
Figure A.3. Estimated number and range of world-wide and regional cases of childhood leukaemia among children under 14 years of age that are possibly attributable to EMF arithmetic mean exposure > 0.3 μT (and the corresponding derived confidence interval). Regional range is based on the lowest level and highest exposure levels from the countries in a given region. Where there was no information from any countries in the region, the lowest and highest exposure levels overall were used.

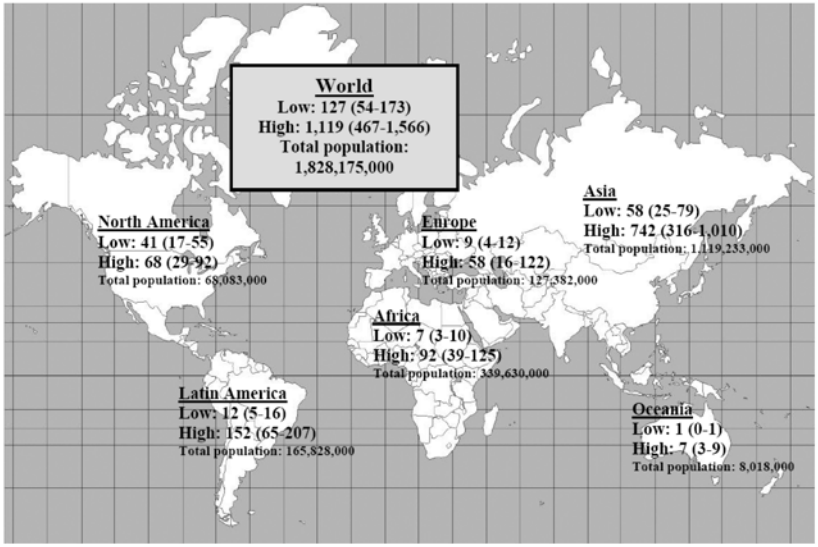

Figure A.4. Estimated number and range of world-wide and regional cases of childhood leukaemia among children under 14 years of age that are possibly attributable to EMF geometric mean exposure ≥ 0.4 μT (and the corresponding derived confidence interval). Regional range is based on the lowest level and highest exposure levels from the countries in a given region. Where there was no information from any countries in the region, the lowest and highest exposure levels overall were used.

Table A.1. Exposure distribution of the arithmetic mean based on exposure of cases in a case-control study or all respondents in an exposure survey

Country	Study	Study type	Measurement	Magnetic field category (μT)				N
				0.1	> 0.1–≤ 0.2	> 0.2–≤ 0.3	> 0.3	
Belgium	Decat, Van den Heuvel & Mulpas, 2005	Exposure survey	24-hr personal	81.9%	11.5%	1.6%	5.1%	251
Canada	McBride et al., 1999 [a]	Case-control	48-hr personal	58.59%	25.93%	10.77%	4.71%	297
Germany	Michaelis et al., 1998 [a]	Case-control	24-hr bedroom	85.23%	9.66%	1.70%	3.41%	176
	Brix et al., 2001	Exposure survey	24-hr personal	73.6%	17.8%	4.1%	4.5%	1952
	Schüz et al., 2001 [b]	Case-control	24-hr bedroom	91.83%	6.42%	0.97%	0.78%	514
Japan	Kabuto et al., 2006 [b]	Case-control	7-day home	88.46%	5.77%	3.85%	1.92%	312
Korea	Yang, Ju & Myung, 2004	Exposure survey	24-hr personal	64.0%	24.2%	4.0%	7.8%	409
UK	UKCCSI, 1999 [b]	Case-control	48-hr home	92.73%	5.31%	1.49%	0.47%	1073
USA	London et al., 1991 [a]	Case-control	24-hr bedroom	67.90%	18.52%	3.09%	10.49%	162
	Linet et al., 1997 [a]	Case-control	24-hr bedroom	63.17%	23.82%	6.43%	6.58%	638
	Zaffanella & Kalton, 1998	Exposure survey	24-hr personal	64.2%	21.1%	7.8%	6.6%	995
	Zaffanella, 1993	Exposure survey	24-hr home	72.3%	17.5%	5.6%	4.6%	987

[a] Based on the distribution for pooled analysis reported by Greenland et al., 2000 .

[b] Exposure categories: < 0.1, 0.1–< 0.2, 0.2–≤ 0.4, ≥ 0.4 μT.

Table A.2. Exposure distribution of the geometric mean based on exposure of cases in a case-control study or all respondents in an exposure survey

Country	Study	Study type	Measurement	Magnetic field category (μT)				N
				< 0.1	0.1–< 0.2	0.2–< 0.4	≥ 0.4	
Belgium	Decat, Van den Heuvel & Mulpas, 2005	Exposure survey	24-hr personal	91.9%	4.1%	2.8%	1.2%	251
Canada	McBride et al., 1999 [a]	Case-control	48-hr personal	63.97%	20.59%	10.66%	4.78%	272
Germany	Michaelis et al., 1998 [a]	Case-control	24-hr bedroom	89.14%	6.86%	2.86%	1.14%	175
UK	UKCCSI, 1999 [a]	Case-control	48-hr home	94.87%	3.54%	1.21%	0.37%	1073
USA	Zaffanella & Kalton, 1998	Exposure survey	24-hr personal	72.6%	17.6%	7.5%	2.3%	995
	Linet et al., 1997 [a]	Case-control	24-hr bedroom	70.25%	18.66%	8.24%	2.86%	595

[a] Based on the distribution for pooled analysis reported by Ahlbom et al., (2000).

Table A.3. Point, low and high estimates of the proportion (AF) and number (AN) of cases in the USA for the hypothetical scenario of 50% reduction in exposure

	Exposures above:		
Arithmetic mean	**0.1 μT**	**0.2 μT**	**0.3 μT**
Proportion of all cases attributable to exposure (AF):			
Current exposure distribution[a]	5.41% (-3.78%, 16.48%)	5.18% (-0.05%, 11.96%)	4.73% (1.65%, 8.73%)
Hypothetical distribution[b]: all exposures decreased by 50%	1.27% (-2.02%, 5.29%)	1.16% (-0.21%, 3.02%)	1.01% (0.34%, 1.93%)
Number of cases attributable to exposure (AN):			
Current exposure distribution	138 (-97, 421)	133 (-1, 306)	121 (42, 223)
Hypothetical distribution: all exposures reduced by 50%	32 (-52, 135)	30 (-5, 77)	26 (9, 49)
Number of cases averted due to exposure reduction	105 (-45, 286)	103 (4, 228)	95 (33, 174)
Geometric mean	**0.1 μT**	**0.2 μT**	**0.4 μT**
Proportion of all cases attributable to exposure (AF):			
Current exposure distribution[a]	3.95% (-2.83%, 12.30%)	2.46% (-0.71%, 6.77%)	1.67% (0.46%, 3.49%)
Hypothetical distribution[b]: all exposures decreased by 50%	0.94% (-0.99%, 3.32%)	0.37% (-0.20%, 1.17%)	0.20% (0.05%, 0.42%)
Number of cases attributable to exposure (AN):			
Current exposure distribution	101 (-72, 315)	63 (-18, 173)	43 (12, 89)
Hypothetical distribution: all exposures decreased by 50%	24 (-25, 85)	10 (-5, 30)	5 (1, 6)
Number of cases averted due to exposure reduction	77 (-47, 230)	53 (-13, 143)	38 (10, 83)

[a] Calculated log-normal distribution based on Zaffanella & Kalton, 1998.

[b] Calculated log-normal distribution based on Zaffanella & Kalton, 1998, with all exposures reduced by 50%

To estimate the impact of a hypothetical scenario where the population's exposure distribution is reduced by 50%, a new exposure distribution was calculated to reflect this change. Calculating the exposure distribution shift requires knowing the mean and standard deviation of the distribution; this information was available for only one of the distributions, the USA EMF Rapid Survey, 1998 (Zaffanella & Kalton, 1998). Hence, AF and AN estimates for exposures greater than 0.1 μT, 0.2 μT, 0.3 μT or 0.4 μT were calculated for the arithmetic mean and geometric mean exposure distributions, before and after making the 50% exposure reduction in the USA (see Table A.3). The difference in the AN reflects the number of cases that would be averted due to the exposure reduction of 50%.

The conventional calculations of AF do not reflect any source of uncertainty other than random error, and informal judgments regarding the effect of possible biases. To provide additional input to policy analysis also formal Bayesian analyses are provided of the impact of high residential magnetic-field exposure (as measured by AF), accounting for uncertainties about study biases as well as uncertainties about exposure distribution. These Bayesian analyses support the idea that the public-health impact of residential fields is likely to be limited, but both no impact and a large impact remain possibilities in light of the available data (Greenland & Kheifets, 2006). The difference between the two analyses varies in both directions, but on the whole the Bayesian results make the conventional results look overoptimistic and overconfident (Table A.4).

Table A.4. Conventional estimates (with 95% confidence limits) and Bayesian (posterior) percentiles for percentage of leukaemia case load attributable to exposure > 0.3 μT versus < 0.3 μT (AF%) in 15 case-control studies of magnetic fields and childhood leukaemia and in four populations with surveys of fields [a]

Reference	Country	Population AF% (95% limits)	
		Conventional	Posterior
Case-control:			
Coghill, Steward & Philips, 1996	England	0.5 (0.2, 0.7)	0.7 (-0.4, 18)
Dockerty et al., 1998	N.Z.	0.9 (0.5, 1.3)	0.9 (-0.5, 20)
Feychting & Ahlbom, 1993	Sweden	3.1 (1.4, 5.2)	8.6 (0.6, 44)

15 GLOSSARY

AC
Alternating current. An electrical current whose magnitude and direction vary cyclically, as opposed to direct current, whose direction remains constant.

Action potential (nerve impulse or "spike")
A sudden brief reversal of the local membrane electrical potential that occurs once a threshold depolarisation has been exceeded and which quickly propagates down a nerve axon conveying "digitally" encoded information.

Acute effect
Effect of short duration and occurring rapidly (usually in the first 24 h or up to 14 d) following a single dose or short exposure to a substance or radiation.

Adverse health effect
A biological effect which has a detrimental effect on mental, physical and/or general well being of exposed people, either in the short term or long term.

Antibody
A class of proteins produced by (B) lymphocytes that recognises and binds to a specific antigen, thereby aiding its elimination, or elimination of the agent, such as a bacterium, expressing it.

Antigen
Any substance, usually (but not always) foreign, that provokes an antigen-specific immune response, such as antibody-binding.

Apoptosis
A specific form of cell death during which cells degrade their own DNA. Apoptosis can occur normally during organ formation, or as a result of DNA or cellular damage.

Autonomic nervous system
A part of the peripheral nervous system that regulates the visceral or "housekeeping" functions of the body, such as heart-rate and blood pressure. It's cell bodies lie either in the central nervous system, or in ganglia in other parts of the body.

Background levels
The amounts of EMF found (that are not due to an obviously specific source) in a typical environment of an industrialized society.

Basic restrictions
Restrictions on exposure to time-varying electric, magnetic, and electromagnetic fields that are based directly on established health effects. Depending upon the frequency of the field, the physical quantities used to specify these restrictions are induced electric field (E), current density (J), specific energy absorption rate (SAR), and power density (S). Only power density in air, outside the body, can be readily measured in exposed individuals.

Bias
A systematic tendency to error as a consequence of the design or conduct of a study.

Biological effect
A measurable change in a biological system in response (for example) to an electromagnetic field.

Biophysical mechanisms
Physical and/or chemical interactions of electric and magnetic fields with biological systems.

Blind study
A study in which the subject or, in the case of studies using animals, tissues or cell cultures, the experimenter, is unaware of whether exposure is to the agent under test or to a neutral or comparison agent until completion of the experiment, in order to avoid unconscious subjective bias affecting the study outcome.

Blood-brain barrier
A physiological "barrier" comprising endothelial and epithelial cells that regulates the composition of cerebrospinal fluid of the central nervous system.

Calcium efflux
The release of calcium ions from a sample into a surrounding solution.

Cancer
An uncontrolled and abnormal proliferation of cells that causes disease.

Carcinogen
An agent that can induce cancer.

Carcinoma
A tumour arising from epithelial tissue (e.g. glands; breast; skin; linings of the urogenital, intestinal and respiratory systems).

Case-control study
An investigation into the extent to which a group of persons with a specific disease (the cases) and comparable persons who do not have the disease (the controls) differ with respect to exposure to putative risk factors.

Causal relationship
A causal relationship occurs between two agents when one causes the other. For example, researchers are studying whether there is a causal relationship between EMF and cancer, meaning that they are studying to see if EMF causes, or affects the progress of, cancer.

Cell signalling (pathways)
A sequence of intracellular changes linking a "signalling event", such as activation of membrane-bound ion channels or ligand-receptors, and a "response", such as a change in gene expression, for example, leading to increased proliferation.

Central nervous system (CNS)
Usually taken to mean the cells, such as neurons and glial cells, of the brain and spinal cord. It also includes the retina, which is formed as an outgrowth of the forebrain.

Chromosome
A single molecule of DNA, comprising a large number of genes and other DNA, together with associated protein molecules that condense during cell division to form a deeply staining, rod-shaped body.

Chronic effect
Consequence which develops slowly and has a long-lasting course (often but not always irreversible).

Circulary polarized
If the electric field is viewed as a point in space, the locus of the end point of the vector will rotate and trace out an ellipse, once each cycle.

Cognition
Information processing by the brain, including processes such as attention, perception, learning, reasoning, comprehending and memory.

Cohort study
An investigation involving the identification of a group of individuals (the cohort) about whom certain exposure information is collected, and the ascertainment of occurrence of diseases at later times. For each individual, information on prior exposure can be related to subsequent disease experience. Cohort studies may be conducted prospectively or retrospectively.

Combined analysis
Analysis of data pertaining to the same topic that have been collected in several different studies. Usually based on individual level data from each of the available studies, rather than on the published findings (see Meta analysis).

Comet assay
A single cell electrophoresis assay in which DNA is caused to migrate away from the nucleus by an applied electric field. The extent of migration gives a measure of DNA damage.

Conductance
The reciprocal of resistance. Symbol: G. Unit: siemens (S).

Conductivity, electrical
The scalar or vector quantity which, when multiplied by the electric field strength, yields the conduction current density; it is the reciprocal of resistivity. Expressed in siemens per meter ($S\ m^{-1}$).

Confidence interval (CI)
An interval calculated from data when making inferences about an unknown parameter. In hypothetical repetitions of the study, the interval will include the parameter in question on a specified percentage of occasions (e.g. 90% for a 90% confidence interval).

Confounding
Spurious findings due to the effect of a variable that is correlated with both the exposure and disease under study.

Contact current
Current flowing between an energized, isolated, conductive (metal) object and ground through an electrical circuit representing the equivalent impedance of the human body.

Continuous exposure
Exposure for durations exceeding the corresponding averaging time. Exposure for less than the averaging time is called short-term exposure.

Continuous wave (CW)
A wave whose successive oscillations are identical under steady-state conditions.

Coronary thrombosis
A blood clot which blocks one of the coronary arteries, leading to a heart attack.

Current density
A vector of which the integral over a given surface is equal to the current flowing through the surface; the mean density in a linear conductor is equal to the current divided by the cross-sectional area of the conductor. Unit: ampere per square meter (A m^{-2}).

Diastole
The period of relaxation of heart muscle, following contraction (systole).

Dielectric constant
See Permittivity.

Dielectric material
A class of materials that act as electric insulators. For this class, the conductivity is presumed to be zero, or very small. The positive and negative charges in dielectrics are tightly bound together so that there is no actual transport of charge under the influence of a field. Such material alters electromagnetic fields because of induced charges formed by the interaction of the dielectric with the incident field.

Differentiation (cellular)
The development of a specialised cellular structure and function from less specialised "precursor" cells such as stem cells which is generally accompanied by a loss of proliferative capacity.

Dipole
A centre-fed open antenna excited in such a way that the standing wave of current is symmetrical about the mid point of the antenna.

Dose
A term for the amount of a chemical or physical agent delivered to a target organ. Since neither the target organ nor the mechanism of delivery are well understood for most biological effects of EMF fields, an EMF dose can sel-

dom be defined, and the concept of exposure metric (see below) is used instead.

Dose-response relationship
Mathematical description of the relationship between the dose and occurrence of the disease.

Dosimetry
Measurement or determination by calculation of the internal electric field strength or induced current density, or of the specific absorption (SA) or specific absorption rate (SAR) distribution in humans or animals exposed to electromagnetic fields.

Double blind study
A volunteer study in which the subject and the experimenter until completion are unaware of whether exposure is to the agent under test or to a neutral or comparison agent, in order to avoid unconscious subjective bias affecting the study outcome.

Duty factor
The ratio of the sum of pulse durations to a stated averaging time. For repetitive phenomena, the averaging time is the pulse repetition period.

Electric and magnetic fields or electromagnetic fields (EMF)
The combination of time-varying electric and magnetic fields.

Electric field
A vector field E measured in volts per metre (V m^{-1}).

Electric field strength (*E*)
Force exerted by an electric field on an electric point charge, divided by the electric charge. Expressed in newtons per coulomb or volts per metre (N C^{-1} = V m^{-1}).

Electrical ground
The earth or a metal surface placed in contact with the earth, or connected to the earth with a conductor.

Electrocardiogram (ECG)
A recording of the electrical activity of the heart from electrodes placed on the body.

Electroencephalogram (EEG)
A recording of the electrical activity of the brain from electrodes placed on the head.

Electromagnetic energy
The energy stored in an electromagnetic field. Expressed in joule (J).

Electromagnetic interference (EMI)
Degradation of the performance of a device, a piece of equipment, or a system caused by an electromagnetic disturbance.

Electroretinogram (ERG)
A recording of the electrical activity of the retina from electrodes placed on the surface of the eye and the head.

Embryo
The stage of prenatal development between the fertilised ovum and the completion of major organ development. In humans, this occurs in the first trimester.

Enteric nervous system
Comprises the intrinsic neurons of the gut, about the same in number (approximately 100 million) as those of the spinal cord, and which exhibit a high degree of independence from the central nervous system.

Epidemiology
The study of the distribution of disease in populations and of the factors that influence this distribution.

Epilepsy
Epileptic seizures arise from an excessively synchronous and sustained discharge of a group of neurons; a persistent increase in neuronal excitability is a key feature.

Event-related (or evoked) potential (ERP or EP)
A recording of the electrical activity of the brain after a stimulus event, such as a visual or auditory stimulus (resulting in VEPs and AEPs respectively). Late components are associated with cognitive processing.

Exposure
The subjection of a person to electric, magnetic, or electromagnetic fields or to contact currents other than those originating from physiological processes in the body and other natural phenomena.

Exposure standard
A standard that limits EMF exposure to humans. See Standard.

Exposure, intermittent
This term refers to alternating periods of exposure and absence of exposure varying from a few seconds to several hours. If exposure lasting a few minutes to a few hours alternates with periods of absence of exposure lasting 18-24 hours (exposure repeated on successive days), “repeated exposure” might be a more appropriate term.

Exposure, long term
This term indicates exposure during a major part of the lifetime of the biological system involved; it may, therefore, vary from a few weeks to many years in duration.

Exposure metric
A single number that summarizes an electric and/or magnetic field exposure over a period of time. An exposure metric is usually determined by a combination of the instrument’s signal processing and the data analysis performed after the measurement.

Exposure, partial-body
Exposure that results when EMF are substantially non-uniform over the body. Fields that are non-uniform over volumes comparable to the human body may occur due to highly directional sources, standing waves, re-radiating sources, or in the near field region of a radiating structure.

Exposure, short term
Exposure for durations less than the corresponding averaging time.

Exposure, whole-body
Pertains to the case in which the entire body is exposed to the incident electromagnetic energy or the case in which the cross section (physical area) of the body is smaller than the cross section of the incident radiation beam.

Extremities
Limbs of the body.

Fetus (foetus)
The stage of prenatal development between the embryo and birth.

Fibrillation (ventricular)
The loss of organised ventricular contractions of the heart.

Field strength
The magnitude of the electric or magnetic field, normally the root-mean-square value.

Free radicals
Highly reactive chemical species (part of a molecule) with an unpaired electron.

Free space
An ideal perfectly homogeneous medium possessing a relative dielectric constant of unity, in which there is nothing to reflect, refract, or absorb energy. A perfect vacuum possesses these qualities.

Frequency
The number of cycles completed by electromagnetic waves in 1 s; usually expressed in hertz (Hz).

Frequency response
An instrument's output as a function of frequency relative to the magnitude of the input signal. Specification of an instrument's frequency response includes the type of filter and its bandwidth.

Gene expression
The production of a functional protein or an RNA molecule from genetic information (genes) encoded by DNA.

Genotoxin
An agent which damages DNA and RNA.

Geomagnetic fields
Magnetic fields originating from the earth (including the atmosphere). Predominantly a static magnetic field, but includes some oscillating components and transients.

Guideline
A recommended limit for a substance or an agent intended to protect human health or the environment.

Haematology
The study of blood; its formation, normal composition, function and pathology.

Harmonic
A frequency which is a multiple of the frequency under consideration.

Health
A state of complete physical, mental and social well-being and not merely the absence of disease or infirmity.

Health hazard
A biological effect that is detrimental to health or well-being.

