated thermo-chromic liquid crystals are suspended uniformly in a gel with the dielectric properties of human muscle tissue. The temperature of the gel is determined by measuring the light scattered from a laser beam that scans through the liquid. The technique has a limited dynamic range and sensitivity.

11.3.2.4 Calorimeters

Calorimetry specifies methods for measuring heat due to biological, chemical, or physical processes that are endothermic or exothermic. Calorimetric methods are suitable for determining average whole-body SAR, but they cannot reveal SAR distributions.

Calorimetry can be subdivided into two types:

- *Direct calorimetry:* The heat is determined directly using calorimeters.
- *Indirect calorimetry:* The amount of expressed heat is determined indirectly by measuring the amount of oxygen consumption and relating it to the oxicaloric equivalent of the reaction.

Basically, calorimetric dosimetry analyzes the heating and cooling processes of an exposed sample. Typical calorimeters used in microwave dosimetry are the Dewer flask calorimeter and the twin-well calorimeter [41].

11.3.3 Measurement Antennas

Different types of broadband matched antennas are usually applied for the frequency-selective exposure assessment of external fields. These measurement antennas are matched to 50 Ω to be compatible with standard RF measurement equipment. They are usually applied for far-field measurements of emissions by cellular telephony base stations, broadcast services, etc. Common broadband RF measurement antennas such as horn or logarithmic periodic antennas have a certain directivity. For example, for an antenna with a 45° beam width, more than 18 measurement directions are necessary for each polarization, since the receiving patterns do not have the shapes of square sectors. This reduces the applicability of these antennas for complex propagation scenarios, that is, locations where the received field is not dominated by a direct line of sight propagation path but by multipath reception. Tuned dipole antennas do not show a directivity in the radial direction, but they lack broadband operation. Conical [42] and biconical [43] antennas have the advantage of nondirectiveness in the radial direction and generally good broadband characteristics. If, for example, the ADD3D method [44] is applied in combination with a conical dipole antenna, the measurement orientations for a fully isotropic scan can be reduced to three different directions. In this case, the

isotropy is obtained by an antenna alignment similar to near-field probes, such that the resulting field is:

$$|E| = \sqrt{|E_1|^2 + |E_2|^2 + |E_3|^2} = \sqrt{|U_1|^2 + |U_2|^2 + |U_3|^2} \cdot AF \tag{11.12}$$

where AF is the frequency-dependent antenna factor in linear quantities (1/m) and U_i is the antenna output voltage at the three different antenna orientations. To obtain the antenna output voltages, a measurement receiver (see Section 11.5.1) connected via a well-characterized cable is applied. The antenna output voltage is:

$$|U_{i_{\text{antenna}}}| = |U_{i_{\text{receiver}}}| \cdot \text{ATT}_{\text{cable}} \tag{11.13}$$

where $|U_{i_{\text{receiver}}}|$ is the voltage measured with the receiver and $\text{ATT}_{\text{cable}}$ the attenuation of the cable in linear units. Other sources of attenuation, for example, attenuators to reduce the Voltage standing wave ratio (VSWR) of the measurement antenna, must be similarly considered.

11.4 Near-Field Scanners

11.4.1 Scanners for Dosimetric Compliance Testing

In dosimetric compliance tests, exposures from RF transmitters operating in close proximity to the body, for example, mobile phones or body-worn wireless devices, are compared to the basic restrictions (see Section 11.2.1). This is a complex task, since the exposure greatly depends on the device design, the position of the device with respect to the body, the external and internal anatomy, as well as the effect of the backscattered field on the device (Figure 11.8). In order to obtain a reliable assessment with acceptable effort, the standards must determine the maximum or 90th percentile exposure for the entire

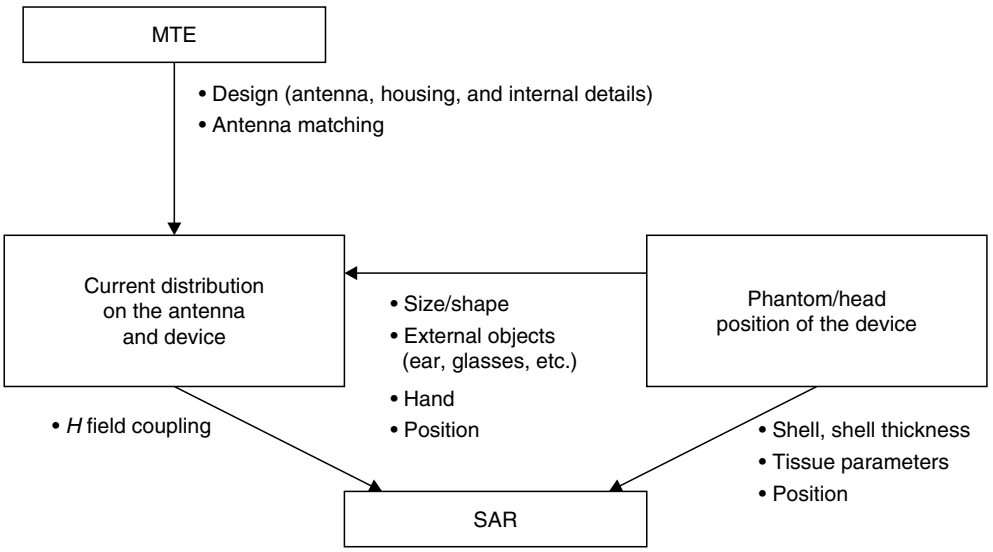

FIGURE 11.8
Overview of impact parameters for dosimetric compliance testing of mobile terminal equipment (MTE).

population that may be operating the DUT. Measurement standards have been developed by different organizations, for example, by the International Electrotechnical Commission (IEC), the Institute of Electrical and Electronics Engineers (IEEE), the Association of Radio Industries and Businesses (ARIB), Korea Electromagnetic Engineering Society (KEES), and others.

In general, a dosimetric evaluation requires the measurement of several hundreds of points distributed over a complex 3-D phantom. The task is divided into (1) searching for the location of the maximum absorption on a 2-D grid and (2) determining the peak spatial SAR value on a fine 3-D grid. Especially at high frequencies, these points must be determined with high accuracy to achieve low measurement uncertainty despite high attenuation and large spatial field variations. Automated dosimetric assessment systems are utilized to perform these compliance tests. A typical configuration of a dosimetric assessment system is shown in Figure 11.9 and Figure 11.10. A computer-controlled six-axis positioner with excellent positioning repeatability of ± 0.2 mm is used to move the dosimetric E field probe within the scanning grid, which can be adaptive, for example, along a surface that is being detected during the scanning job. The different field probe designs have already been discussed in Section 11.3.1. Phantoms, for example, the specific anthropomorphic mannequin (SAM) phantom, elliptical phantom, etc., and tissue-simulating liquids (see Table 11.2) have been developed and validated with respect to the 90th percentile requirements [45]. A detailed description is provided by Schmid et al. [18]. Because of the strong curvature of the SAM phantom, sufficient accuracy can be obtained only when the measurements are taken with the probes aligned normal to the phantom boundary. The most elaborated components, procedures, and algorithms are employed (Figure 11.10), and an expanded total uncertainty ($k = 2$) for the compliance test of less than 20% can be achieved with even better repeatability.

It should be noted that this approach provides reliable conservative estimates of the maximum peak spatial SAR that might occur in the user population but little information about the exposure of specific tissues.

11.4.2 Fast Dosimetric Scanners