Immune system
The body's primary defence against abnormal growth of cells (i.e. tumours) and infectious agents such as bacteria, viruses, and parasites.

Impedance, wave
The ratio of the complex number (vector) representing the transverse electric field at a point, to that representing the transverse magnetic field at that point. Expressed in ohm (Ω).

Implantation
The attachment of the early embryo to the uterine wall.

In vitro
Experimental studies of cells or tissues, usually in a sustaining oxygenated, fluid medium. Literally means “in glass”, isolated from the living organism and artificially maintained, as in a test tube or culture dish.

In vivo
Occurring within the whole living body. ‘In life’; experimental studies of processes in living organisms.

Latency
The time between exposure to an injurious agent and the manifestation of a response.

Leukocyte
A white blood cell.

Lymphocyte
White blood cells produced in lymphoid tissue that initiate adaptive, antigen-specific immune responses. Some T-lymphocytes are cytotoxic; B-lymphocytes secrete antibodies.

Macrophage
A phagocytic cell derived from myeloid progenitor cells found in various tissues.

Magnetic field strength (*H*)
A field vector, *H*, that is equal to the magnetic flux density divided by the permeability of the medium. Expressed in units of amperes per meter (A m^{-1}).

Magnetic flux density (*B*)
The force on a moving unit positive charge at a point in a magnetic field per unit velocity. A vector field quantity, *B*, expressed in tesla (T).

Malignant
Neoplasms or tumours that have become invasive.

Meta-analysis
Analysis of data pertaining to the same topic that have been collected in several different studies. Usually refers to an analysis based on published findings from individual studies, rather than on the original data sets (see Combined analysis).

Metabolic rate
See Resting metabolic rate.

Metabolism
The biochemical reactions by which energy is made available for the use of an organism from the time a nutrient substance enters, until it has been utilized and the waste products eliminated.

Metastasis
Tumour cells that leave their site of origin and migrate to other sites in the body.

Micronucleus
Chromosome fragments that have not been lost on cell division.

Mutation
A stable heritable change in the DNA at a specific site in the in the genome of a cell by an agent (mutagen) such as ionising radiation.

Natural killer (NK) cells
Lymphocytes that are not antigen-specific but nevertheless bind to and kill certain tumour and virus-infected cells.

Neonate, neonatal
Newly born.

Neoplasm
New growth of abnormal tissue.

Neural network
Group of interacting neurons.

Neural tube defect
A defect of the newly formed precursor of the central nervous system, commonly anencephaly (failure of brain to develop), encephalocele (cyst of the brain), and spina bifida (defects in the closure of the neural tube).

Neuron
Nerve cell, specialised for the transmission of neural information.

Neurotransmitter
A substance released by a neuron that causes a post-synaptic response that is relatively quick in onset (< 1 ms) and short (< 10's ms) in duration, as distinct from the more prolonged action of neuromodulators.

Neutrophil
Phagocytic white blood cells derived from myeloid progenitor cells.

Non-differential measurement errors
Errors in exposure assessment that do not depend on whether or not someone develops the disease under study.

Occupational exposure
Exposure experienced by adults who are generally exposed under known conditions and are trained to be aware of potential risk and to take appropriate precautions.

Odds ratio
The ratio of the odds of disease occurrence in a group with exposure to a factor to that in an unexposed group; within each group, the odds are the ratio of the numbers of diseased and non-diseased individuals.

Oncogene
A gene which contributes to cancer in a dominant fashion through the mutation and/or abnormal expression of a gene (proto-oncogene) involved in regulating cell proliferation.

Operant behaviour
Behaviour, such as pressing a lever, which is "shaped" by rewards (such as food pellets) or punishment (such as a mild electric shock).

Organogenesis
The process of organ formation in developing organisms.

Peripheral nervous system (somatic)
The part of the nervous system that mainly deals with the voluntary and conscious aspects of neural control such as voluntary muscle (motor) contraction and sensations such as those of warmth or pressure. The cell bodies lie within the spinal cord, but the peripheral nerves (axons) terminate on muscle fibres or in specialised sensory receptors throughout the body.

Permeability
The scalar or tensor quantity whose product by the magnetic field strength is the magnetic flux density. Note: For isotropic media, the permeability is a scalar; for anisotropic media, a matrix.
Synonym: absolute permeability. If the permeability of a material or medium

is divided by the permeability of vacuum (magnetic constant) μ_0, the result is termed relative permeability (μ). Unit: henry per metre (H m^{-1}).

Permittivity; dielectric constant
A constant defining the influence of an isotropic medium on the forces of attraction or repulsion between electrified bodies. Symbol: ε. Unit: farad per metre (F m^{-1}).

Permittivity, relative
The ratio of the permittivity of a dielectric to that of a vacuum. Symbol: ε_r.

Phase
Of a periodic phenomenon, the fraction of a period through which the time has advanced relative to an arbitrary time origin.

Phosphene
The perception of flickering light in the periphery of the visual field induced by non-visual means such as a trans-retinal electric current.

Prospective study
An epidemiological study in which data on exposures and disease outcome are collected as the events occur, unlike a retrospective study (see below). Some cohort studies are conducted prospectively.

Public exposure
All exposure to EMF experienced by members of the general public, excluding occupational exposure and exposure during medical procedures.

Recall bias
Bias resulting from the tendency of a class of subjects to recall relevant events better than other subjects.

Reference level
EMF exposure level provided for practical exposure assessment purposes to determine whether the basic restrictions are likely to be exceeded. Some reference levels are derived from relevant basic restrictions using measurement and/or computational techniques and some address perception and adverse indirect effects of exposure to EMF.

Reinforcement (behavioural)
An action such as reward or punishment that increases the likelihood of a certain behaviour.

Relative risk
The ratio of the disease rate in the group under study to that in a comparison group, with adjustment for confounding factors such as age, if necessary.

Reproductive effects
Effects on reproduction which may include, but not be limited to, alterations in sexual behaviour, onset of puberty, fertility, gestation, parturition, lactation, pregnancy outcomes, premature reproductive senescence, or modifications in other functions that are dependent on the integrity of the reproductive system.

Resonance
The change in amplitude occurring as the frequency of the wave approaches or coincides with a natural frequency of the medium.

Retrospective study
An epidemiological study in which data on exposures and disease outcome are collected some time after the event, unlike a prospective study (see above). Examples include case-control studies and some cohort studies.

Root-mean-square (RMS)
Certain electrical effects are proportional to the square root of the mean value of the square of a periodic function (over one period). This value is known as the effective value or the root-mean-square (RMS) value, since it is derived by first squaring the function, determining the mean value of the squares obtained, and extracting the square root of the mean value to determine the end result.

Safety factor
A reduction factor incorporated into limits in standards or guidelines that allows for uncertainties in the determination of a threshold level of exposure, above which established health effects begin to appear.

Selection bias
Bias resulting from a faulty way to select subjects for a study. Epidemiological studies depend on a reliable comparison between subjects with a disease and a reference population as to their exposure. If the subjects chosen for a study are not representative of the corresponding population, the comparison becomes flawed and the association between disease and exposure becomes biased.

Shield
A mechanical barrier or enclosure provided for protection. The term is modified in accordance with the type of protection afforded; e.g., a magnetic shield is a shield designed to afford protection against magnetic fields.

Short term exposure
See exposure, short term

Significance level
The probability of obtaining a result at least as extreme as that observed in the absence of a raised risk. A result that would arise less than 1 in 20 times in the absence of an underlying effect is often referred to as being “statistically significant”.

Sinus arrhythmia
The normal variation of heart rate during the breathing cycle.

Spatial average
The root mean square of the field over an area equivalent to the vertical cross section of the adult human body, as applied to the measurement of electric or magnetic fields in the assessment of whole-body exposure.

Spot measurements
Magnetic field measurements taken at various individual locations throughout a room or area.

Standard
1) A documented agreement containing technical specifications or other precise criteria to be used consistently as rules, guidelines or definitions of characteristics to ensure that materials, products, processes and services are fit for their purpose.
2) A legally enforceable limit for a substance or an agent intended to protect human health or the environment. Exceeding the standard could result in unacceptable harm.

Static field
A field vector that does not vary with time.

Statistical power
The probability that, with a specified degree of confidence, an underlying effect of a given magnitude will be detected in a study.

Synapse
A junction between two neurons, or between a neuron and a muscle fibre, that allows the transmission of electrical information, usually by means of a chemical transmitter (neurotransmitter) released from the presynaptic terminal of one neuron onto the closely juxtaposed post-synaptic terminal of the other.

Systole
The period of contraction of heart muscle following relaxation (diastole).

Teratogen
An agent that can cause birth defects.

Threshold
The lowest dose of an agent at which a specified measurable effect is observed and below which it is not observed.

Thrombosis
Blocking of an artery or vein by a blood clot.

Time-weighted average (TWA)
The average of various measurements, each of which is given more or less weight according to how much time a person is likely to spend in the spot where that measurement was taken. The term is used more generally to indicate the average of field levels over a specific amount of time. This is one method used to summarize exposure to exposure to magnetic fields.

Transcription factor
A protein that binds to a DNA sequence with a “regulatory” function thereby, directly or indirectly, affecting the initiation of transcription.

Transformation
Conversion of cells to a state of unrestrained growth in culture, resembling or identical with a tumour-forming (tumorigenic) state.

Transgenic organism
A genetically modified organism, which has foreign DNA such as a gene stably integrated into its genome.

Transients
Brief bursts of high frequency fields, usually resulting from mechanical switching of AC electricity.

Transmission lines
High voltage power lines that carry large quantities of power over large distances.

Tumour
A growth of tissue resulting from abnormal cell proliferation.

Tumour initiator
An agent that can produce an initial carcinogenic event such as a mutation.

Tumour progression
The process by which initiated and promoted cells become increasingly malignant.

Tumour promoter
An agent that can stimulate the proliferation (clonal expansion) of initiated cells.

Tumour suppressor gene
A normal cellular gene involved in regulating cell proliferation whose mutation and/or abnormal expression can contribute to cancer in a recessive manner.

Vasoconstriction
The contraction of blood vessels, making them narrower.

Vasodilatation (or vasodilation)
The relaxation of blood vessels, making them wider.

Vigilance tasks
Responding to unusual and infrequent stimuli (signals) occurring against a background of usual and frequent stimuli (events). Vigilance can be either visual or auditory.

Voltage-gated ion channel
Cell membrane proteins that allow the passage of particular ion species across the cell membrane in response to the opening of a molecular "gate" which is steeply sensitive to the transmembrane voltage. They are associated with electrical excitability.

Wavelength (λ)
The distance between two successive points of a periodic wave in the direction of propagation, in which the oscillation has the same phase. Symbol: λ. Unit: metre (m).

Wild type (gene)
The gene that is found in nature or in the standard laboratory stock for a given organism.

Working memory
An active system for temporarily storing and manipulating information needed in the execution of complex cognitive tasks.

16 RESUME ET RECOMMANDATIONS RELATIVES AUX ETUDES A MENER

La présente monographie des critères d'hygiène de l'environnement porte sur les effets éventuels sur la santé d'une exposition à des champs électriques et magnétiques d'extrêmement basse fréquence (EBF). On y examine les caractéristiques physiques des champs EBF ainsi que les sources d'exposition et le mesurage des champs. Toutefois, ses principaux objectifs sont d'examiner la littérature scientifique sur les effets biologiques d'une exposition aux champs EBF afin de pouvoir évaluer les risques pour la santé associés à l'exposition à ces champs et d'utiliser cette évaluation du risque sanitaire pour formuler des recommandations relatives aux programmes de protection sanitaire à l'intention des autorités nationales.

Les fréquences qui nous occupent sont situées au-dessus de 0 Hz et jusqu'à 100 kHz. La majorité des études a porté sur les effets des champs magnétiques à la fréquence des réseaux (50 ou 60 Hz), quelques études seulement portant sur les champs électriques à ces mêmes fréquences. En outre, un certain nombre d'études a été réalisé sur les champs magnétiques de très basse fréquence (VLF, 3–30 kHz), liés aux champs magnétiques à gradient commuté utilisés dans l'imagerie par résonance magnétique et aux champs VLF plus faibles, émis par les terminaux à écran cathodique et les postes de télévision.

Ce document récapitule les principales conclusions et recommandations de chaque section ainsi que les conclusions générales du processus d'évaluation des risques sanitaires. Les termes utilisés dans cette monographie pour indiquer le "poids de la preuve" en faveur d'un effet donné sur la santé sont les suivants. Les éléments d'appréciation sont "limités" lorsqu'ils ne se rapportent qu'à une seule étude ou lorsqu'il reste des questions sans réponse concernant la conception, la conduite ou l'interprétation d'un certain nombre d'études. On dit que les éléments d'appréciation sont "insuffisants" lorsque les études ne peuvent être interprétées comme montrant la présence ou l'absence d'un effet du fait d'insuffisances importantes sur le plan qualitatif ou quantitatif, ou lorsqu'aucune donnée n'est disponible.

On a également recensé des lacunes importantes dans les connaissances et on a résumé dans la section intitulée "Recommandations de recherche" les études nécessaires pour les combler.

16.1 Résumé

16.1.1 Sources, mesurage et expositions

Les champs électriques et magnétiques existent partout où de l'électricité est produite, transmise ou distribuée dans des lignes ou des câbles électriques, ou utilisée dans des appareils électriques. Depuis que l'électricité fait partie intégrante de notre mode de vie moderne, ces champs sont omniprésents dans notre environnement.

L'intensité du champ électrique se mesure en volts par mètre (V m^{-1}) ou en kilovolts par mètre (kV m^{-1}) et l'induction magnétique en teslas (T), ou plus communément en milliteslas (mT) ou en microteslas (μT).

Dans les habitations, l'exposition aux champs magnétiques à la fréquence du réseau ne montre pas de variations spectaculaires dans le monde. La moyenne géométrique du champ magnétique dans les habitations se situe entre 0,025 et 0,07 μT en Europe et entre 0,055 et 0,11 μT aux Etats-Unis. Les valeurs moyennes du champ électrique dans les habitations sont de l'ordre de plusieurs dizaines de volts par mètre. Au voisinage de certains appareils domestiques, les valeurs instantanées du champ magnétique peuvent atteindre quelques centaines de microteslas. A proximité des lignes électriques à haute tension, les champs magnétiques atteignent près de 20 μT et les champs électriques jusqu'à plusieurs milliers de volts par mètre.

Peu d'enfants subissent, là où ils habitent, des expositions à des champs magnétiques de 50 ou 60 Hz dont la moyenne dans le temps est supérieure aux niveaux associés avec une incidence accrue de leucémie infantile (voir section 16.1.10). Près de 1 à 4% d'entre eux ont des expositions moyennes supérieures à 0,3 μT et seuls 1 à 2% des expositions médianes supérieures à 0,4 μT.

L'exposition professionnelle, bien qu'elle soit principalement due à des champs à la fréquence du réseau, peut également comporter l'exposition à d'autres fréquences. Les expositions moyennes au champ magnétique sur les lieux de travail se sont avérées plus élevées au sein des "professions liées à l'électricité" que dans les autres, telles que par exemple le travail de bureau. Elles sont comprises entre 0,4 et 0,6 μT pour les électriciens et les ingénieurs en électricité et autour de 1,0 μT pour les agents travaillant sur les lignes électriques, les expositions les plus élevées concernant les soudeurs, les conducteurs de trains et les opérateurs de machines à coudre (plus de 3 μT). Les expositions maximales aux champs magnétiques sur les lieux de travail peuvent atteindre près de 10 mT et sont invariablement associées à la présence de conducteurs transportant des courants forts. Dans le secteur de l'alimentation électrique, les agents peuvent être exposés à des champs électriques atteignant 30 kV m^{-1}.

16.1.2 Champs électriques et magnétiques dans l'organisme

L'exposition à des champs électriques et magnétiques EBF externes induit des champs et des courants électriques dans l'organisme. La dosimétrie décrit le rapport entre le champ externe et les champ électriques et la densité de courant induits dans l'organisme, ou d'autres paramètres associés à l'exposition à ces champs. Le champ électrique et la densité de courant induits localement présentent un intérêt particulier parce qu'ils sont en rapport avec la stimulation des tissus excitables tels que nerfs et muscles.

Le corps de l'homme et des animaux perturbe sensiblement la distribution spatiale d'un champ électrique EBF. Aux fréquences basses, le corps est un bon conducteur et les lignes du champ perturbé à l'extérieur de l'organisme sont presque perpendiculaires à la surface du corps. Des charges

oscillantes sont induites à la surface de l'organisme exposé et ce sont elles qui produisent des courants dans l'organisme. Les principales caractéristiques de la dosimétrie concernant l'exposition de l'homme aux champs électriques EBF sont les suivantes:

- Le champ électrique à l'intérieur de l'organisme est normalement cinq ou six fois plus faible que le champ électrique externe.
- Lorsque le champ vertical est la cause principale de l'exposition, la direction dominante des champs induits est également verticale.
- Pour un champ électrique externe donné, les champs induits les plus forts le sont dans le corps humain en contact parfait avec le sol par l'intermédiaire des pieds (mise à la terre électrique) et les champs les plus faibles dans le corps isolé du sol ("espace libre").
- Le courant total circulant dans un organisme en contact parfait avec le sol est déterminé par la taille et la forme de l'organisme (notamment la posture), plutôt que par la conductivité des tissus.
- La distribution des courants induits dans les divers organes et tissus est déterminée par la conductivité de ces tissus et organes.
- La distribution d'un champ électrique induit est également fonction des conductivités, mais moins que celle du courant induit.
- Il existe également un phénomène indépendant dans lequel le courant est produit dans l'organisme du fait d'un contact avec un objet conducteur situé dans un champ électrique.

Concernant les champs magnétiques, la perméabilité des tissus est la même que celle de l'air, de sorte que le champ dans les tissus est le même que le champ extérieur. Le corps de l'homme et des animaux ne perturbe pas sensiblement ce champ. La principale interaction des champs magnétiques est l'induction, suivant la loi de Faraday, de champs électriques et des densités de courant associées dans les tissus conducteurs. Les principales caractéristiques de la dosimétrie concernant l'exposition de l'homme aux champs magnétiques EBF sont les suivantes:

- Le champ et le courant électrique induit dépendent de l'orientation du champ extérieur. Les champs induits dans l'organisme dans son ensemble sont plus grands lorsque le champ est aligné de l'avant vers l'arrière du corps, mais, pour certains organes, les valeurs les plus élevées s'observent lorsque le champ est appliqué de côté.
- Les champs électriques les plus faibles sont induits par un champ magnétique orienté le long de l'axe vertical du corps.
- Pour une intensité et une orientation donnée du champ magnétique, l'intensité des champs électriques induits dans un organisme augmentent avec sa taille.

- La distribution du champ électrique induit est modifiée par la conductivité des divers organes et tissus. Ceux-ci ont un effet limité sur la distribution de la densité du courant induit.

16.1.3 Mécanismes biophysiques

Il faut évaluer la plausibilité des divers mécanismes proposés d'interaction directe et indirecte des champs électriques et magnétiques EBF. En particulier, on veut savoir si on peut distinguer un "signal" produit dans un processus biologique par l'exposition à un champ, d'un bruit aléatoire intrinsèque, et si le mécanisme remet en question les principes et connaissances scientifiques actuels. De nombreux mécanismes ne deviennent plausibles qu'à des intensités de champs supérieures à un certain niveau. Néanmoins, l'absence de mécanismes plausibles répertoriés n'exclut pas la possibilité d'effets sur la santé même avec des champs très faibles, pour autant qu'on respecte les principes scientifiques fondamentaux.

Parmi les nombreux mécanismes proposés concernant l'interaction directe des champs avec le corps humain, il en est trois qui pourraient opérer à des intensités de champs plus faibles que les autres: les champs électriques induits dans les réseaux de neurones, les paires de radicaux libres et la présence de magnétite.

Les champs électriques induits dans les tissus par l'exposition à des champs électriques ou magnétiques EBF vont directement stimuler les fibres nerveuses simples myélinisées, et il s'agit d'un mécanisme plausible sur le plan biophysique, lorsque l'intensité du champ interne dépasse quelques $V\ m^{-1}$. Des champs beaucoup plus faibles peuvent modifier la transmission synaptique dans les réseaux neuronaux, au contraire des cellules isolées. Ce traitement du signal par les systèmes nerveux est communément employé par les organismes multicellulaires pour détecter les signaux environnementaux faibles. On a proposé une limite inférieure pour la discrimination par les réseaux nerveux de 1 mV/m, mais, d'après les données actuelles, des valeurs seuils situées autour de 10 à 100 $mV\ m^{-1}$ semblent plus probables.

Le mécanisme des paires de radicaux libres est une modalité acceptée par laquelle les champs magnétiques peuvent modifier des types particuliers de réactions chimiques. On décrit généralement une augmentation de la concentration de radicaux libres sous exposition à des champs faibles et une diminution dans des champs intenses. On a observé ces augmentations dans des champs magnétiques de moins de 1 mT. Il semblerait qu'il y ait un lien entre ce mécanisme et le système de navigation des oiseaux au cours de leur migration. Pour des raisons théoriques et parce que les modifications produites par les champs magnétiques EBF et statiques sont analogues, on pense que des champs à la fréquence du réseau, bien moins intenses que le champ géomagnétique d'environ 50 μT, sont peu susceptibles d'être biologiquement importants.

Les cristaux de magnétite, qui sont de petits cristaux ferromagnétiques d'oxyde de fer de diverses formes, se retrouvent dans les tissus animaux et humains, même si c'est à l'état de traces. Comme les radicaux libres,

ils ont été reliés au système d'orientation et de navigation des animaux migrateurs, bien que la présence de quantités de magnétite à l'état de traces dans le cerveau humain ne lui confère pas d'aptitude à détecter le champ géomagnétique faible. Les calculs basés sur des hypothèses extrêmes laissent à penser que le seuil des effets des champs EBF sur les cristaux de magnétite se situe autour de 5 μT.

Les autres interactions biophysiques directes des champs, comme la cassure des liaisons chimiques, les forces exercées sur les particules chargées et les divers mécanismes de "résonance" en bande étroite ne sont pas considérées comme apportant des explications plausibles aux interactions avec les champs rencontrés dans les environnements publics et professionnels.

Concernant les effets indirects, la charge électrique de surface induite par les champs électriques peut être perçue et entraîner des microchocs douloureux lorsque l'on touche un objet conducteur. Des courants de contact peuvent se produire lorsque, par exemple, de jeunes enfants touchent un robinet de baignoire dans certaines habitations. Cela produit de petits champs électriques, peut-être au-dessus du niveau de bruit de fond, dans la moelle osseuse. Toutefois, on ignore s'ils présentent un risque pour la santé.

Les lignes à haute tension produisent des nuages d'ions chargés électriquement par suite de la décharge par effet couronne. Il semble qu'elles pourraient accroître le dépôt des polluants de l'air sur la peau et dans les voies aériennes, avec d'éventuelles conséquences indésirables pour la santé. Toutefois, il semble peu probable que les ions de la couronne aient plus qu'un effet minime, si ce n'est nul, sur les risques sanitaires à long terme même chez les sujets les plus exposés.

Aucun des trois mécanismes directs évoqués ci-dessus ne semble constituer une cause plausible d'incidence accrue des maladies aux niveaux d'exposition généralement rencontrés. En réalité, ils ne deviendraient plausibles qu'à des intensités bien plus élevées, et les mécanismes indirects n'ont pour l'instant pas été suffisamment étudiés. Cette absence de mécanisme répertorié plausible n'exclut pas la possibilité d'effets indésirables pour la santé, mais crée véritablement un besoin de preuves plus solides venant de la biologie et de l'épidémiologie.

16.1.4 Neurocomportement

L'exposition à des champs électriques à la fréquence du réseau provoque des réponses biologiques bien définies, allant de la perception simple à la gêne, par biais des effets de la charge électrique de surface. Ces réponses dépendent de l'intensité du champ, des conditions environnementales ambiantes et de la sensibilité individuelle. Les seuils de perception directe chez 10% des volontaires se situent entre 2 et 20 kV m^{-1}, tandis que 5% trouvent que des valeurs de 15 à 20 kV m^{-1} sont gênantes. La décharge d'étincelles qu'émet une personne avec le sol est douloureuse pour 7% des volontaires dans un champ de 5 kV m^{-1}. Les seuils pour une décharge à partir d'un objet chargé à travers une personne ayant les pieds au sol dépend de la taille de l'objet et exigent par conséquent une évaluation précise.

Les champs magnétiques de forte intensité et pulsés peuvent stimuler les tissus nerveux périphériques ou centraux; de tels effets peuvent se produire au cours des examens d'imagerie par résonance magnétique (IRM) et sont utilisés dans la stimulation magnétique transcrânienne. Le seuil de champ électrique nécessaire pour provoquer une stimulation nerveuse directe pourrait ne pas dépasser quelques volts par mètre (V/m). Ce seuil est probablement constant sur une gamme de fréquences située entre quelques hertz (Hz) et quelques kilohertz (kHz). Les personnes souffrant d'épilepsie ou prédisposées à cette maladie risquent d'être plus sensibles aux champs électriques EBF induits dans le système nerveux central (SNC). En outre, la sensibilité à la stimulation électrique du SNC semble très probablement être associée à des antécédents familiaux de crises convulsives et à l'utilisation d'antidépresseurs tricycliques, de neuroleptiques et autres médicaments qui abaissent le seuil convulsivogène.

La fonction de la rétine, qui fait partie du SNC, peut être modifiée par l'exposition à des champs magnétiques EBF beaucoup plus faibles que ceux qui provoquent une stimulation nerveuse directe. Une sensation d'éclairs lumineux, appelés phosphènes magnétiques ou magnéto-phosphènes, résulte de l'interaction du champ électrique induit avec les cellules de la rétine électriquement excitables. La valeur seuil du champ électrique induit dans le liquide extracellulaire de la rétine a été estimée entre 10 et 100 mV m^{-1} à 20 Hz. Cependant, une incertitude considérable est attachée à ces valeurs.

Les données relatives à d'autres effets neuro-comportementaux observés dans les études sur des volontaires, par exemple les effets sur l'activité électrique du cerveau, la cognition, le sommeil, l'hypersensibilité et l'humeur sont moins nettes. En général, ces études ont été effectuées à des niveaux d'exposition situés au-dessous de ceux nécessaires pour provoquer les effets décrits ci-dessus et n'ont produit que des effets au mieux subtils et transitoires. Les conditions nécessaires pour déclencher ces réponses ne sont aujourd'hui pas bien connues. Il semblerait qu'il existe des effets sur le temps de réaction et sur une moindre précision observée dans l'exécution de certaines tâches cognitives, ce que viennent conforter les résultats d'études sur l'activité électrique générale du cerveau. Les études cherchant à déterminer si les champs magnétiques modifient la qualité du sommeil ont donné des résultats variables. Il est possible que cette variabilité puisse être attribuée en partie aux différences observées dans la conception de ces études.

Certaines personnes affirment être hypersensibles aux champs électromagnétiques en général. Toutefois, les données des études de provocation en double aveugle laissent à penser que les symptômes rapportés ne sont pas liés à l'exposition aux champs magnétiques EBF.

Il n'y a que des données contradictoires et peu concluantes indiquant que l'exposition aux champs électriques et magnétiques EBF puissent provoquer des symptômes dépressifs ou des suicides. Ainsi, ces données sont considérées comme insuffisantes.

Chez les animaux, la possibilité qu'une exposition aux champs EBF puisse modifier les fonctions neuro-comportementales a été explorée sous divers angles et pour toute une série de conditions d'exposition. Peu d'effets ont été établis avec certitude. Il y a des preuves convaincantes que les champs électriques à la fréquence du secteur peuvent être détectés par les animaux, très probablement par suite d'effets de charge de surface, et puissent provoquer une stimulation ou un stress bénin transitoire. Chez le rat, le seuil de détection se situe entre 3 et 13 kV m^{-1}. On a montré que des champs supérieurs à 50 kV m^{-1} provoquaient une réaction d'aversion chez les rongeurs. Les autres modifications éventuelles dues aux champs sont moins bien définies; les études en laboratoire n'ont permis d'obtenir que des effets subtils et transitoires. Il semblerait que l'exposition aux champs magnétiques puisse moduler les fonctions des systèmes de neurotransmetteurs opioïdes et cholinergiques dans le cerveau, ce qui est conforté par les résultats d'études s'intéressant aux effets sur l'analgésie et sur l'acquisition et l'exécution de tâches liées à la mémoire spatiale.

16.1.5 Système neuroendocrinien

Les résultats des études effectuées chez des volontaires, ainsi que des études épidémiologiques en milieu résidentiel et professionnel, laissent à penser que le système neuroendocrinien n'est pas affecté par l'exposition à des champs électriques ou magnétiques à la fréquence du réseau. Cela vaut particulièrement pour les concentrations circulantes d'hormones spécifiques du système neuroendocrinien, notamment la mélatonine, libérée par l'épiphyse, et pour un certain nombre d'hormones impliquées dans le contrôle du métabolisme et de la physiologie de l'organisme libérées par l'hypophyse. On a parfois observé des différences infimes dans la chronologie de la libération de la mélatonine associées à certaines caractéristiques de l'exposition, mais ces résultats n'ont pas été uniformes. Il est très difficile d'éliminer certains facteurs de confusion dus à toutes sortes d'éléments environnementaux et du mode de vie qui pourraient également modifier les concentrations d'hormones. La plupart des études en laboratoire sur les effets de l'exposition aux EBF sur les concentrations nocturnes de mélatonine chez des volontaires ont montré qu'elle n'avait aucun effet lorsqu'on avait pris soin de neutraliser les éventuels facteurs de confusion.

Parmi les nombreuses études réalisées chez l'animal pour analyser les effets des champs électriques et magnétiques à la fréquence du réseau sur les concentrations pinéales et sériques de mélatonine chez le rat, certaines ont rapporté que l'exposition entraînait une suppression nocturne de la mélatonine. Les changements de concentration de mélatonine observés dans des études antérieures portant sur des expositions à des champs électriques allant jusqu'à 100 kV m^{-1} n'ont pas pu être reproduits. Les résultats d'une série d'études plus récentes, qui ont montré que les champs magnétiques polarisés circulairement supprimaient les concentrations nocturnes de mélatonine, ont perdu du poids du fait de comparaisons inappropriées entre animaux exposés et témoins historiques. Les données d'autres expériences réalisées chez les rongeurs, couvrant des degrés d'intensité allant de quelques microteslas à

5 mT, ont été ambiguës, certains résultats montrant une dépression de la mélatonine et d'autres aucune modification. Chez les animaux se reproduisant à une saison déterminée, la preuve d'un effet de l'exposition à des champs à la fréquence du réseau sur les concentrations de mélatonine et sur l'état reproductif dépendant de la mélatonine est principalement négative. Aucun effet convaincant sur les concentrations de mélatonine n'a été observé dans une étude réalisée chez des primates non humains chroniquement exposés à des champs à la fréquence du réseau, bien qu'une étude préliminaire effectuée sur deux animaux ait rapporté une suppression de la mélatonine en réponse à une exposition irrégulière et intermittente.

Les effets de l'exposition à des champs EBF sur la production de mélatonine ou sa libération dans des épiphyses isolées ont été variables, bien que relativement peu d'études in vitro aient été effectuées. Les éléments de preuve indiquant que l'exposition aux EBF interfère avec l'action de la mélatonine sur les cellules de cancer du sein in vitro sont particulièrement intéressants. Toutefois, ce système souffre de l'inconvénient que les lignées cellulaires montrent fréquemment en culture une dérive génotypique et phénotypique qui peut empêcher leur transfert entre laboratoires.

Aucun effet réplicable n'a été observé sur les hormones liées au stress de l'axe hypophyso-surrénalien de toutes sortes d'espèces de mammifères, à l'exception possible d'un stress de courte durée faisant suite au début d'une exposition à un champ électrique EBF suffisamment intense pour être perçu. De la même façon, alors que peu d'études ont été effectuées, on a observé des effets principalement négatifs ou irréguliers au niveau des concentrations d'hormones de croissance et d'hormones participant au contrôle de l'activité métabolique, ou associées au contrôle de la reproduction et du développement sexuel.

Dans l'ensemble, ces données n'indiquent pas que les champs électriques et/ou magnétiques EBF modifient le système neuroendocrinien et ont des répercussions indésirables sur la santé humaine, et les éléments de preuve sont donc considérés comme insuffisants.

16.1.6 Troubles neurodégénératifs

L'hypothèse a été émise suivant laquelle l'exposition aux champs EBF serait associée à plusieurs maladies neurodégénératives. Concernant la maladie de Parkinson et la sclérose en plaques, le nombre d'études est faible et rien ne permet de penser qu'il y ait une association avec ces maladies.

Pour la maladie d'Alzheimer et la sclérose latérale amyotrophique (SLA), davantage d'études ont été publiées. Certains de ces rapports laissent à penser que les personnes ayant des professions dans le secteur de l'électricité pourraient avoir un risque accru de SLA. Jusqu'ici, aucun mécanisme biologique n'a été établi qui pourrait expliquer une telle association, la maladie ayant pu apparaître à cause de facteurs de confusion liés à ce type de professions, par exemple les chocs électriques. Dans l'ensemble, les éléments en faveur d'une association entre exposition aux EBF et SLA sont considérés comme insuffisants. Les quelques études portant sur l'association entre

exposition aux EBF et maladie d'Alzheimer ont donné des résultats variables. Toutefois, la meilleure qualité des études axées sur la morbidité par Alzheimer, plutôt que sur la mortalité, n'indique aucune association. Dans l'ensemble, les éléments en faveur d'une association entre l'exposition aux EBF et la maladie d'Alzheimer sont insuffisants.

16.1.7 Troubles cardio-vasculaires

Les études expérimentales sur l'exposition à court et long terme indiquent que si le choc électrique constitue un risque manifeste pour la santé, les autres effets cardio-vasculaires dangereux associés aux champs EBF ont peu de chances de se produire aux niveaux d'exposition communément rencontrés dans l'environnement naturel ou professionnel. Bien qu'on ait signalé dans la littérature diverses modifications cardio-vasculaires, la majorité des effets sont mineurs et les études n'ont pas donné de résultats homogènes. Aucune des études de la morbidité et de la mortalité des maladies cardio-vasculaires n'a montré d'association avec l'exposition, sauf une. Le fait de savoir s'il existe une association entre l'exposition et l'altération du contrôle autonome du coeur donne lieu à bien des conjectures. Dans l'ensemble, les éléments dont on dispose ne sont pas en faveur d'une association entre exposition aux EBF et maladie cardio-vasculaire.

16.1.8 Immunologie et hématologie

Les données concernant les effets des champs électriques ou magnétiques EBF sur des constituants du système immunitaire sont généralement peu homogènes. La plupart des populations cellulaires et marqueurs fonctionnels ne sont pas perturbés par l'exposition. Cependant, dans certaines études humaines réalisées avec des champs allant de 10 μT à 2 mT, on a observé des modifications des cellules Natural Killer (NK), qui ont montré à la fois une augmentation et une diminution de leur nombre, et dans la numération leucocytaire totale qui a montré soit une absence de modification, soit une diminution du nombre de leucocytes. Dans des études réalisées chez l'animal, on a observé une diminution de l'activité des cellules NK chez la souris femelle, mais pas chez les mâles ni chez des rats des deux sexes. Les numérations leucocytaires ont également montré une certaine variabilité, avec des diminutions ou une absence de modification, rapportées dans différentes études. Les expositions auxquelles étaient soumis les animaux allaient de 2 μT à 30 mT. La difficulté qu'il y a à interpréter les effets potentiels de ces données sur la santé est due aux grandes variations enregistrées dans les conditions d'exposition et environnementales, ainsi qu'au nombre relativement faible de sujets testés et à la vaste gamme des paramètres biologiques étudiés.

Il y a eu peu d'études sur les effets des champs magnétiques EBF sur le système hématologique. Dans les expériences évaluant les numérations leucocytaires différentielles, les expositions allaient de 2 μT à 2 mT. Aucun effet constant de l'exposition aiguë aux champs magnétiques EBF ou aux champs magnétiques et électriques EBF combinés n'a été trouvé dans les études réalisées chez l'homme ou chez l'animal.

Par conséquent, d'une manière générale, les éléments en faveur d'effets des champs électriques ou magnétiques EBF sur les systèmes immunitaire et hématologique sont considérés comme insuffisants.

16.1.9 Reproduction et développement

Dans l'ensemble, les études épidémiologiques n'ont pas montré d'association entre leurs résultats dans le domaine de la reproduction de l'homme et l'exposition maternelle ou paternelle à des champs EBF. Il existe des éléments en faveur d'un risque accru de fausse-couche associé à l'exposition maternelle au champ magnétique, mais ils sont insuffisants.

Les effets d'expositions aux champs électriques EBF jusqu'à 150 kV m^{-1} ont été évalués chez plusieurs espèces de mammifères, notamment dans des études sur l'exposition de grands groupes et sur plusieurs générations. Les résultats montrent systématiquement qu'il n'y a aucun effet indésirable sur le développement.

L'exposition de mammifères aux champs magnétiques EBF jusqu'à 20 mT n'entraîne pas de malformations externes, squelettiques ou viscérales grossières. Certaines études montrent une augmentation des anomalies mineures du squelette chez le rat et la souris. Ces variations sont relativement courantes dans les études de tératologie et sont souvent considérées comme sans signification biologique. Toutefois, des effets subtils des champs magnétiques sur le développement squelettique ne peuvent être écartés. Très peu d'études ont été publiées sur les effets sur la reproduction et il est impossible d'en tirer des conclusions.

Plusieurs études sur des modèles expérimentaux autres que mammifères (embryons de poulets, poissons, oursins et insectes) ont donné des résultats indiquant que les champs magnétiques EBF de l'ordre du microtesla peuvent perturber le début du développement. Mais les résultats de ces modèles expérimentaux ont moins de poids dans l'évaluation générale de la toxicité sur le développement que ceux des études correspondantes réalisées chez les mammifères.

Dans l'ensemble, les éléments en faveur d'effets sur le développement et la reproduction sont insuffisants.

16.1.10 Cancer

La classification du Centre International de Recherche sur le Caner (CIRC, IARC) des champs magnétiques EBF comme étant "peut-être cancérogènes pour l'homme" (IARC, 2002) est basée sur l'ensemble des données disponibles en 2001. L'examen de la littérature dans la présente monographie des critères d'hygiène de l'environnement est principalement axé sur des études publiées après l'analyse du CIRC.

Epidémiologie

La classification du CIRC a été fortement influencée par les associations observées dans les études épidémiologiques sur la leucémie infantile.

Le fait de classer ces éléments comme étant limités n'est pas modifié avec l'adjonction de deux études sur la leucémie infantile publiées après 2002. Depuis la publication de la monographie du CIRC, les éléments relatifs à d'autres cancers chez l'enfant restent insuffisants.

Un certain nombre de rapports a été publié à la suite de la monographie du CIRC concernant le risque de cancer du sein chez la femme adulte associé à l'exposition à des champs magnétiques EBF. Ces études sont de taille plus importante que les précédentes et moins susceptibles de présenter des biais et sont dans l'ensemble négatives. Elles ont donc considérablement affaibli les éléments en faveur d'une association entre exposition à des champs magnétiques EBF et risque de cancer du sein chez la femme et ne vont plus du tout dans le sens d'une telle association.

Dans le cas des tumeurs cérébrales et des leucémies chez l'adulte, les nouvelles études publiées après la monographie du CIRC ne modifient pas la conclusion selon laquelle les éléments en faveur d'une association entre champs magnétiques EBF et ces maladies restent insuffisants.

Pour les autres maladies et tous les autres cancers, les éléments restent insuffisants.

Etudes sur les animaux de laboratoire

Il n'existe actuellement aucun modèle animal approprié de la forme de leucémie infantile la plus commune, la leucémie aiguë lymphoblastique. Trois études indépendantes à grande échelle effectuées chez le rat n'ont fourni aucune preuve d'un effet des champs magnétiques EBF sur l'incidence des tumeurs mammaires spontanées. La plupart des études rapportent l'absence d'effets des champs magnétiques EBF sur la leucémie ou le lymphome dans les modèles murins. Plusieurs études à grande échelle et à long terme effectuées chez des rongeurs n'ont montré aucune augmentation systématique d'aucun type de cancer, notamment des tumeurs hématopoïétiques, mammaires, cérébrales et cutanées.

Un nombre non négligeable d'études a examiné les effets des champs magnétiques EBF sur les tumeurs mammaires induites chimiquement chez le rat. Elles ont obtenu des résultats variables qui peuvent être dus entièrement ou partiellement à des différences dans les protocoles expérimentaux, par exemple à l'utilisation de sous-souches particulières. La plupart des études sur les effets de l'exposition à des champs magnétiques EBF sur des modèles de leucémie/lymphome chimiquement induits ou induits par le rayonnement n'ont pas montré d'effets. Les études sur les lésions hépatiques précancéreuses, les tumeurs cutanées et cérébrales chimiquement induites ont en majorité rapporté l'absence d'effets. Une étude a signalé une accélération de la genèse tumorale cutanée induite par les UV après exposition à des champs magnétiques EBF.

Deux groupes ont signalé des niveaux accrus de lésions des brins d'ADN dans le tissu cérébral suite à une exposition *in vivo* à des champs magnétiques EBF. Toutefois, d'autres groupes, en utilisant toutes sortes de

modèles murins de génotoxicité, n'ont trouvé aucun signe d'effets génotoxiques. Les résultats des études s'intéressant aux effets non génotoxiques en rapport avec le cancer ne permettent pas de tirer des conclusions.

Dans l'ensemble, rien ne permet de penser que l'exposition à des champs magnétiques EBF seule puisse provoquer des tumeurs. Les éléments indiquant que l'exposition à un champ magnétique EBF peut favoriser le développement d'une tumeur lorsqu'elle est associée à des facteurs cancérogènes sont insuffisants.

Etudes in vitro

En général, les études sur les effets de l'exposition de cellules à un champ EBF ont montré qu'il n'y avait pas d'effets génotoxiques pour des intensités de champ inférieures à 50 mT. Il existe cependant une exception notable, à savoir les données d'études récentes signalant une altération de l'ADN à des champs aussi faibles que 35 µT; cependant, ces études sont encore en cours d'évaluation et notre compréhension de ces résultats reste incomplète. Tout porte également à croire que les champs magnétiques EBF peuvent interagir avec des agents altérant d'ADN.

Il n'y a pas de preuve nette d'une activation des gènes associés au contrôle du cycle cellulaire par des champs magnétiques EBF. Cependant, il faut encore mener des études systématiques analysant la réponse de l'ensemble du génome.

De nombreuses autres études à l'échelle cellulaire, par exemple sur la prolifération cellulaire, le phénomène d'apoptose, le signal calcique et la transformation maligne, ont donné des résultats non homogènes ou ne permettant pas de tirer de conclusions.

Conclusion générale

Les nouvelles études réalisées chez l'homme, chez l'animal et in vitro et publiées depuis la monographie du CIRC en 2002 ne modifient en rien la classification générale des champs magnétiques EBF, considérés comme cancérogènes possibles pour l'homme.

16.1.11 Evaluation du risque pour la santé

D'après la Constitution de l'OMS, la santé est un état de bien-être physique, mental et social complet et pas simplement l'absence de maladie ou d'infirmité. Une évaluation du risque est un cadre conceptuel pour un examen structuré des informations utiles à l'estimation des résultats sur la santé ou l'environnement. L'évaluation du risque sanitaire peut être utilisée comme un élément de la gestion du risque qui englobe toutes les activités nécessaires pour parvenir à des décisions relatives au fait qu'une exposition exige ou non des mesures particulières et la mise en oeuvre de celles-ci.

Dans l'évaluation des risques pour la santé de l'homme, de solides données concernant l'homme, chaque fois qu'elles sont disponibles, sont généralement plus instructives que celles recueillies chez l'animal. Les

études chez l'animal et les études in vitro peuvent étayer les données des études chez l'homme, combler les lacunes laissées par les études chez l'homme, ou être utilisées pour prendre une décision relative aux risques lorsque les études chez l'homme sont insuffisantes ou absentes.

Toutes les études, qu'elles aient des résultats positifs ou négatifs (présence ou absence d'effets), doivent être évaluées et jugées pour elles-mêmes puis toutes ensembles à partir des données disponibles. Il est important de déterminer dans quelle mesure une série d'éléments modifie la probabilité pour qu'une exposition provoque un résultat. Les éléments de preuve de l'existence d'un effet sont généralement renforcés si les résultats de différents types d'études (épidémiologiques et expérimentales) laissent entrevoir la même conclusion et/ou lorsque de multiples études du même type donnent le même résultat.

Effets aigus

Des effets biologiques aigus ont été établis pour une exposition aux champs électriques et magnétiques EBF dans la gamme de fréquences allant jusqu'à 100 kHz, effets qui peuvent avoir des conséquences indésirables sur la santé. Par conséquent, des limites d'exposition sont nécessaires. Il existe des directives internationales qui traitent de cette question. L'observance de ces directives assure une protection suffisante contre les effets aigus.

Effets chroniques

Les données scientifiques laissant à penser que l'exposition quotidienne chronique à des champs magnétiques à la fréquence du réseau, de faible intensité (au-dessus de 0,3–0,4 μT), constitue un risque pour la santé sont basées sur des études épidémiologiques mettant en évidence un profil homogène de risque de leucémie infantile accru. Les incertitudes de cette évaluation du risque incluent le biais de sélection des témoins et les erreurs de classification de l'exposition sur la relation entre champs magnétiques et leucémie infantile. En outre, pratiquement toutes les données de laboratoire et toutes les données mécanistiques ne vont pas dans le sens d'une association entre champs magnétiques EBF de faible intensité et modifications de fonctions biologiques ou de l'état sanitaire. Ainsi, tout bien considéré, les éléments de preuve ne sont pas suffisamment solides pour être considérés comme établissant un lien de causalité, mais le sont suffisamment pour rester préoccupants.

Bien que l'on n'ait pas pu établir une relation de cause à effet entre l'exposition à un champ magnétique EBF et la leucémie infantile, son effet possible sur la santé publique a été calculé en partant du principe de causalité de façon à fournir un élément potentiellement utile à la politique de santé. Toutefois, ces calculs dépendent fortement de la distribution de l'exposition et d'autres hypothèses et sont par conséquent très imprécis. En partant du principe que l'association est causale, le nombre de cas de leucémie infantile dans le monde qui pourrait être attribué à l'exposition peut, selon les estimations, se situer entre 100 et 2400 cas par an. Toutefois, cela ne représente que

0,2 à 4,9% de l'incidence annuelle totale des cas de leucémie, estimée à 49 000 dans le monde en 2000. Ainsi, dans le contexte mondial, l'impact sur la santé publique, pour autant qu'il y en ait, serait limité et incertain.

On a étudié un certain nombre d'autres maladies à la recherche d'une association éventuelle avec une exposition aux champs magnétiques EBF. Parmi elles figurent des cancers de l'enfant et de l'adulte, la dépression, le suicide, des dysfonctionnements de l'appareil reproducteur, des troubles du développement, des modifications immunologiques et des maladies neurologiques. Les données scientifiques en faveur d'un lien entre champs magnétiques EBF et l'une quelconque de ces maladies sont beaucoup plus ténues que pour la leucémie infantile et, dans certains cas (par exemple, s'agissant des maladies cardio-vasculaires ou du cancer du sein), elles sont suffisantes pour que l'on soit assuré que les champs magnétiques EBF ne provoquent pas ces maladies.

16.1.12 Mesures de protection

Il est essentiel de mettre en application des limites d'exposition de façon à se protéger des effets indésirables établis de l'exposition aux champs électriques et magnétiques EBF. Ces limites d'exposition doivent être basées sur un examen rigoureux de toutes les données scientifiques pertinentes.

Seuls des effets aigus ont été établis et il existe deux directives internationales relatives aux limites d'exposition (ICNIRP, 1998a; IEEE, 2002) destinées à protéger contre ces effets.

En même temps que ces effets aigus attestés, il existe des incertitudes concernant l'existence d'effets chroniques, à cause des éléments limités qui existent en faveur d'un lien entre exposition aux champs magnétiques EBF et leucémie infantile. Par conséquent, il est justifié de faire appel à des stratégies prudentes. Toutefois, il n'est pas recommandé de réduire les valeurs limites figurant dans les normes relatives à l'exposition jusqu'à un niveau arbitraire au nom du principe de précaution. De telles pratiques sapent les fondements scientifiques sur lesquels les limites sont basées et risquent de constituer une approche coûteuse, mais pas nécessairement efficace, d'assurer la protection.

La mise en œuvre d'autres types de mesures de précaution adaptées pour réduire l'exposition est raisonnable et justifiée. Toutefois, l'énergie électrique apporte des bienfaits évidents sur le plan sanitaire, social et économique et il ne faut pas que ces mesures les mettent en péril. Qui plus est, étant donné la faiblesse des éléments en faveur d'un lien entre exposition aux champs magnétiques EBF et leucémie infantile et les effets limités sur la santé publique si un tel lien existe, il est malaisé de déterminer les bienfaits qu'apporterait pour la santé une réduction de l'exposition. Ainsi, le coût des mesures de précaution doit être très bas. Le coût de la mise en oeuvre des réductions d'exposition variera d'un pays à l'autre, ce qui fait qu'il est très difficile de formuler une recommandation générale visant à équilibrer les coûts face à un risque potentiel imputable aux champs EBF.

Compte tenu de ce qui précède, les recommandations qui suivent ont été formulées.

- Les responsables de l'élaboration des politiques sanitaires doivent établir des lignes directives concernant l'exposition aux champs EBF à l'intention du grand public et des entreprises. Les directives internationales constituent la meilleure source d'orientation, aussi bien pour les niveaux d'exposition que pour les principes de l'évaluation scientifique des risques.
- Les responsables de l'élaboration des politiques doivent mettre en place un programme de protection contre les champs EBF comportant la mesure des champs de toutes origines pour veiller à ce que les limites d'exposition ne soient pas dépassées pour le grand public et lors d'expositions professionnelles.
- A condition de ne pas mettre en péril les bienfaits apportés sur le plan sanitaire, social et économique par l'énergie électrique, la mise en œuvre de mesures de précaution à très bas coût afin de réduire l'exposition est raisonnable et justifiée.
- Les responsables de l'élaboration des politiques sanitaires, les autorités locales et les fabricants doivent mettre en œuvre des mesures à très bas coût lorsqu'ils construisent de nouvelles installations et conçoivent un nouvel équipement, notamment de nouveaux appareils.
- Il faut envisager d'apporter des modifications aux pratiques de l'ingénierie afin de réduire l'exposition aux EBF des appareils ou dispositifs, à condition qu'elles se conjuguent avec d'autres avantages, par exemple une meilleure sécurité ou un coût faible ou nul.
- Lorsque l'on envisage d'apporter des changements aux sources EBF existantes, il faut étudier les possibilités de réduction du champ EBF en même temps que les aspects liés à la sécurité, à la fiabilité et au volet économique du projet.
- Les autorités locales doivent faire appliquer les réglementations relatives aux installations électriques afin de réduire les courants de terre non intentionnels lorsque l'on construit de nouvelles installations ou que l'on refait les installations existantes, tout en conservant la sécurité. Des mesures proactives visant à recenser les violations de ces règles ou les problèmes existants dans les installations électriques seraient coûteuses et peu susceptibles d'être justifiées.
- Les autorités nationales doivent mettre en œuvre une stratégie de communication efficace et ouverte pour permettre une prise de décision éclairée par toutes les parties prenantes ; celle-ci doit comprendre des informations sur la façon dont les personnes peuvent réduire leur propre exposition.

- Les autorités locales doivent améliorer la planification des installations émettrices de champs EBF, notamment en procédant à des consultations plus larges entre l'industrie, les pouvoirs publics locaux et les citoyens lorsqu'il s'agit d'implanter d'importantes sources EBF.
- Les pouvoirs publics et l'industrie doivent promouvoir des programmes de recherche visant à réduire l'incertitude des données scientifiques concernant les effets sanitaires de l'exposition aux champs EBF.

16.2 Recommandations en matière de recherche

La détermination des lacunes dans les connaissances relatives aux effets sanitaires possibles d'une exposition aux champs EBF constitue une part essentielle de cette évaluation du risque sanitaire. Il en a résulté les recommandations qui suivent relatives à la recherche à venir (résumées au Tableau 1).

La priorité des priorités pour la recherche est de s'intéresser aux fréquences intermédiaires, se situant communément entre 300 Hz et 100 kHz, étant donné l'actuel manque de données les concernant. Une très faible partie du corpus de connaissances nécessaires pour une évaluation du risque a été rassemblée et la plupart des études existantes ont donné des résultats variables, qui doivent être mieux étayés. Les normes générales de constitution d'une base de données sur les fréquences intermédiaires, qui soit suffisante pour l'évaluation du risque sanitaire, comprennent l'évaluation de l'exposition, des études épidémiologiques, des études sur l'homme en laboratoire et des études sur l'animal et sur les cellules (in vitro) (ICNIRP, 2003; ICNIRP, 2004; Litvak et al., 2002).

Pour toutes les études sur des volontaires, il est obligatoire que la recherche sur les sujets humains soit effectuée en conformité totale avec les principes éthiques, y compris les dispositions de la déclaration d'Helsinki (WMA, 2004).

Pour les études de laboratoire, on accordera la priorité aux réponses notifiées (i) pour lesquelles il y a au moins quelques éléments de réplication ou de confirmation, (ii) qui sont potentiellement en rapport avec la cancérogenèse (par exemple, la génotoxicité), (iii) qui sont suffisamment solides pour permettre une analyse mécanistique et (iv) qui se produisent dans des modèles mammifères ou humains.

16.2.1 Sources, mesurage et expositions

La caractérisation plus précise des habitations ayant une exposition élevée aux EBF dans différents pays, afin de déterminer la contribution relative des sources internes et externes, ainsi que l'influence des pratiques en matière d'installation électrique/de mise à la terre et autres caractéristiques des habitations, pourraient fournir des indications concernant une méthode pertinente de mesure de l'exposition pour les évaluations épidémiologiques. Mieux connaître l'exposition fœtale et infantile aux champs EBF en est une

composante importante, surtout s'agissant de l'exposition à un chauffage électrique par le sol ou aux transformateurs dans les immeubles.

On soupçonne que, dans certains cas d'exposition professionnelle, les limites d'exposition aux champs EBF des directives actuelles sont dépassées. Davantage d'informations sont nécessaires sur l'exposition professionnelle (y compris aux fréquences qui ne sont pas celles du réseau) liée par exemple à l'entretien des lignes sous tension, au travail à l'intérieur ou à proximité de l'entrefer des aimants d'IRM (et donc des champs EBF à gradient commuté) et aux réseaux de transport de l'électricité. De la même façon, des connaissances supplémentaires sont nécessaires concernant l'exposition du grand public qui pourrait approcher les limites des directives, notamment s'agissant de sources telles que les systèmes de sécurité, les systèmes de démagnétisation des bibliothèques, les appareils de cuisson par induction et de chauffage de l'eau.

L'exposition à des courants de contact a été proposée comme explication possible de l'association entre champs magnétiques EBF et leucémie infantile. Des recherches sont nécessaires dans des pays autres que les Etats-Unis d'Amérique afin d'évaluer la possibilité que les pratiques de mise à la terre et de plomberie utilisées dans les habitations donnent naissance à des courants de contact. Ces études auront la priorité dans les pays dans lesquels les résultats épidémiologiques concernant les EBF et la leucémie infantile sont significatifs.

16.2.2 Dosimétrie

Dans le passé, la plupart des recherches en laboratoire était fondée sur les courants électriques induits dans l'organisme, et la dosimétrie était ainsi axée sur cette quantité. Ce n'est que récemment que les travaux ont commencé à explorer les rapports entre exposition externe et champs électriques induits. Pour mieux comprendre les effets biologiques, on a besoin de davantage de données sur les champs électriques internes dans différentes conditions d'exposition.

Il faudrait procéder à une estimation des champs électriques internes dus à l'influence combinée des champs électriques et magnétiques externes dans différentes configurations. L'addition vectorielle des champs électriques et magnétiques qui sont sans relation de phase et variables dans l'espace est nécessaire pour déterminer les restrictions de base à respecter.

Très peu d'évaluations ont été effectuées sur des modèles précis de femme enceinte et de fœtus comportant une modélisation anatomique appropriée. Il est important d'estimer l'éventuelle induction de champs électriques chez le fœtus en relation avec le problème de la leucémie infantile car les expositions tant professionnelles que résidentielles de la mère sont importantes.

Il faut affiner encore les modèles micro-dosimétriques pour pouvoir tenir compte de l'architecture cellulaire des réseaux nerveux et autres systèmes infra-organiques complexes dont on sait qu'ils sont plus sensibles

aux effets induits par le champ électrique. Ce processus de modélisation doit également se pencher sur les influences s'exerçant sur les potentiels électriques de la membrane cellulaire et sur la libération des neurotransmetteurs.

16.2.3 Mécanismes biophysiques

Il y a trois sujets principaux pour lesquels il y a des limites évidentes à la compréhension que l'on a des mécanismes: les paires de radicaux libres, les particules magnétiques présentes dans l'organisme et le rapport signal/bruit dans les systèmes multicellulaires, tels que les réseaux neuronaux.

Le mécanisme des paires de radicaux libres est l'un des mécanismes d'interaction de faible intensité les plus plausibles, mais il reste à montrer qu'il est capable d'assurer la médiation d'effets importants dans le métabolisme et le fonctionnement cellulaire. Il est particulièrement important de comprendre quelle est la limite inférieure d'exposition à laquelle il agit, de façon à pouvoir estimer s'il pourrait ou non constituer un mécanisme pertinent de cancérogenèse. Etant donné les études récentes dans lesquelles les espèces oxygénées radicalaires ont été augmentées dans les cellules immunitaires exposées aux champs EBF, il est recommandé d'utiliser comme modèle cellulaire, pour l'analyse du potentiel de ce mécanisme des paires de radicaux libres, des cellules du système immunitaire qui produisent des espèces oxygénées radicalaires dans le cadre de leur réponse immunitaire.

Bien que la présence de particules magnétiques (cristaux de magnétite) dans le cerveau humain ne semble pas, d'après ce que l'on sait actuellement, conférer une sensibilité aux champs magnétiques EBF environnementaux, les approches théoriques et expérimentales à venir devraient déterminer si une telle sensibilité pourrait exister dans certaines conditions. En outre, toute modification du mécanisme des paires de radicaux libres évoqué ci-dessus, engendrée par la présence de magnétite, devrait être recherchée.

Il convient d'analyser de façon approfondie la mesure dans laquelle des mécanismes multicellulaires opèrent dans le cerveau pour augmenter le rapport signal/bruit, afin d'élaborer un cadre théorique permettant de quantifier le phénomène ou de déterminer ses limites. L'étude complémentaire du seuil et de la fréquence de réponse dans les réseaux neuronaux de l'hippocampe et d'autres parties du cerveau devrait être effectuée in vitro.

16.2.4 Neuro-comportement

Il est recommandé d'effectuer des études sur des volontaires en laboratoire sur les effets possibles sur le sommeil et sur la réalisation de tâches mentalement éprouvantes, au moyen d'approches méthodologiques harmonisées. Il faut préciser les réponses dose-réponse à des densités de flux magnétique supérieures à celles utilisées auparavant, et pour une gamme élargie de fréquences (c'est-à-dire dans la gamme des kilohertz).

Les études sur des adultes volontaires et sur les animaux laissent à penser que des effets cognitifs aigus peuvent se produire avec les expositions à court terme à des champs électriques ou magnétiques intenses. La caractérisation de ces effets est très importante pour l'élaboration de limites relatives à l'exposition, mais on manque de données précises concernant les effets dépendant du champ chez l'enfant. La mise en oeuvre d'études en laboratoire de la cognition et des modifications de l'électroencéphalogramme (ECG) enregistrées chez les personnes exposées aux champs EBF est recommandée, notamment chez les adultes régulièrement soumis à une exposition professionnelle et chez les enfants.

Les études comportementales sur des animaux immatures offrent un indicateur utile des effets cognitifs éventuels chez l'enfant. Les effets possibles d'une exposition pré- et postnatale aux champs magnétiques EBF sur le développement du système nerveux et la fonction cognitive devraient être étudiés. Ces études pourraient être utilement complétées par l'analyse des effets de l'exposition aux champs magnétiques EBF et aux champs électriques induits sur la croissance des cellules nerveuses au moyen de coupes de cerveaux ou de neurones en culture.

Il est nécessaire de s'intéresser plus avant aux conséquences sanitaires potentielles que laissent entrevoir les données expérimentales montrant des réponses opioïdes et cholinergiques chez l'animal. Les études portant sur la modulation des réponses opioïdes et cholinergiques chez l'animal doivent être étendues et il convient de définir des paramètres d'exposition et le fondement biologique de ces réponses comportementales.

16.2.5 Système neuroendocrinien

La base de données existante relative à la réponse neuroendocrinienne n'indique pas que l'exposition aux champs EBF pourrait avoir des effets indésirables sur la santé humaine. Par conséquent, aucune recommandation relative à des recherches supplémentaires n'est formulée.

16.2.6 Troubles neurodégénératifs

Plusieurs études ont montré un risque accru de sclérose latérale amyotrophique dans les "professions liées à l'électricité". On considère qu'il est important d'étudier cette association plus avant, de façon à découvrir si les champs magnétiques EBF font partie des causes de cette maladie neurodégénérative rare. Cette recherche demande de grandes études de cohortes prospectives comportant des informations sur l'exposition aux champs magnétiques EBF, aux chocs électriques et à d'autres facteurs de risque.

Il n'est pas certain que les champs magnétiques EBF constituent un facteur de risque de la maladie d'Alzheimer. Les données actuellement disponibles ne sont pas suffisantes et cette association doit être analysée de façon approfondie. L'utilisation des données de morbidité plutôt que de mortalité revêt une importance particulière.

16.2.7 Troubles cardio-vasculaires

Des recherches plus approfondies sur l'association entre champs magnétiques EBF et risque de maladie cardiovasculaire ne sont pas considérées comme une priorité.

16.2.8 Immunologie et hématologie

Les modifications observées dans les paramètres immunitaires et hématologiques d'adultes exposés aux champs magnétiques EBF ont montré des variations et il n'y a pratiquement aucune donnée issue de la recherche qui soit disponible sur les enfants. Par conséquent, la recommandation est de mener des études sur les effets de l'exposition aux EBF sur le développement des systèmes immunitaires et hématopoïétiques chez le jeune animal.

16.2.9 Reproduction et développement

Il semblerait qu'il y ait un risque accru de fausse couche associé à l'exposition aux champs magnétiques EBF. Etant donné l'effet potentiellement important pour la santé publique d'une telle association, une recherche épidémiologique approfondie est recommandée.

16.2.10 Cancer

La priorité des priorités pour la recherche dans ce domaine consiste à résoudre le conflit entre les données épidémiologiques (qui montrent une association entre l'exposition aux champs magnétiques EBF et un risque accru de leucémie infantile) et les données expérimentales et mécanistiques (qui ne sont pas en faveur d'une telle association). Il est recommandé que les épidémiologistes et les spécialistes des sciences expérimentales collaborent dans ce domaine. Pour que les nouvelles études épidémiologiques soient instructives, elles doivent être axées sur de nouveaux aspects de l'exposition, sur l'interaction potentielle avec d'autres facteurs ou sur les groupes fortement exposés, ou doivent être novatrices à un autre titre dans ce domaine de recherche. De plus, il est également recommandé de mettre à jour les analyses existantes groupées, en ajoutant les données des études récentes et en donnant un nouvel éclairage à ces analyses.

Les études sur les tumeurs cérébrales chez l'enfant ont donné des résultats variables. Comme pour la leucémie infantile, une analyse groupée des études sur ces tumeurs serait très instructive et elle est donc recommandée. Une telle analyse globale peut, à peu de frais, donner un aperçu plus vaste et meilleur des données existantes, notamment sur l'existence d'un biais de sélection et, si les études sont suffisamment homogènes, peut offrir une meilleure estimation du risque.

Concernant le cancer du sein chez l'adulte, des études plus récentes ont montré de façon convaincante qu'il n'y avait aucune association avec l'exposition aux champs magnétiques EBF. Par conséquent, d'autres recherches sur une telle association devraient se voir accorder une très faible priorité à l'avenir.

Concernant la leucémie et le cancer du cerveau chez l'adulte, la recommandation est de mettre en œuvre de grandes cohortes de sujets exposés professionnellement qui existent. Les études sur l'exposition professionnelle, les analyses et les méta-analyses groupées relatives à la leucémie et au cancer du cerveau ont donné des résultats variables et peu concluants. Toutefois, de nouvelles données ont été publiées par la suite qui devraient être utilisées pour actualiser ces analyses.

La priorité est d'examiner les données épidémiologiques en établissant des modèles animaux et in vitro appropriés pour les réponses aux champs magnétiques EBF de faible intensité, modèles qui soient largement transférables d'un laboratoire à l'autre.

Les modèles de rongeurs transgéniques utilisés pour l'étude de la leucémie infantile doivent être développés de façon à fournir des modèles animaux expérimentaux permettant d'étudier les effets de l'exposition aux champs magnétiques EBF. Par ailleurs, pour les études existantes sur l'animal, la majorité des données disponibles indiquent qu'il n'y a pas d'effets cancérogènes dus aux seuls champs magnétiques EBF. Il faut par conséquent accorder un rang de priorité élevé aux études in vitro et chez l'animal dans lesquelles les champs magnétiques EBF sont rigoureusement évalués en tant que cofacteurs de la cancérogenèse.

Concernant les autres études in vitro, les expériences faisant état d'effets génotoxiques de l'exposition à un champ magnétique EBF intermittent doivent être reproduites.

16.2.11 Mesures de protection

Il est recommandé d'effectuer des recherches sur l'élaboration de politiques de protection sanitaire et sur la mise en oeuvre de celles-ci dans les secteurs où il n'y a pas de certitude scientifique, plus précisément sur le recours au principe de précaution, l'interprétation de ce dernier et l'évaluation des effets des mesures de précaution prises contre les champs magnétiques EBF et autres agents rangés dans les "cancérogènes possibles pour l'homme". Lorsqu'il y a incertitude quant au risque sanitaire potentiel qu'un agent représente pour la société, des mesures de précaution peuvent être justifiées pour garantir la protection appropriée du grand public et des travailleurs. Seules des recherches limitées ont été effectuées dans ce domaine pour les champs magnétiques EBF et, parce qu'elles sont importantes, des recherches complémentaires sont nécessaires. Elles permettront peut-être aux pays d'intégrer le principe de précaution dans leurs politiques de protection de la santé.

Il est conseillé de procéder à une recherche approfondie sur la perception du risque et la communication sur les risques spécifiquement axée sur les champs électromagnétiques. Les facteurs psychologiques et sociologiques qui influent sur la perception du risque en général ont été largement étudiés. Toutefois, une recherche limitée a été menée pour analyser l'importance relative de ces facteurs dans le cas des champs électromagnétiques ou pour répertorier d'autres facteurs qui seraient spécifiques aux

champs électromagnétiques. Les études récentes laissent à penser que les mesures de précaution qui véhiculent implicitement des messages de risque peuvent modifier la perception du risque en augmentant ou en réduisant l'inquiétude. Des études approfondies dans ce domaine sont par conséquent justifiées.

Il convient de mener à bien une recherche sur l'élaboration d'une analyse coût-bénéfice/coût-efficacité afin d'atténuer l'exposition aux champs magnétiques EBF. Le recours à des analyses coût/bénéfice et coût/efficacité, afin d'évaluer si une orientation politique est bénéfique pour la société, a fait l'objet de recherches dans de nombreux secteurs de l'action des pouvoirs publics. L'élaboration d'un cadre qui recensera les paramètres nécessaires pour pouvoir effectuer cette analyse s'agissant des champs magnétiques EBF est nécessaire. Vu les incertitudes de l'évaluation, il faudra incorporer des paramètres quantifiables et non quantifiables.

Tableau 1. Recommandations de recherche

Sources, mesures et expositions	**Priorité**
Caractérisation approfondie des habitations soumises à une forte exposition au champ magnétique EBF dans différents pays	Moyenne
Recensement des lacunes dans les connaissances concernant l'exposition professionnelle aux EBF, par exemple s'agissant de l'IRM	Elevée
Evaluation de la capacité des installations électriques domestiques, en dehors des Etats-Unis d'Amérique, à induire des courants de contact chez l'enfant	Moyenne
Dosimétrie	
Dosimétrie numérique complémentaire reliant les champs électriques et magnétiques externes aux champs électriques internes, en particulier s'agissant de l'exposition à des champs électriques et magnétiques combinés dans diverses orientations	Moyenne
Calcul des champs et courants électriques induits chez la femme enceinte et chez le fœtus	Moyenne
Affinement des modèles micro-dosimétriques prenant en compte l'architecture cellulaire des réseaux nerveux et autres systèmes tissulaires complexes	Moyenne
Mécanismes biophysiques	
Etude approfondie des mécanismes des paires de radicaux dans les cellules immunitaires qui génèrent des espèces radicalaires de l'oxygène dans le cadre de leur fonction phénotypique	Moyenne
Etude théorique et expérimentale approfondie du rôle possible de la magnétite dans la sensibilité au champ magnétique EBF	Faible

Détermination des seuils de réponse aux champs électriques internes induits par les EBF sur les systèmes multicellulaires, comme les réseaux nerveux, à l'aide de méthodes théoriques et in vitro	Elevée
Neurocomportement	
Etudes cognitives, sur le sommeil et l'EEG de volontaires, notamment des enfants et des sujets exposés professionnellement, dans un large éventail de fréquences EBF à des densités de flux élevées	Moyenne
Etudes de la fonction cognitive chez l'animal après exposition pré- et postnatale	Moyenne
Etude approfondie des réponses opioïdes et cholinergiques chez l'animal	Faible
Troubles neurodégénératifs	
Etudes complémentaires sur le risque de sclérose latérale amyotrophique dans les professions liées à l'électricité et en rapport avec une exposition à un champ magnétique EBF et de maladie d'Alzheimer en rapport avec l'exposition à un champ magnétique EBF	Elevée
Immunologie et hématologie	
Etudes sur les conséquences de l'exposition à un champ magnétique EBF sur le développement des systèmes immunitaires et hématopoïétiques chez le jeune animal	Faible
Reproduction et développement	
Etude complémentaire sur le lien éventuel qui existerait entre fausses couches et exposition à un champ magnétique EBF	Faible
Cancer	
Actualisation des analyses groupées existantes sur la leucémie infantile à l'aide des nouvelles données	Elevée
Analyses groupées des études existantes sur les tumeurs cérébrales chez l'enfant	Elevée
Mise à jour des méta-analyses existantes relatives à la leucémie et aux tumeurs cérébrales chez l'adulte et aux cohortes de sujets exposés professionnellement	Moyenne
Mise au point de modèles murins transgéniques de leucémie infantile utilisables dans les études sur les EBF	Elevée
Evaluation des effets co-cancérogènes au moyen d'études in vitro chez l'animal	Elevée
Tentative de reproduction des études de génotoxicité in vitro	Moyenne
Mesures de protection	
Recherche sur l'élaboration de politiques de protection de la santé et sur leur mise en oeuvre dans les secteurs où il n'y a pas de certitude scientifique	Moyenne

Recherche complémentaire sur la perception du risque et la communication sur les risques axée sur les champs électromagnétiques	Moyenne
Elaboration d'une analyse coût-bénéfice/coût-efficacité pour l'atténuation des champs EBF	Moyenne

17 РЕЗЮМЕ И РЕКОМЕНДАЦИИ ДЛЯ ДАЛЬНЕЙШИХ ИССЛЕДОВАНИЙ

В настоящей монографии, посвященной медицинским критериям окружающей среды (МКОС), рассматриваются возможное влияние на здоровье воздействия электрического и магнитного полей сверхнизкой частоты (СНЧ). В монографии рассматриваются физические характеристики полей СНЧ, а также источники излучения и измерения. Однако главная цель состоит в обзоре научной литературы, касающейся биологических эффектов воздействия полей СНЧ для того, чтобы оценить риск для здоровья, возникающий в связи с воздействием этого поля, и использовать эту оценку риска для здоровья для составления рекомендаций, предназначенных для национальных органов, занимающихся программами защиты здоровья.

Рассматриваемые частоты находятся в диапазоне от 0 Гц до 100 кГц. Значительное большинство исследований проводилось в отношении магнитных полей промышленной частоты (50 или 60 Гц) и лишь немногие исследования касались электрических полей промышленной частоты. Кроме того, было проведено несколько исследований, касающихся полей очень низких частот (ОНЧ, 3–30 кГц), магнитных полей переменного градиента, применяющихся в магнитно-резонансной томографии, и более слабых полей ОНЧ, создаваемых видеодисплейными терминалами и телевизорами.

В данной главе обобщаются основные выводы и рекомендации по каждому разделу, а также общие выводы в отношении процесса оценки риска для здоровья. В монографии для выражения убедительности данных по отношению к определенному медицинскому результату используются следующие термины. Данные именуются «ограниченными», когда они являются результатом лишь одного исследования или когда имеются нерешенные вопросы, касающиеся постановки, проведения или интерпретации ряда исследований. Термин «неадекватные» данные используется в тех случаях, когда исследования нельзя истолковать таким образом, чтобы показать наличие либо отсутствие какого-либо эффекта вследствие существенных качественных или количественных ограничений или в тех случаях, когда данные отсутствуют.

Были также выявлены основные пробелы в информации и исследования, которые необходимо провести для ликвидации этих пробелов, они были обобщены в разделе, озаглавленном «Рекомендации в отношении научных исследований».

17.1 Резюме

17.1.1 Источники, измерения и воздействия на организм человека

Электрические и магнитные поля существуют повсюду, где генерируется, транспортируется или распределяется электроэнергия по

линиям или кабелям электропередачи или используется в электрических приборах. Поскольку использование электричества является неотъемлемой частью нашего современного образа жизни, эти поля повсеместно существуют в нашем окружении.

Напряженность электрического поля измеряется в вольтах на метр (В/м) или в киловольтах на метр (кВ/м), а в отношении магнитных полей индукция изменяется в теслах (Тл) или чаще в миллитеслах (мТл) или в микротеслах (мкТл).

Воздействие магнитных полей промышленной частоты в местах проживания людей в различных странах мира отличается незначительно. Среднее геометрическое значение интенсивности магнитного поля в домашних условиях колеблется от 0,025 и 0,07 мкТл в Европе и 0,055 и 0,11 мкТл в США. Среднее значение напряженности электрического поля в домашних условиях находится в пределах нескольких десятков вольт на метр. В непосредственной близости от некоторых приборов мгновенные значения магнитной индукции могут составлять несколько сотен микротесла. Вблизи линий электропередачи магнитные поля достигают приблизительно 20 мкТл, а напряженность электрических полей может составлять несколько тысяч вольт на метр.

Лишь незначительное количество детей подвержены воздействию магнитных полей частотой 50 или 60 Гц в домашних условиях ,с уровнями, усредненными по времени воздействия, превышающими уровни, которые обусловливают повышенную заболеваемость детей лейкемией (см. Раздел 17.1.10). Приблизительно 1%-4% подвергаются воздействию магнитной индукции, превышающей 0,3 мкТл и лишь 1%–2% подвергаются усредненному воздействию, превышающему 0,4 мкТл.

Производственное воздействие, хотя и обусловленное, главным образом, полями промышленной частоты, может также включать в себя воздействие других частот. Средняя экспозиция к магнитному полю на рабочем месте оказалась выше у работников «электрических профессий», нежели у лиц с другими занятиями, такими как работа в офисе, и составляла от 0,4–0,6 мкТл для электриков и электроинженеров до приблизительно 1,0 мкТл для рабочих, обслуживающих линии электропередачи, при наиболее высоких уровнях воздействия для таких профессий, как сварщики, водители электровозов и операторы швейных машин (свыше 3 мкТл). Максимальная интенсивность магнитного поля на рабочем месте может достигать приблизительно 10 мТл, и это неизменно связано с высокими значениями пропускаемого в проводах электротока. В секторе электроснабжения работающие могут подвергаться воздействию электрических полей, значение которых составляет до 30 кВ/м.

17.1.2 Электрические и магнитные поля в организме

При воздействии внешних электрических и магнитных полей сверхнизких частот в организме наводятся электрические поля и токи. При помощи измерений выявлена взаимосвязь между внешними полями и наведенным электрическим полем и плотностью тока в организме или другими параметрами, обусловленными воздействием этих полей. Локально индуцированное электрическое поле и плотность тока представляют особый интерес, поскольку они могут стимулировать возбудимые ткани, такие как нервные и мышечные волокна.

Организм человека и животных в значительной степени видоизменяет пространственное распределение электрического поля СНЧ. На низких частотах тело является хорошим проводником, и искаженные линии поля вне организма практически перпендикулярны поверхности тела. На поверхности подвергающегося воздействию организма возникают колеблющиеся заряды, которые индуцируют токи внутри организма. Основные результаты дозиметрии, касающиеся воздействия электрических полей СНЧ на организм человека, выглядят следующим образом:

- Электрическое поле, имеющееся внутри организма, обычно обладает напряженностью на пять или шесть порядков меньшей, чем внешнее электрическое поле.
- При действии на организм поля преимущественно вертикальной направленности, преобладающая направленность наведенных полей также вертикальна.
- При данном внешнем электрическом поле наиболее сильные поля наводятся в теле человека, ноги которого плотно контактируют с землей (электрически заземлены), и наиболее слабые поля наводятся в теле, изолированном от земли (в “свободном пространстве”).
- Общий ток, протекающий в теле, находящемся в тесном контакте с землей, определяется преимущественно габаритами и формой тела (включая позу), а не проводимостью тканей.
- Распределение наведенных токов по различным органам и тканям определяется проводимостью этих тканей.
- Распределение наведенного электрического поля также обусловлено проводимостью, однако в меньшей степени, нежели наведенный ток.
- Имеет место также явление, состоящее в том, что в теле возникает ток при наличии контакта с проводящим предметом, находящимся в электрическом поле.

Что касается магнитных полей, то для них проницаемость тканей та же, что и проницаемость воздуха, поэтому магнитное поле в тканях такое же, как и внешнее поле. Организмы человека и животных не вносят существенного возмущения в поле. Основным результатом воздействия магнитных полей является индукция электрических полей, открытая Фарадеем и обусловленная плотностью тока в проводящих тканях. Основные результаты измерения воздействия магнитных полей СНЧ на организм человека состоят в следующем:

- Наведенное электрическое поле и ток зависят от ориентации внешнего поля. Наведенные поля в организме в целом достигают наибольшего значения в тех случаях, когда линии поля идут в направлении от фронтальной к задней части тела, однако в отношении отдельных органов наивысшие значения достигаются в тех случаях, когда линии поля имеют боковую направленность (от края до края).
- Наиболее слабые электрические поля индуцируются магнитным полем, ориентированным вдоль вертикальной оси тела.
- При определенной напряженности и ориентации магнитного поля более сильные электрические поля наводятся в более массивном теле.
- Распределение наведенного электрического поля обусловлено проводимостью различных органов и тканей. Они оказывают ограниченное влияние на распределение плотности наведенного тока.

17.1.3 Биофизические механизмы

Различные предлагаемые механизмы прямого и косвенного взаимодействия электрических и магнитных полей СНЧ изучаются на предмет обоснованности, в частности, в какой степени “сигнал”, индуцированный в биологическом процессе в результате воздействия какого-либо поля, может быть выделен из флуктуационного шума, и противоречит ли этот механизм научным принципам и нынешним научным знаниям. Действие многих механизмов становится очевидным лишь при значениях поля, превышающих определенный уровень. Тем не менее, отсутствие выявленных очевидных механизмов не исключает возможности воздействия на здоровье даже при весьма низких уровнях поля при условии того, что это не противоречит основным научным принципам.

Из многочисленных предлагаемых механизмов прямого взаимодействия полей с организмом человека выделяются три механизма в качестве вероятно действующих при более низких интенсивностях поля, нежели другие: индуцированные электрические поля в нейронных сетях радикальные пары и магнетиты.

Электрические поля, наведенные в тканях электрическими или магнитными полями СНЧ, непосредственно стимулируют одиночные миелиновые нервные волокна биофизически понятным образом в тех случаях, когда напряженность внутреннего поля превышает несколько вольт на метр. В отличие от отдельных клеток значительно более слабые поля могут оказывать влияние на синаптическую передачу в нейронных сетях . Подобная обработка сигналов нервными системами обычно используется многоклеточными организмами для выявления слабых сигналов окружающей среды. Было высказано предположение, что нижним пределом интенсивности сигнала, различаемого нейронной сетью, является 1 мВ/м, однако, учитывая современные данные, более вероятными представляются пороговые значения в диапазоне 10–100 мВ/м.

Механизм действия радикальных пар является общепринятым пониманием того, каким образом магнитные поля могут оказывать влияние на специфические типы химических реакций, обычно путем увеличения концентрации реактивных свободных радикалов в слабых полях и снижения концентраций в сильных полях. Эти увеличения проявлялись в магнитных полях с индукцией менее 1 мТл. Имеются определенные данные, увязывающие этот механизм со способностью перелетных птиц определять направление перелета. Также, исходя из теоретических предпосылок, и в силу того, что изменения, вызываемые СНЧ и постоянными магнитными полями сходны, предполагается, что поля промышленной частоты с интенсивностью значительно меньшей, чем геомагнитное поле с индукцией около 50 мкТл, вряд ли могут иметь существенное биологическое значение.

Магнетитовые кристаллы, мелкие ферромагнитные кристаллы оксидов железа различной формы, присутствуют в тканях животных и человека, хотя и в незначительных количествах. Подобно свободным радикалам их присутствие связывают со способностью мигрирующих животных к ориентированию и навигации, хотя присутствие чрезвычайно малых количеств магнетита в мозге человека не наделяет его способностью выявлять наличие слабого геомагнитного поля. Расчеты, основанные на крайних предположениях, позволяют сделать вывод о том, что нижний предел эффектов воздействия полей СНЧ на магнетитовые кристаллы составляет 5 мкТл.

Другие виды прямого биофизического воздействия полей, такие как нарушение химических связей, воздействие на заряженные частицы и различные механизмы узкополосного “резонанса” не рассматриваются, что продиктовано желанием дать достоверное объяснение воздействию полей, которое имеет место в повседневной жизни и

Что касается непрямых эффектов, поверхностные электрические заряды, индуцируемые электрическими полями могут ощущаться, они могут приводить к болезненным микроударам при соприкасании с проводящим предметом. Контактные токи могут

возникать, когда, например, дети касаются водопроводного крана в ванной. При этом возникают незначительные электрические поля в костном мозге, значение которых, возможно, превышает фоновый уровень. Однако, представляет ли это риск для здоровья, неизвестно.

Высоковольтные линии электропередач продуцируют большое количество электрически заряженных ионов при коронном разряде. Предполагается, что они способствуют отложению переносимых воздухом загрязняющих веществ на коже и в дыхательных путях, что, возможно, отрицательно сказывается на здоровье. Однако представляется маловероятным, чтобы ионы, появляющиеся в результате коронного разряда, обладали более чем незначительным или вообще каким-либо влиянием на долгосрочный риск для здоровья даже у тех лиц, которые экспонированы в наибольшей степени.

Ни один из трех прямых механизмов не представляет собой достоверную причину увеличения заболеваемости при тех уровнях воздействия, которым обычно подвергаются люди. Фактически они становятся достоверными при более значительных уровнях, а косвенные механизмы изучены в недостаточной степени. Подобное отсутствие установленного достоверного механизма не исключает возможности неблагоприятного влияния на здоровье, но порождает необходимость располагать более прочными фактическими данными из области биологии и эпидемиологии.

17.1.4 Нейроповедение

Воздействие электрических полей промышленной частоты вызывает вполне определенные биологические реакции - от ощущения раздражения вплоть до поверхностных электрических разрядов. Эти реакции зависят от напряженности поля, условий окружающей среды и индивидуальной чувствительности. Порог непосредственного восприятия у 10% добровольцев находился в пределах от 2 до 20 кВ/м, в то время как у 5% было выявлено раздражающее действие, при напряженности поля 15–20 кВ/м . Искровые разряды от человека к земле воспринимали как болезненные 7% добровольцев, находившихся в поле с напряженностью в 5 кВ/м. Пороговое значение для разряда от заряженного предмета через заземленного человека зависит от габаритов этого предмета и поэтому требует конкретной оценки.

Поле высокой напряженности, быстро пульсирующие магнитные поля могут стимулировать ткани периферической или центральной нервной системы. Подобные явления могут возникать во время проведения магниторезонансной томографии и используются при транскраниальной магнитной стимуляции. Пороговое значение наведенного электрического поля для прямой стимуляции нерва может находиться на уровне всего лишь нескольких вольт на метр. Это пороговое значение, по-видимому, является постоянным в диапазоне частот от нескольких герц до нескольких килогерц. Лица, страдающие эпилепсией или предрасположенные к ней, по-видимому, являются

более чувствительными к индуцированным СНЧ электрическим полям в центральной нервной системе (ЦНС). Кроме того, чувствительность к электростимуляции ЦНС, по-видимому, обусловлена наличием в семье людей, страдающих эпилептическими припадками, а также использованием трициклических антидепрессантов, нейролептиков и других лекарств, понижающих эпилептический порог.

На функцию сетчатки, являющейся частью ЦНС, могут оказать влияние гораздо более слабые СНЧ магнитные поля , нежели те, которые вызывают прямую нервную стимуляцию. Ощущения вспышек света, именуемые «магнитными фосфенами» или «магнитофосфенами», возникают в результате взаимодействия индуцированного электрического поля с электрически возбудимыми клетками сетчатки. Пороговая напряженность наведенного электрического поля в околоклеточной жидкости сетчатки, согласно подсчетам, составляет от 10 до 100 мВ/м на частоте 20 Гц. Однако этим значениям присуща значительная неопределенность.

Менее ясными представляются данные в отношении других нейроповеденческих результатов, полученных в ходе исследований с участием добровольцев, такие как влияние на электрическую активность мозга, когнитивные функции, сон, сверхчувствительность и настроение. В целом подобные исследования проводились при уровнях воздействия ниже тех, которые необходимы для того, чтобы индуцировать вышеописанные явления. В результате были получены данные, в лучшем случае свидетельствующие о слабых и преходящих последствиях. Условия, необходимые для того, чтобы уяснить подобные реакции, в настоящее время определены недостаточно четко. Имеются данные, позволяющие предположить наличие обуславливаемого полем влияния на время реакции и снижение тщательности выполнения некоторых когнитивных задач, что подтверждается результатами исследований в отношении общей электрической активности мозга. Исследования в отношении того, оказывают ли магнитные поля влияние на качество сна, дают неоднородные результаты. Возможно, эта неоднородность частично объясняется различиями в постановке исследований.

Некоторые люди заявляют о своей повышенной чувствительности к электромагнитным полям в целом. Однако данные двойных слепых провокационных исследований позволяют предположить, что заявляемые симптомы не связаны с воздействием электромагнитных полей.

Имеются лишь разнородные и неубедительные данные о том, что воздействие электрических и магнитных полей СНЧ вызывает депрессивные симптомы или суициды. В силу этого данные считаются недостаточными.

Что касается животных, то возможность того, что воздействие полей СНЧ может влиять на нейроповеденческие функции, изучалась в

ряде различных направлений при различных условиях воздействия. Неопровержимых результатов получено было немного. Имеются убедительные свидетельства того, что электрические поля промышленной частоты могут ощущаться животными скорее всего путем ощущения поверхностного заряда и могут вызывать кратковременное возбуждение или легкий стресс. Крысы чувствуют наличие поля в диапазоне интенсивностей от 3 до 13 кВ/м. Было обнаружено, что грызуны не переносят напряженность поля, превышающую 50 кВ/м. Другие возможные последствия, обусловленные воздействием поля, определены в значительно меньшей степени; лабораторные исследования свидетельствуют лишь о незначительных и кратковременных эффектах. Имеются данные о том, что воздействие магнитных полей может изменить действие опиоида и холинергических нейромедиаторных систем мозга. Это подтверждается результатами исследований, в которых изучалось воздействие полей на обезболивание, а также на пространственное запоминание и выполнение пространственных задач.

17.1.5 Нейроэндокринная система

Результаты исследований, проведенных с участием добровольцев, а также эпидемиологических исследований в местах проживания и в условиях производственных воздействий, позволяют предположить, что на нейроэндокринную систему не оказывает неблагоприятного влияния воздействие электрических или магнитных полей промышленной частоты. Это относится в особенности к уровням циркуляции специфических гормонов в нейроэндокринной системе, в том числе мелатонина, выделяемого шишковидной железой, а также ряда гормонов, участвующих в управлении обменом веществ и физиологическими процессами, которые выделяются гипофизом. Незначительные отличия наблюдались в отношении времени выделения мелатонина, что было обусловлено некоторыми особенностями воздействия, однако эти результаты не проявляются последовательно. Весьма трудно устранить возможное вмешательство различных экологических факторов и факторов образа жизни, которые могут также отражаться в уровнях гормонов. В большинстве лабораторных исследований по изучению эффектов воздействия полей СНЧ на уровни мелатонина у добровольцев в ночное время, после того, как были приняты меры, исключающие влияние мешающих факторов, никакого эффекта обнаружено не было.

Было проведено большое количество исследований на животных с целью изучения результатов воздействия электрических и магнитных полей промышленной частоты на уровни мелатонина в шишковидной железе и в сыворотке у крыс. В некоторых исследованиях отмечалось, что воздействие полей приводило к супрессии мелатонина в ночное время. Изменения в уровнях мелатонина, впервые наблюдавшиеся в ранних исследованиях при воздействии электрического поля до 100 кВ/м, повторно получать не

удалось. Результаты ряда более недавних исследований, в которых показывалось, что циркулярно поляризованные магнитные поля понижают уровень мелатонина в ночное время, слабо выглядят на фоне неподходящих сравнений с результатами, полученными для данных животных и более ранними результатами. Данные, полученные в результате других экспериментов с грызунами, в которых уровни интенсивности магнитного поля изменялись в диапазоне от нескольких микротесла до 5 мТл, носили двойственный характер в связи с тем, что в некоторых опытах происходило подавление мелатонина, а в других не отмечалось никаких изменений. У животных с сезонным циклом размножения результаты воздействия полей промышленной частоты на уровень мелатонина и обуславливаемый мелатонином репродуктивный статус, главным образом, отрицательные. Никаких убедительных свидетельств в отношении уровней мелатонина не было обнаружено в исследовании на человекообразных обезьянах, хронически подвергаемых воздействию полей промышленной частоты, хотя в более раннем исследовании с использованием двух животных отмечалась супрессия секреции мелатонина в результате нерегулярного и интермиттирующего воздействия полей.

Результаты воздействия СНЧ полей на продукцию и выделение мелатонина в изолированной шишковидной железе различались, хотя исследований in vitro проводилось немного. Данные о том, что воздействие полей СНЧ вмешивается в воздействие мелатонина на раковые клетки молочной железы, вызывают интерес. Однако недостатком этого является тот факт, что в клеточных линиях нередко наблюдается генотипическая и фенотипическая изменчивость в культуре, которая может препятствовать воспроизводству эксперимента в других лабораториях.

Никаких устойчивых результатов обнаружено не было в отношении обуславливающих стресс гормонов гипофизарно-адреналиновой оси у различных видов млекопитающих при одном возможном исключении возникновения кратковременного стрессового состояния, возникающего в связи с воздействием электрического поля СНЧ на достаточно заметном уровне. Аналогичным образом, несмотря на то, что было проведено небольшое количество исследований, наблюдались большей частью отрицательные или противоречивые результаты в отношении уровней гормона роста и гормонов, участвующих в регулировании метаболизма или связанных с контролем репродуктивного и сексуального развития.

В целом, эти данные не указывают на то, что электрические и/или магнитные поля СНЧ оказывают влияние на нейроэндокринную систему таким образом, чтобы это производило неблагоприятное воздействие на здоровье человека, и поэтому эти данные считаются недостаточными.

17.1.6 Нейродегенеративные расстройства

Высказывалось предположение, что воздействие полей СНЧ обусловливает ряд нейродегенеративных заболеваний. В отношении болезни Паркинсона и множественного склероза количество исследований было незначительным, и доказательства взаимосвязи с этими заболеваниями отсутствуют. Что касается болезни Альцгеймера и бокового амиотрофического склероза, было опубликовано больше исследований. В ряде этих сообщений высказывается предположение, что лица, работающие в электроустановках, имеют больший риск бокового амиотрофического склероза. До сих пор не установлено никакого биологического механизма, который мог бы объяснить эту взаимосвязь, хотя это явление могло иметь место вследствие наличия неучтенных факторов, связанных с электрическими профессиями, как, например, удары электротоком. В целом, данные о взаимосвязи между воздействием полей СНЧ и боковым амиотрофическим склерозом считаются недостаточными.

Результаты нескольких исследований взаимосвязи между воздействием полей СНЧ и болезнью Альцгеймера противоречивы. Однако более качественные научные исследования, в которых основное внимание уделяется не смертности, а заболеваемости болезнью Альцгеймера, не указывают на какую-либо взаимосвязь. В целом, данные о взаимосвязи между воздействием полей СНЧ и болезнью Альцгеймера недостаточны.

17.1.7 Сердечно-сосудистые расстройства

Экспериментальные исследования как кратковременного, так и длительного воздействия указывают на то, что хотя электрошок является явной опасностью для здоровья, другие опасные последствия сердечно-сосудистого характера, связанные с полями СНЧ вряд ли могут возникнуть при уровнях воздействия, которые обычно имеют место в производственной и окружающей среде. Хотя в литературе сообщалось о различных сердечно-сосудистых изменениях, большинство последствий незначительны, и результаты, как в рамках самих исследований, так и при сравнении с другими исследованиями, противоречивы. За одним исключением: ни в одном из исследований по поводу заболеваемости и смертности, обусловленных сердечно-сосудистыми заболеваниями, не показана взаимосвязь с воздействием электрических или магнитных полей. Вопрос о том, существует ли взаимосвязь между воздействием полей и нарушением автономного контроля сердца, остается предметом догадок. В целом, данные не свидетельствуют о связи между воздействием полей СНЧ и сердечно-сосудистыми заболеваниями.

17.1.8 Иммунология и гематология

Данные о воздействии электрических или магнитных полей СНЧ на компоненты иммунной системы обычно противоречивы. На многие клеточные популяции и функциональные маркеры поля не

оказывают никакого влияния. Однако в некоторых исследованиях с участием человека и с использованием полей от 10 мкТл до 2 мТл наблюдались изменения в естественных клетках-киллерах, число которых как уменьшалось, так и увеличивалось, а также в клетках белой крови, число которых оставалось без изменений или уменьшалось. В исследованиях на животных у самок мышей отмечалось уменьшение активности естественных клеток-киллеров, однако этого не наблюдалось у самцов мышей или у крыс обоего пола. Подсчет числа клеток белой крови также был противоречивым. В различных исследованиях сообщалось об уменьшении их числа или об отсутствии каких-либо изменений. В опытах на животных использовался еще более широкий диапазон - от 2 мкТл до 30 мТл. Трудность толкования потенциального влияния на здоровье при указанных данных объясняется значительными колебаниями в условиях воздействия полей и окружающих условий, сравнительно небольшим числом тестируемых субъектов и широким разнообразием конечных результатов.

Было проведено несколько исследований в отношении воздействия магнитных полей СНЧ на гематологическую систему. В ходе экспериментов по оценке дифференциации количества клеток красной крови дозы воздействия изменялись в диапазоне от 2 мкТл до 2 мТл. Никаких последовательных результатов острого воздействия магнитных полей СНЧ или сочетанного электрического и магнитного поля СНЧ не было обнаружено при проведении исследований с участием человека или животных.

В силу этого, в целом, данные в отношении последствий воздействия электрических или магнитных полей СНЧ на иммунную и гематологическую систему считаются недостаточными.

17.1.9 Воспроизводство и развитие

В целом, эпидемиологические исследования не указывают на какую-либо взаимосвязь нарушений репродуктивной функции человека в связи с воздействием полей СНЧ на мать или отца. Имеются некоторые данные об увеличении риска выкидыша, связанного с воздействием магнитного поля на будущую мать, однако эти данные являются недостаточными.

Воздействие электрических полей СНЧ с уровнями вплоть до 150 кВ/м изучалось на нескольких видах млекопитающих. Сюда относятся изучение крупных популяций и воздействие полей на протяжении нескольких поколений. Результаты исследований устойчиво указывают на отсутствие каких-либо отрицательных последствий для развития.

Воздействие магнитных полей СНЧ с уровнями до 20 мТл на млекопитающих не приводит к значительным нарушениям формирования внешних признаков, внутренних органов или скелета. В некоторых исследованиях указывается на увеличение частоты

незначительных скелетных аномалий у крыс и мышей. Скелетные изменения являются сравнительно распространенным результатом тератологических исследований и нередко считаются биологически незначимыми . Однако нельзя исключать трудноуловимые влияния магнитных полей на развитие скелета. Исследований, в которых рассматриваются репродуктивные последствия, было опубликовано очень мало, и из них нельзя делать каких-либо выводов.

В нескольких исследованиях на экспериментальных моделях, не относящихся к классу млекопитающих (куриные эмбрионы, рыбы, морские ежи и насекомые), сообщается о результатах, которые указывают на то, что магнитные поля СНЧ в пределах микротеслы могут вносить нарушения в ранние этапы развития. Однако результаты изучения экспериментальных моделей, не относящихся к млекопитающим, имеют меньшую ценность при общей оценке токсичности в отношении развития, нежели исследования в этой области, касающиеся млекопитающих.

В целом, данные о последствиях для развития и репродуктивной системы являются недостаточными.

17.1.10 Онкологические заболевания

Классификация МАИР, относящая магнитные поля СНЧ к "возможно канцерогенным для человека" (IARC, 2002) основана на всех имеющихся данных до 2001 года включительно. Обзор литературы в данной монографии посвящен главным образом исследованиям, появившимся после обзора МАИР.

Эпидемиология

Классификация МАИР в значительной мере опирается на взаимосвязи, выявленные в ходе эпидемиологических исследований лейкозов у детей. Классификационная характеристика этих данных в качестве имеющих ограниченный характер не изменяется в связи с добавлением двух дополнительных исследований в области лейкозов у детей, опубликованных после 2002 года. Со времени публикации монографии МАИР данные в отношении других онкологических заболеваний у детей остаются недостаточными.

После публикации монографии МАИР появился ряд сообщений, касающихся риска рака молочной железы у взрослых, обусловленного воздействием магнитного поля СНЧ. Эти исследования шире, чем предыдущие и более беспристрастные, и в целом они дают отрицательный ответ. С наличием этих исследований данные о взаимосвязи между воздействием магнитного поля СНЧ и риском рака молочной железы, значительно ослабили свою позицию и не свидетельствуют о взаимосвязи подобного рода.

По поводу рака головного мозга и лейкозов у взрослых, новые исследования, опубликованные после монографии МАИР, не меняют

вывод о том, что общий объем данных о взаимосвязи между магнитными полями СНЧ и риском этих заболеваний остается недостаточным.

Для всех других видов онкологических болезней, данные по-прежнему остаются недостаточными.

Лабораторные исследования на животных

В настоящее время подходящая животная модель для наиболее распространенной формы детского лейкоза, острого лимфобластного лейкоза, отсутствует. Три независимых крупномасштабных исследования, где были использованы крысы, не дали никаких данных в отношении взаимосвязи между воздействием магнитных полей СНЧ и заболеваемостью спонтанным раком молочной железы. В большинстве исследований сообщается об отсутствии связи воздействия магнитных полей СНЧ с лейкозом или лимфомой у грызунов. В нескольких крупномасштабных и продолжительных исследованиях с использованием грызунов не было выявлено какого-либо устойчивого увеличения заболеваемости каким-либо онкологическим заболеванием, в т.ч. заболеванием кроветворных органов, молочной железы, головного мозга и кожи.

В значительном числе исследований изучалось воздействие магнитных полей СНЧ на химически индуцированные опухоли молочной железы у крыс. Непоследовательность полученных результатов может объясняться в целом или частично различиями в проведении экспериментов, такими как использование специфических линий. Большинство исследований воздействия магнитного поля СНЧ на модели лейкоза/лимфомы, индуцированные химическим путем или радиацией, дают отрицательный ответ. В исследованиях повреждений печени, предшествующих новообразованиям, опухолей кожи, индуцированных химическим путем, и опухолей головного мозга сообщается главным образом об отрицательных результатах. В одном исследовании сообщается об активизации индуцированных ультрафиолетом опухолей кожи после воздействия магнитных полей СНЧ.

Две группы сообщают об увеличении числа разрывов цепочек ДНК в тканях головного мозга после воздействия in vivo магнитными полями СНЧ. Однако в других группах, использовавших различные модели генотоксичности у грызунов, данных о генотоксичности обнаружено не было. Результаты исследований, в которых изучалось не генотоксическое воздействие применительно к раку, неубедительны.

В целом, свидетельства о том, что воздействие магнитных полей СНЧ само по себе вызывает опухоли, отсутствуют. Данные о том, что воздействие магнитного поля СНЧ в сочетании с канцерогенами может активизировать развитие опухоли, недостаточны.

Исследования in vitro

Обычно в исследованиях воздействия поля СНЧ на клетки не выявляется генотоксичности при интенсивности поля менее 50 мТл. Заметным исключением являются данные недавнего исследования, в котором сообщается о повреждении ДНК при магнитной индукции всего лишь 35 мкТл. Однако эти исследования еще оцениваются, и, как мы понимаем, результаты являются неполными. Все больше появляется данных о том, что магнитные поля СНЧ могут взаимодействовать с агентами, наносящими повреждения ДНК.

Явные доказательства того, что активация при помощи магнитных полей СНЧ генов, участвующих в управлении клеточным циклом, отсутствуют. Однако систематические исследования с целью анализа реакции генома в целом еще необходимо провести.

Во многих других исследованиях на клеточном уровне, например в отношении клеточной пролиферации, апоптоза, кальциевой сигнализации и злокачественной трансформации, получены непоследовательные и неубедительные результаты.

Общий вывод

Опубликованные после монографии МАИР 2002 г. новые исследования на человеке, животных и in vitro не изменяют общую классификацию магнитных полей СНЧ как возможного канцерогена для человека.

17.1.11 Оценка риска для здоровья

В соответствии с Уставом ВОЗ здоровье является состоянием полного физического, душевного и социального благополучия, а не только отсутствием болезней и физических дефектов. Оценка риска представляет собой концептуальную схему структурированного изучения информации, имеющей отношение к медицинским или экологическим последствиям. Оценка риска для здоровья может использоваться в качестве вводного элемента процесса управления факторами риска, который охватывает все действия, которые необходимо произвести, чтобы решить, необходимо ли предпринимать какие-либо конкретные меры в отношении данной опасности, а также принятие этих мер.

При оценке риска для здоровья, достоверные данные в отношении здоровья человека, в тех случаях, когда они имеются, обычно более информативны, чем данные, полученные на животных. Исследования на животных и исследования in vitro могут подкреплять данные исследований о здоровье человека, заполнять пробелы в изучении здоровья человека или использоваться при принятии решений в опасных случаях, когда исследований с участием человека недостаточно или когда они отсутствуют.

Всякие исследования, имеющие как положительные, так и отрицательные результаты, необходимо подвергать оценке и обсуждать, исходя из их собственных достоинств, а затем рассматривать их все в совокупности, придерживаясь метода весомости доказательств. Важно определить, в какой степени какая-либо совокупность доказательств изменяет вероятность того, что определенное воздействие вызывает некий результат. Данные в отношении последствий обычно более убедительны, если результаты различных видов исследований (эпидемиологических и лабораторных) указывают на один и тот же вывод и/или когда многие исследования одного и того же типа приводят к одинаковому результату.

Острые эффекты

Острые биологические эффекты были установлены в связи с воздействием электрических и магнитных полей от крайне и сверхнизких до ОНЧ в диапазоне частот до 100 кГц. Это воздействие может иметь отрицательные последствия для здоровья. В силу этого необходимо устанавливать пределы воздействия. Существуют международные рекомендации по данному вопросу. Соблюдение этих рекомендаций обеспечивает надлежащую защиту от острых последствий.

Хронические эффекты

Научные данные, позволяющие предположить, что ежедневное хроническое низкоинтенсивное (более 0,3–0,4 мкТл) воздействие магнитного поля промышленной частоты представляет собой риск для здоровья, основаны на эпидемиологических исследованиях, свидетельствующих об устойчивой картине увеличения риска развития лейкоза у детей. Неопределенность оценки риска связана с тем, какое влияние может оказать неправильная классификация отклонений в контрольной и экспонированной выборках на наблюдаемую взаимосвязь между магнитными полями и лейкозами у детей. Кроме того, практически все лабораторные и механистические данные не свидетельствуют о взаимосвязи между слабыми магнитными полями СНЧ и нарушениями биологических функций или состоянием заболевания. Таким образом, в целом данные не являются достаточно убедительными, чтобы их можно было рассматривать в качестве причинных, однако они достаточно весомы, чтобы оставаться предметом озабоченности.

Несмотря на то, что причинная связь между воздействием магнитного поля и детскими лейкозами не установлена, возможное влияние его на здоровье населения должно было бы рассчитываться, допуская причинно-следственную связь, для того, чтобы включать это в политику как потенциально полезный элемент. Вместе с тем подобные расчеты в значительной степени зависят от распределения воздействия и других предположений и в силу этого являются неточными. Если

исходить из того, что взаимосвязь является причинной, то количество случаев лейкозов у детей во всем мире, которые могли бы быть обусловлены воздействием магнитного поля, согласно расчету может составить от 100 до 2400 случаев в год. Однако это составляет 0,2 – 4,9% от общего числа случаев лейкозов, которое во всем мире в 2000 г. составляло 49 000. Таким образом, в глобальном плане влияние на здоровье населения, если таковое имеется, будет ограниченным и неопределенным. Был изучен ряд других заболеваний на предмет возможной обусловленности воздействием магнитного поля СНЧ. К ним относятся онкологические заболевания детей и взрослых, депрессия, самоубийства, репродуктивные дисфункции, нарушение развития, иммунологические модификации и неврологические болезни. Научные данные, подтверждающие взаимосвязь между магнитными полями СНЧ и каким-либо из заболеваний, гораздо слабее, чем в отношении лейкозов у детей, а в некоторых случаях (например, в том, что касается сердечно-сосудистых заболеваний или рака молочной железы) данные достаточны для того, чтобы была уверенность в том, что магнитные поля не являются причиной заболевания.

17.1.12 Мероприятия по защите

Для защиты против выявленных негативных последствий воздействия электрических и магнитных полей СНЧ необходимо устанавливать предельные уровни их воздействия. Эти нормативы должны быть определены на основе тщательного изучения всех необходимых научных данных.

Определенным образом были выявлены лишь эффекты острых воздействий, и для защиты от них разработаны две международные рекомендации, касающиеся предельно допустимых уровней воздействия (ICNIRP, 1998a; IEEE, 2002).

Наряду с определенно выявленными эффектами острых воздействий существуют неопределенности о наличии эффектов хронических воздействий в силу ограниченности данных о взаимосвязи между воздействием магнитных полей СНЧ и лейкозами у детей. Поэтому необходимо проявлять осторожный подход. Однако во имя предосторожности не рекомендуется занижать до какого-либо произвольного уровня нормативы предельных уровней воздействия, определенные в рекомендациях. Это подрывает научные основы, на которых построены эти нормативы, и, возможно, окажется дорогостоящим и необязательно эффективным способом защиты.

Осуществление других приемлемых мер предосторожности по снижению воздействия поля обоснованно и необходимо. Однако электроэнергия приносит несомненную пользу в здравоохранении, социальной и экономической областях, и меры предосторожности не должны ставить под угрозу эти преимущества. Кроме того, учитывая недостаточность данных о взаимосвязи между воздействием полей СНЧ и детскими лейкозами, а также ограниченное влияние на здоровье

населения, если такая взаимосвязь имеется, преимущества мер по снижению воздействия полей на здоровье неясны. Таким образом, расходы на меры предосторожности должны быть весьма незначительными. Стоимость осуществления мер по снижению влияния полей в различных странах будет различна, что затрудняет разработку общей рекомендации в отношении уравновешивания расходов с потенциальной угрозой полей СНЧ.

Ввиду вышеизложенного, рекомендуется нижеследующее.

- Разработчикам политики необходимо устанавливать нормативы воздействия полей СНЧ, как для населения в целом, так и для условий профессиональных воздействий. Наилучшим руководством для определения обоих уровней воздействия и принципов научного пересмотра их являются международные рекомендации.
- Разработчикам политики необходимо организовать программы защиты от электрических и магнитных полей СНЧ, предусматривающие измерения полей от всех источников, с тем чтобы предельно допустимые уровни воздействия не превышались ни для населения в целом, ни для работающих.
- При условии того, что медицинские, социальные и экономические блага, предоставляемые электроэнергией, не поставлены под угрозу, оправдано и необходимо осуществление как можно более дешевых мер предосторожности по снижению воздействия полей.
- Разработчикам политики, плановикам и производителям необходимо предусматривать соблюдение дешевых мер защиты при строительстве новых сооружений и проектировнаии нового оборудования, включая электроприборы.
- Следует предусматривать внесение изменений в инженерную практику, направленных на снижение воздействия полей СНЧ, создаваемых оборудованием или приборами при условии, что при этом сохраняются другие дополнительные преимущества, такие как бóльшая безопасность и достигается это при незначительных или нулевых расходах.
- При переходе от одного типа оборудования к другому наряду с соображениями безопасности, надежности работы и экономичности необходимо учитывать проблему снижения интенсивности полей СНЧ, создаваемых этими приборами.
- Местным органам при строительстве новых установок или при замене старых, не упуская из внимания вопросы безопасности, необходимо регламентировать прокладку кабелей и проводов таким образом, чтобы это способствовало снижению непроизвольно возникающих токов в земле.

Активные меры по выявлению нарушений или существующих проблем в проложенных электрокабелях могут оказаться дорогостоящими и вряд ли будут оправданы.

- Национальным органам необходимо осуществлять эффективную и открытую стратегию коммуникаций, с тем чтобы все участники принимали информированные решения. Эта стратегия должна предусматривать информацию в отношении того, каким образом отдельные лица могут сами снизить воздействие полей.
- Местные органы должны улучшить планирование установок, являющихся источником СНЧ электромагнитных полей, предусматривая более активную консультацию с промышленностью, местным правительством и гражданами в процессе определения местоположения основных источников электромагнитных полей СНЧ.
- Правительство и промышленность должны содействовать проведению научно-исследовательских программ, направленных на понижение уровня неопределенности научных данных в отношении последствий воздействия полей СНЧ на человека.

17.2 Рекомендации для научных исследований

Выявление пробелов в знаниях, касающихся возможных последствий воздействия полей СНЧ для здоровья является главной составной частью оценки этого риска для здоровья. Нижеследующие рекомендации (обобщенные в Таблице 1) излагаются в отношении дальнейших научных исследований.

В качестве важнейшей необходимости требуется проведение дальнейших исследований в отношении промежуточных частот , под которыми обычно понимаются частоты от 300 Гц до 100 кГц, учитывая имеющийся пробел в этой области. Очень небольшой объем данных из необходимой базы знаний для оценки риска для здоровья был собран, и в большинстве существующих исследований результаты непоследовательны и нуждаются в дополнительном подтверждении. Общие требования формирования достаточной базы данных в отношении промежуточных частот с точки зрения оценки риска для здоровья состоят в оценке воздействия, эпидемиологических и лабораторных исследованиях с участием человека, а также в исследованиях на животных и на клеточном уровне (in vitro) (ICNIRP, 2003; ICNIRP, 2004; Litvak et al., 2002).

Для всех исследований с участием добровольцев настоятельно необходимо, чтобы исследования с участием человека проводились в полном согласии с этическими принципами, учитывая положения Хельсинской декларации (WMA, 2004).

Что касается лабораторных исследований, необходимо уделять приоритетное внимание опубликованным результатам, (i) в отношении которых имеются хотя бы скудные данные о воспроизведении или подтверждении, (ii) которые потенциально имеют отношение к канцерогенезу (например, генотоксичность), (iii) которые достаточно убедительны для использования механистического анализа и (iv) в которых присутствуют системы млекопитающих или человека.

17.2.1 Источники, измерения и воздействие на организм

Дальнейшая классификация жилья в различных странах, где имеет место высокий уровень воздействия полей СНЧ, с целью определения сравнительного воздействия внутренних и внешних источников полей, влияния порядка прокладки проводов и заземления, а также других характеристик жилья может помочь выявить соответствующие количественные характеристики воздействия, необходимые для эпидемиологической оценки. Важной частью этого является лучшее понимание воздействия полей СНЧ на плод в утробе матери и на детей, в особенности воздействие нагревательных электрокабелей в панелях пола жилых помещений и трансформаторов в многоквартирных зданиях.

Есть подозрение, что в некоторых случаях производственного воздействия СНЧ полей нынешние рекомендуемые нормативы экспозиции превышаются. Необходимо иметь больше информации в отношении воздействия полей (включая частоты, отличные от промышленной), связанных с условиями работы, например, работа по обслуживанию воздушных линий электропередачи под напряжением, работа внутри или вблизи створа магнита магнитно-резонансного томографа (и в силу этого воздействие полей СНЧ с переменным градиентом) и работа на транспортных системах. Аналогичным образом необходимо располагать дополнительными знаниями о подверженности воздействию населения, которое может оказаться близким к рекомендуемым нормативам, в том числе со стороны таких источников, как системы безопасности, библиотечные системы размагничивания, индукционное приготовление пищи и водонагревательные приборы.

Воздействие контактных токов предлагалось в качестве возможного объяснения взаимосвязи магнитных полей СНЧ с лейкозом у детей. Необходимы исследования в других странах, помимо США, для оценки возможности того, что порядок заземления электропроводки в жилых домах и прокладки водопроводов может способствовать возникновению контактных токов в жилье. Подобные исследования должны проводиться в приоритетном порядке в странах, в которых эпидемиологические данные в отношении полей СНЧ и лейкозов у детей вызывают озабоченность.

17.2.2 Дозиметрия

В прошлом большая часть лабораторных исследований основывалась на наведенных в организме электрических токах в качестве основного измеряемого параметра, и поэтому дозиметрические показатели определялись этим количественным фактором. Лишь недавно стали проводить работу по изучению взаимосвязи между воздействием внешнего поля и индуцированными электрическими полями. Чтобы лучше понимать биологические эффекты, необходимо иметь больше данных о внутренних электрических полях, возникающих при различных внешних воздействиях.

Необходимо произвести расчеты внутренних электрических полей, вызываемых совместным воздействием внешних электрических и магнитных полей в различных сочетаниях. Расчеты векторного сложения колебаний в различной фазе и воздействия электрических и магнитных полей в соответствии с их пространственным изменением необходимы для оценки основных вопросов, касающихся соблюдения нормативов.

До сих пор проводилось очень мало расчетов по перспективной модели беременной женщины и плода с учетом необходимого анатомического моделирования. Важное значение имеет расчет вероятного возрастания индукции электрических полей в плоде с точки зрения возможности возникновения лейкозов у детей. При этом большую роль играет производственное и внепроизводственное воздействие поля на материнский организм .

Имеется необходимость дополнительного усовершенствования микродозиметрических моделей, учитывающих клеточную архитектуру нейронных сетей и других сложных систем органов, которые более чувствительны к воздействию наведенных электрических полей. Этот процесс моделирования также должен принимать во внимание влияние на электрические потенциалы клеточной мембраны и на выделение нейромедиаторов.

17.2.3 Биофизические механизмы

Имеются три основных области, где довлеют очевидные ограничения для нынешнего понимания таких механизмов как механизма радикальных пар, магнитных частиц в организме и соотношений сигнал-шум в многоклеточных системах, таких как нейронные сети.

Механизм радикальных пар является одним из более вероятных механизмов низкоинтенсивного взаимодействия, однако еще надо доказать, что он способен вызывать значительные изменения в клеточном метаболизме и функциях. Особенно важно понять нижний предел воздействия, на котором он проявляется, с тем чтобы судить о том, может или не может этот механизм иметь отношение к

канцерогенезу. Учитывая недавние исследования, при которых в иммунных клетках, подвергавшихся воздействию полей СНЧ, происходило усиление активных форм кислорода, рекомендуется использовать в качестве клеточных моделей для изучения возможностей механизма радикальных пар клетки иммунной системы, которые генерируют реактивные формы кислорода.

Хотя наличие магнитных частиц (магнетитовые кристаллы) в головном мозге человека согласно нынешним данным, не свидетельствует о какой-либо чувствительности к магнитным полям СНЧ в окружающей среде, в дальнейших теоретических и экспериментальных работах необходимо изучить, может ли при определенных условиях подобная чувствительность существовать. Кроме того, следует продолжить изучение всех влияний, которые может оказывать наличие магнетитов на вышеупомянутый механизм радикальных пар.

Необходимо проводить дальнейшее изучение того, в какой степени функционируют в мозгу многоклеточные механизмы в плане улучшения соотношения сигнал-шум, с тем, чтобы разработать теоретические принципы количественного исчисления этого явления или определения его предельных значений. Методом in vitro необходимо проводить дальнейшее изучение порога и частотной реакции нейронных сетей в гиппокампе и других частях мозга.

17.2.4 Нейроповедение

Рекомендуется проводить лабораторные исследования с привлечением добровольцев по вопросу о возможном влиянии полей на сон и на выполнение задач, требующих умственного напряжения, придерживаясь согласованной методологии,. Необходимо выявить зависимость реакции от интенсивности поля при более высоких значениях магнитной индукции, по сравнению с использовавшимися ранее, а также в широком диапазоне частот (т.е. в килогерцовом диапазоне).

Исследования с участием взрослых добровольцев и с использованием животных позволяют предположить, что при кратковременном воздействии интенсивных электрических или магнитных полей могут иметь место острые когнитивные последствия. Для разработки нормативов воздействия чрезвычайно важно представлять себе эти последствия, однако конкретные данные, касающиеся обусловленных полем результатов воздействия на организм детей, отсутствуют. Рекомендуется провести лабораторные исследования когнитивной функции и изменений в электроэнцефалограмме (ЭЭГ) у лиц, подвергшихся воздействию полей СНЧ, в том числе взрослых, регулярно подвергающихся производственным воздействиям, а также у детей.

Поведенческие исследования с использованием детенышей животных могут дать ценные данные для изучения возможных

когнитивных последствий у детей. Следует изучить возможные последствия пре- и постнатального воздействия магнитных полей СНЧ на развитие нервной системы и когнитивные функции. Полезным дополнением к этим исследованиям может оказаться изучение последствий воздействия магнитных полей СНЧ и наведенных электрических полей на рост нервных клеток с использованием срезов головного мозга и нейронных культур.

Имеется необходимость дальнейшего изучения потенциальных последствий для здоровья, о которых позволяют предполагать экспериментальные данные об опиоидных и холинергических реакциях у животных. Следует расширить изучение модификации опиоидных и холинергических реакций у животных и определить параметры воздействия и биологическую основу подобных поведенческих реакций.

17.2.5 Нейроэндокринная система

Существующая база данных в отношении реакции нейроэндокринной системы не указывает на то, что воздействие полей СНЧ оказывает неблагоприятное влияние на здоровье человека. Поэтому в рекомендациях в отношении дополнительных исследований нет необходимости.

17.2.6 Нейродегенеративные расстройства

В ряде исследований наблюдалось увеличение риска бокового амиотрофического склероза у лиц, по роду занятий связанных с электричеством. Считается важным изучить эту взаимосвязь более подробно для того, чтобы выявить, участвуют ли магнитные поля СНЧ в возникновении этого редкого нейродегенеративного заболевания. Для этого требуется проведение крупномасштабных проспективных когортных исследований с информацией о воздействии магнитного поля СНЧ, о наличии ударов электрическим током, а также о воздействии других потенциальных факторов риска.

Остается сомнительным, являются ли магнитные поля СНЧ фактором риска в развитии болезни Альцгеймера. Имеющиеся в настоящее время данные недостаточны, и эту взаимосвязь необходимо изучить более подробно. Особое значение имеет использование данных о заболеваемости, а не о смертности.

17.2.7 Сердечно-сосудистые нарушения

Дополнительные исследования взаимосвязи между магнитными полями СНЧ и риском сердечно-сосудистых заболеваний приоритетными не считаются.

17.2.8 Иммунология и гематология

В изменениях, наблюдаемых в отношении иммунологических и гематологических параметров у взрослых, подвергшихся воздействию

магнитных полей СНЧ, обнаруживается непоследовательность, а также в основном отсутствуют данные исследований в отношении детей. Поэтому рекомендация состоит в том, чтобы проводить исследования о последствиях воздействия полей СНЧ на развитие иммунной и кроветворной систем у животных раннего возраста.

17.2.9 Репродуктивные аспекты и развитие

Имеются определенные данные об увеличении риска выкидыша, обусловленного воздействием магнитного поля СНЧ. Принимая во внимание потенциально значимое влияние подобной взаимосвязи на здоровье населения, рекомендуется проведение дополнительных эпидемиологических исследований.

17.2.10 Онкологические заболевания

Наиболее приоритетным вопросом в этой области является разрешение противоречий между эпидемиологическими данными (которые указывают на взаимосвязь между воздействием магнитного поля СНЧ и увеличением риска лейкозов у детей) и экспериментальными и механистическими данными (которые на эту взаимосвязь не указывают). По этому вопросу рекомендуется проведение совместной работы эпидемиологов и ученых экспериментаторов. Чтобы новые эпидемиологические исследования оказались информативными, они должны быть сосредоточены на новых аспектах воздействия поля, на потенциальном взаимодействии с другими факторами или на группах лиц, подвергшихся высокоинтенсивному воздействию, или иным образом быть новаторскими в этой области исследований. Кроме того, также рекомендуется обновить существующие сводные данные путем дополнения данными недавних исследований и путем нового понимания результатов анализа.

Исследования в области рака головного мозга у детей дают неоднозначные результаты. Также как и в случае лейкозов у детей, сводный анализ исследований рака мозга у детей должен быть весьма информативным, и в силу этого таковой рекомендуется. Сводный анализ подобного рода может при небольшой стоимости дать более глубокое и более совершенное понимание существующих данных, включая возможность селекции ошибок при отборе, и, в том случае, если исследования достаточно однородны, может содействовать получению наиболее точной оценки риска.

Что касается рака молочной железы у взрослых, в самых последних исследованиях убедительно показано, что нет никакой взаимосвязи с воздействием магнитных полей СНЧ. Поэтому дополнительным исследованиям этой взаимосвязи следует придавать второстепенное значение.

В отношении лейкозов у взрослых и рака головного мозга рекомендация состоит в том, чтобы обновить информацию по

существующим крупным когортам лиц, подвергающимся производственным воздействиям Результаты исследований в области медицины труда, совокупных данных и мета-анализов по лейкозам и раку головного мозга неоднозначны и неубедительны. Однако недавно были опубликованы новые данные, и их следует использовать для обновления вышеуказанных результатов.

Первоочередные действия состоят в том, чтобы изучить эпидемиологические данные путем реализации моделей in vitro и с использованием животных по исследованию реакций на низкоинтенсивные магнитные поля СНЧ, которые могли бы применяться в условиях различных лабораторий.

Следует разработать трансгенные модели грызунов для изучения лейкозов у детей, с тем чтобы имелись необходимые экспериментальные животные модели для изучения последствий воздействия магнитного поля СНЧ. В противном случае, согласно имеющимся сегодня результатам исследований на животных, изолированно одни магнитные поля СНЧ не оказывают никакого канцерогенного действия. Поэтому приоритетный характер следует придавать исследованиям in vitro и на животных, в которых магнитные поля СНЧ были бы тщательно изучены в качестве сопутствующих канцерогенным факторам.

Что касается других исследований in vitro, то эксперименты, в которых сообщается о генотоксичных эффектах интермиттирующего воздействия магнитного поля СНЧ, должны быть повторены в других условиях.

17.2.11 Мероприятия по защите

Проведение исследований в области разработки политики охраны здоровья и осуществление этой политики в тех областях, где имеется научная неопределенность, рекомендуется, в особенности в отношении мер предосторожности, толкование мер предосторожности и оценки воздействия мер предосторожности с точки зрения магнитных полей СНЧ и других агентов, классифицируемых в качестве «возможных канцерогенов для человека». В тех случаях, когда имеется неуверенность в отношении потенциального риска для здоровья, создаваемого каким-либо агентом, для общества, должны быть обеспечены меры предосторожности, с тем чтобы создать необходимую защиту для населения и работающих. По данному вопросу, касающемуся воздействия магнитных полей СНЧ, было проведено лишь ограниченное число исследований, и в силу важности этого вопроса необходимо заниматься более активными исследованиями. Это может помочь странам сделать меры предосторожности частью своей политики в области охраны здоровья.

Рекомендуется проведение дополнительных исследований в отношении восприятия риска и коммуникации, которые конкретно затрагивают вопрос об электромагнитных полях. Психологические и

социологические факторы, которые влияют на восприятие риска в целом, были всесторонне изучены. Однако число исследований, направленных на анализ сравнительного значения этих факторов в случае электромагнитных полей или по выявлению других факторов, которые обусловлены электромагнитными полями, является ограниченным. Недавние исследования позволяют предположить, что меры предосторожности, некоторые несут в себе сообщения о риске, могут изменить восприятие риска, усиливая или сглаживая озабоченность этим вопросом. Поэтому необходимы более глубокие исследования в этой области.

Следует проводить исследования по разработке методов анализа издержки-преимущества/издержки-эффективность с точки зрения уменьшения воздействия магнитных полей СНЧ. Использование методов анализа издержки–преимущества и издержки–эффективность для оценки того, является ди данная политическая опция преимуществом для общества, было изучено во многих областях общественной политики. Необходима разработка схемы, которая установит параметры, необходимые для того, чтобы проводить такое изучение магнитных полей СНЧ. В силу неопределенности оценки необходимо предусматривать параметры, которые поддаются количественной оценке, и те, которые не поддаются такой оценке.

Таблица 1. Рекомендации для дальнейших исследований

Источники, измерения и воздействия	Приоритетность
Дальнейшая характеристика жилых помещений с высоким воздействием магнитного поля СНЧ в различных странах	Средняя
Выявление пробелов в знаниях относительно воздействия полей СНЧ на рабочих местах, как например при магниторезонансной томографии	Высокая
Изучение возможности возникновения контактных токов у детей в связи с особенностями электропроводки в жилых помещениях вне США	Средняя
Дозиметрия	
Дополнительные дозиметрические расчеты, увязывающие внешние электрические и магнитные поля с внутренними электрическими полями, в особенности в том, что касается совокупного воздействия электрических и магнитных полей различной ориентации	Средняя
Расчет индуцированных электрических полей и токов у беременных женщин и в плоде	Средняя
Дальнейшее уточнение микродозиметрических моделей, учитывающих клеточную архитектуру нейронных сетей и другие сложные системы подорганов	Средняя

Биофизические механизмы	
Дальнейшие исследования механизмов радикальных пар в иммунных клетках, которые генерируют активные формы кислорода в процессе своей фенотипической функции	Средняя
Дальнейшие теоретические и экспериментальные исследования возможной роли магнетитов в чувствительности к магнитному полю СНЧ	Низкая
Определение пороговых реакций на внутренние электрические поля, индуцированные полями СНЧ, в многоклеточных системах, таких как нейронные сети, с использованием теоретических методов и методов in vitro	Высокая
Нейроповедение	
Когнитивные исследования, изучение сна и электроэнцефалограмм у добровольцев, в том числе у детей и лиц, подверженных воздействию полей по роду работы с применением широкого диапазона частот СНЧ при высоких плотностях потока	Средняя
Исследование влияния пре- и постнатального воздействия полей на последующее развитие когнитивной функции у животных	Средняя
Дальнейшее изучение опиоидных и холинергических реакций у животных	Низкая
Нейродегенеративные расстройства	
Дополнительное изучение риска бокового амиотрофического склероза у «лиц электрических профессий» в связи с экспозицией к СНЧ магнитному полю, а также болезни Альцгеймера в связи с воздействием магнитного поля СНЧ	Высокая
Иммунология и гематология	
Изучение последствий воздействия магнитного поля СНЧ на развитие иммунной и кроветворной систем у животных раннего возраста	Низкая
Репродуктивные аспекты и развитие	
Дополнительные исследования возможной связи между выкидышем и воздействием магнитного поля СНЧ	Низкая
Онкологические заболевания	
Обновление новой информацией существующих сводных результатов в отношении лейкозов у детей	Высокая
Совокупный анализ существующих исследований возникновения опухолей мозга у детей	Высокая
Обновление существующих мета-анализов, касающихся лейкозов у взрослых и опухолей мозга, а также когорт лиц, подверженных профессиональному воздействию полей по роду своих занятий	Средняя

Создание моделей детского лейкоза на базе трансгенных грызунов для использования в изучении полей СНЧ	Высокая
Оценка совместного канцерогенного действия путем исследований in vitro и на животных	Высокая
Попытка воспроизводства исследований в области генотоксичности, проводимых in vitro	Средняя
Защитные меры	
Исследования по разработке политики в области охраны здоровья и осуществление мер в тех областях, где имеется научная неопределенность	Средняя
Дальнейшие исследования в области восприятия риска и коммуникаций в отношении электромагнитных полей	Средняя
Разработка методов анализа издержки-преимущества / издержки-эффективность для смягчения результатов воздействия полей СНЧ	Средняя

18 RESUMEN Y RECOMENDACIONES PARA ESTUDIOS POSTERIORES

En la presente monografía sobre Criterios de Salud Ambiental (EHC) se abordan los posibles efectos en la salud de la exposición a campos eléctricos y magnéticos de frecuencias extremadamente bajas (ELF). En ella se examinan las características físicas de los campos ELF, así como las fuentes de exposición y la medición. Sin embargo, sus principales objetivos son la revisión de la literatura científica sobre los efectos biológicos de la exposición a campos de ELF, a fin de evaluar cualquier riesgo para la salud proveniente de la exposición a dichos campos y utilizar esta evaluación de los riesgos de salud en la formulación de recomendaciones a las autoridades nacionales sobre los programas de protección de la salud.

Las frecuencias bajo consideración están comprendidas en el rango por encima de 0 Hz a 100 kHz. La inmensa mayoría de los estudios se han realizado sobre campos magnéticos en frecuencia de energía (50 ó 60 Hz) y muy pocos utilizando campos eléctricos en frecuencia de energía. Además, se han realizado varios estudios sobre campos de muy baja frecuencia (VLF, 3–30 kHz), campos magnéticos de gradientes invertidos utilizados en la imaginología de resonancia magnética y campos de VLF más débiles que emiten los monitores de visualización y los televisores.

En este capítulo se resumen las principales conclusiones y recomendaciones de cada sección, así como las conclusiones globales del proceso de evaluación de los riesgos de salud. Los términos utilizados en esta monografía para describir el peso de la evidencia para un resultado de salud determinado son los siguientes. Se dice que la evidencia es "limitada" cuando se reduce a un solo estudio o cuando hay cuestiones por resolver en relación con el diseño, la realización o la interpretación de varios estudios. La evidencia es "insuficiente" cuando no se puede interpretar que los estudios demuestran la presencia o la ausencia de un efecto debido a limitaciones cualitativas o cuantitativas importantes, o cuando no se dispone de datos.

También se encontraron brechas fundamentales en los conocimientos, y en la sección titulada "Recomendaciones para la investigación" se han resumido las investigaciones necesarias para llenar esas brechas.

18.1 Resumen

18.1.1 Fuentes, mediciones y exposiciones

Donde quiera que se genera, transmite o distribuye electricidad en tendidos o cables eléctricos o se utiliza en aparatos eléctricos existen campos eléctricos y magnéticos. Dado que el uso de la electricidad forma parte integrante de nuestro sistema de vida moderno, estos campos están omnipresentes en nuestro ambiente.

La unidad de intensidad de campo eléctrico es el voltio por metro ($V\ m^{-1}$) o el kilovoltio por metro ($kV\ m^{-1}$) y para los campos magnéticos la densidad de flujo se mide en teslas (T), o más habitualmente en militeslas (mT) o en microteslas (μT).

La exposición residencial a campos magnéticos en frecuencia de energía no registra grandes variaciones en todo el mundo. La media geométrica del campo magnético en los hogares oscila entre 0,025 y 0,07 μT en Europa y entre 0,055 y 0,11 μT en los Estados Unidos. Los valores medios de los campos eléctricos entre el hogar son del orden de varias decenas de voltios por metro. En las proximidades de determinados aparatos eléctricos, los valores instantáneos del campo magnético pueden llegar a ser de unos pocos cientos de microteslas. Cerca de las líneas de energía, los campos magnéticos llegan a ser de alrededor de 20 μT y los campos eléctricos de varios miles de voltios por metro.

Son pocos los niños que tienen una exposición residencial promedio en el tiempo a campos magnéticos de 50 ó 60 Hz superior a los niveles asociados con un aumento de la incidencia de la leucemia infantil (ver la sección 18.1.10). Entre el 1% y el 4% tienen una exposición media superior a 0,3 μT y sólo del 1% al 2% tienen una exposición media que supera los 0,4 μT.

La exposición ocupacional, aunque predominantemente debido a los campos en frecuencia de energía, también puede incluir otras frecuencias. Se ha encontrado que el promedio de la exposición a campos magnéticos en el lugar de trabajo para las ocupaciones relacionadas con la electricidad es superior al de otros trabajos tales como el trabajo de oficina, con valores que oscilan entre 0.4–0.6 μT para los electricistas y los ingenieros eléctricos y alrededor de 1.0 μT en los trabajadores de líneas de energía, siendo máxima la exposición de los soldadores, los maquinistas de ferrocarril y los operadores de máquinas de coser (por encima de 3 μT). Las exposiciones máximas a campos magnéticos en el lugar de trabajo pueden llegar a ser de alrededor de 10 mT y están asociadas de manera invariable con la presencia de conductores portadores de corrientes altas. En la industria del suministro de energía eléctrica, los trabajadores pueden estar expuestos a campos eléctricos de hasta 30 kV m^{-1}.

18.1.2 Campos eléctricos y magnéticos dentro del cuerpo

La exposición a campos eléctricos y magnéticos externos de frecuencias extremadamente bajas induce campos eléctricos y corrientes dentro del cuerpo. La dosimetría describe la relación entre los campos externos y el campo eléctrico y la densidad de corriente inducidos en el cuerpo, u otros parámetros asociados con la exposición a estos campos. El campo eléctrico y la densidad de corriente inducidos localmente son de especial interés debido a que están relacionados con la estimulación de los tejidos excitables, tales como los nervios y los músculos.

Los cuerpos de las personas y animales perturban significativamente la distribución espacial de un campo eléctrico de ELF. En bajas frecuencias, el cuerpo es un buen conductor y las líneas del campo perturbado externas al cuerpo son casi perpendiculares a la superficie de éste. En la superficie del cuerpo expuesto se inducen cargas oscilantes, que a su vez inducen corrientes dentro del cuerpo. Las características fundamentales de la

dosimetría para la exposición de las personas a campos eléctricos ELF son las siguientes:

- El campo eléctrico dentro del cuerpo suele ser de cinco a seis órdenes de magnitud inferior al campo eléctrico externo.
- Cuando la exposición es fundamentalmente al campo vertical, la dirección predominante de los campos inducidos también es vertical.
- Para un campo eléctrico externo determinado, los campos inducidos más fuertes corresponden al cuerpo humano en perfecto contacto con el suelo a través de los pies (eléctricamente aterrado) y los campos inducidos más débiles corresponden al cuerpo aislado del suelo (en "espacio libre").
- El flujo total de corriente en un cuerpo en perfecto contacto con el suelo esta determinado por el tamaño y la forma del cuerpo (incluida la postura) antes que la conductividad de los tejidos.
- La distribución de las corrientes inducidas a través de los diversos órganos y tejidos está determinada por la conductividad de dichos tejidos.
- La distribución de un campo eléctrico inducido también es afectada por la conductividad, pero menos que la corriente inducida.
- También hay un fenómeno independiente en el que la corriente se produce en el cuerpo por medio del contacto con un objeto conductor situado en un campo eléctrico.

Para los campos magnéticos, la permeabilidad de los tejidos es igual a la del aire, de manera que el campo en un tejido es igual al campo externo. Los cuerpos de las personas y de los animales no perturba significativamente el campo. La principal interacción de los campos magnéticos corresponde a la inducción de Faraday de campos eléctricos y las densidades de corriente asociadas en los tejidos conductores. Las características fundamentales de la dosimetría para la exposición de los seres humanos a campos magnéticos de ELF son las siguientes:

- El campo eléctrico y la corriente inducidos dependen de la orientación del campo externo. Los campos inducidos en el cuerpo considerado en conjunto son máximos cuando el campo está alineado de la parte anterior a la posterior del organismo, pero en algunos órganos concretos los valores máximos corresponden al campo alineado de un costado al otro.
- Los campos eléctricos más débiles son inducidos por un campo magnético orientado a lo largo del eje vertical del cuerpo.
- Para una intensidad y una orientación determinadas del campo magnético, se inducen campos eléctricos más altos en los cuerpos de mayor tamaño.

- La distribución del campo eléctrico inducido es afectada por la conductividad de los diversos órganos y tejidos. Éstos tienen un efecto limitado en la distribución de la densidad de corriente inducida.

18.1.3 Mecanismos biofísicos

Se examina la posibilidad de diversos mecanismos de interacción directa e indirecta propuestos para los campos eléctricos y magnéticos de ELF, en particular si una "señal" generada en un proceso biológico por la exposición a un campo se puede discriminar del ruido aleatorio inherente, y si el mecanismo desafía los principios científicos y los conocimientos científicos actuales. Muchos mecanismos se hacen posibles solamente en campos por encima de una intensidad determinada. No obstante, la ausencia de mecanismos posibles identificados no excluye la posibilidad de efectos en la salud incluso con niveles de campo muy bajos, siempre que se sigan los principios científicos básicos.

Entre los numerosos mecanismos propuestos para la interacción directa de los campos dentro del cuerpo humano, hay tres que destacan más que los otros por su potencial actuación a niveles más bajos del campo: los campos eléctricos inducidos en redes neurales, los pares de radicales y la magnetita.

Los campos eléctricos inducidos en los tejidos por la exposición a campos eléctricos o magnéticos de ELF estimulan directamente las fibras nerviosas mielinizadas aisladas de una forma posible desde el punto de vista biofísico cuando la intensidad del campo interno es superior a algunos voltios por metro. La transmisión sináptica en las redes neurales, en contraposición a las células aisladas, se puede ver afectada por campos mucho más débiles. Los organismos multicelulares suelen utilizar tal procesamiento de la señal por los sistemas nerviosos para detectar señales ambientales débiles. Para la discriminación en la red neural, se ha propuesto un límite inferior de 1 mV m^{-1}, pero de acuerdo con la evidencia actual parecen más probables valores umbral de alrededor de 10–100 mV m^{-1}.

El mecanismo par radical es una manera aceptada en que los campos magnéticos pueden influir en tipos específicos de reacciones químicas, por lo general aumentando las concentraciones de radicales libres reactivos en los campos bajos y reduciéndolas en los campos altos. Este aumento se ha visto en campos magnéticos de menos de 1 mT. Existe algunas evidencias que vinculan este mecanismo a la navegación de las aves durante la migración. Sobre una base teórica y debido a que los cambios producidos por los campos magnéticos de ELF y estáticos son similares, se sugiere que es poco probable que los campos en frecuencias de energía muy inferiores al campo geomagnético de unos 50 μT tenga mucha importancia biológica.

En los tejidos de los animales y seres humanos se encuentran cristales de magnetita, pequeños cristales ferromagnéticos de óxido de hierro de diversas formas, aunque en cantidades insignificantes. Al igual que los radicales libres, se han relacionado con la orientación y la navegación en los ani-

males migratorios, aunque la presencia de cantidades insignificantes de magnetita en el cerebro humano no confiere la capacidad de detectar el débil campo geomagnético. Los cálculos basados en hipótesis extremas parecen indicar para los efectos de los campos de ELF en los cristales de magnetita un límite inferior de 5 μT.

Otras interacciones biofísicas directas de los campos, tales como la ruptura de enlaces químicos, las fuerzas sobre las partículas cargadas y los diversos mecanismos de "resonancia" de banda estrecha, no parecen explicar de manera verosímil las interacciones en los niveles de campo encontrados en los entornos público y ocupacional.

Con respecto a los efectos indirectos, la carga eléctrica superficial inducida por campos eléctricos puede se percibida y dar lugar a microchoques dolorosos al tocar un objeto conductor. Se pueden producir corrientes de contacto cuando, por ejemplo, los niños pequeños tocan un grifo en la bañera de algunos hogares. Esto produce en la médula ósea pequeños campos eléctricos, posiblemente por encima de los niveles de ruido de fondo. Sin embargo, se desconoce si representan un riesgo para la salud.

Las líneas de energía eléctrica de alto voltaje producen nubes de iones con carga eléctrica como consecuencia de la descarga de tipo corona. Se ha sugerido que podría aumentar la deposición sobre la piel y en las vías respiratorias dentro del cuerpo de los contaminantes del aire, posiblemente con efectos adversos en la salud. Sin embargo, parece probable que los iones del efecto corona tengan efectos escasos o nulos en los riesgos de salud a largo plazo, incluso en las personas más expuestas.

Ninguno de los tres mecanismos directos considerados anteriormente parece ser una causa posible del aumento de incidencia de enfermedades a los niveles de exposición que suele encontrar la población. De hecho, solamente comienzan a ser posibles a niveles varios órdenes de magnitud superiores, y los mecanismos indirectos todavía no se han investigado suficientemente. Esta ausencia de un mecanismo posible identificado no excluye la posibilidad de efectos adversos en la salud, pero hace necesaria la obtención de evidencias más sólidas a partir de la biología y la epidemiología.

18.1.4 Neurocomportamiento

La exposición a campos eléctricos en frecuencia de energía provoca respuestas biológicas bien definidas, que van desde la percepción hasta las molestias, por medio de los efectos de la carga eléctrica superficial. Estas respuestas dependen de la intensidad del campo, las condiciones ambientales y la sensibilidad individual. Los umbrales para la percepción directa por el 10% de un grupo de voluntarios fueron de 2 a 20 kV m^{-1}, mientras que el 5% encontraron molestias con 15–20 kV m^{-1}. Se observó que la descarga de chispas de la persona al suelo era dolorosa en el 7% de los voluntarios en un campo de 5 kV m^{-1}. Los umbrales para la descarga a partir de un objeto cargado a través de una persona aterrada eléctricamente dependen del tamaño del objeto, por lo que se requiere una evaluación específica.

Los campos magnéticos rápidamente pulsantes de intensidad elevada pueden estimular el tejido nervioso periférico o central; tales efectos se pueden presentar durante los procedimientos de imaginología por resonancia magnética (IRM) y se utilizan en la estimulación magnética transcraneal. Las intensidades umbrales de un campo eléctrico inducido para la estimulación directa de los nervios podrían ser de apenas unos voltios por metro. El umbral probablemente es constante dentro de un rango de frecuencias entre unos pocos hertzios y algunos kilohertzios. Es probable que las personas que sufren epilepsia o están predispuestas a ella sean más susceptibles a los campos eléctricos de ELF inducidos en el sistema nervioso central (SNC). Además, la sensibilidad del SNC al estímulo eléctrico está probablemente asociada con un historial familiar de convulsiones y el uso de antidepresivos tricíclicos, agentes neurolépticos y otros fármacos que reducen el umbral de convulsión.

La función de la retina, que forma parte del SNC, puede verse afectada por la exposición a campos magnéticos de ELF mucho más débiles que los causantes de una estimulación directa de los nervios. La interacción del campo eléctrico inducido con las células de la retina excitables eléctricamente da lugar a una sensación de destellos luminosos, denominados fosfenos magnéticos o magnetofosfenos. Las intensidades umbral de los campos eléctricos inducidos en el fluido extracelular de la retina se ha estimado que están comprendidas entre unos 10 y 100 mV m^{-1} a 20 Hz. Sin embargo, existe una incertidumbre considerable la en relación con estos valores.

La evidencia de otros efectos neurocomportamentales en estudios con voluntarios, tales como los efectos en la actividad eléctrica del cerebro, la cognición, el sueño, la hipersensibilidad y el humor, son menos claras. En general, dichos estudios se han realizado con niveles de exposición por debajo de los necesarios para inducir los efectos descritos anteriormente, y en el mejor de los casos solamente se han obtenido evidencias de efectos sutiles y transitorios. Las condiciones necesarias para que se den tales respuestas no están bien definidas por el momento. Hay algunos indicios que parecen indicar la existencia de efectos dependientes del campo sobre el tiempo de reacción y sobre la precisión reducida en la realización de algunas funciones cognitivas, que están respaldados por los resultados de estudios sobre la actividad eléctrica general del cerebro. En los estudios en los que se investigó si los campos magnéticos afectaban a la calidad del sueño se han reportado resultados inconsistentes. Es posible que estas inconsistencias puedan atribuirse en parte a diferencias en el diseño de los estudios.

Algunas personas afirman que son hipersensibles a los CEM en general. Sin embargo, los resultados obtenidos en estudios doble ciego de provocación parecen indicar que los síntomas notificados no guardan relación con la exposición a dichos campos.

Las únicas evidencias que la exposición a campos eléctricos y magnéticos de ELF provoca síntomas depresivos o el suicidio son inconsistentes y no concluyentes. Por lo tanto, la evidencia es considerada inadecuada.

En animales, se ha estudiado desde varias perspectivas la posibilidad de que la exposición a campos de ELF afecte a las funciones neurocomportamentales, utilizando una serie de condiciones de exposición. Son pocos los efectos sólidamente establecidos. Existe evidencia convincente que los animales pueden detectar campos eléctricos en frecuencia de energía, muy probablemente como consecuencia de los efectos de la carga superficial, que pueden provocar agitación transitoria o un estrés ligero. En las ratas, la gama de detección está comprendida entre 3 y 13 kV m^{-1}. Se ha comprobado que los roedores muestran rechazo hacia las intensidades de campo superiores a 50 kV m^{-1}. Otros posibles cambios dependientes del campo no están bien definidos; los estudios de laboratorio solamente han proporcionado evidencias de efectos sutiles y transitorios. Existen algunas evidencias que la exposición a campos magnéticos puede modular las funciones de los sistemas de neurotransmisores opioides y colinérgicos en el cerebro, respaldadas por los resultados de estudios en los que se investigaron los efectos en la analgesia y en la adquisición y el desempeño de funciones de memoria espacial.

18.1.5 Sistema neuroendocrino

Los resultados de varios estudios en voluntarios, así como de estudios epidemiológicos residenciales y ocupacionales, sugieren que el sistema neuroendocrino no es afectado adversamente por la exposición a campos eléctricos o magnéticos en frecuencias de energía. Esto se aplica particularmente a los niveles circulantes de hormonas específicas del sistema neuroendocrino, como la melatonina, liberada por la glándula pineal (epífisis), y a varias hormonas liberadas por glándula pituitaria (hipófisis) que intervienen en el control del metabolismo y la fisiología del cuerpo. A veces se observaron ligeras diferencias en el tiempo de la liberación de la melatonina relacionadas con ciertas características de la exposición, pero estos resultados no fueron consistentes. Es muy difícil eliminar la posible confusión debida a diversos factores ambientales y al estilo de vida que también podrían influir en los niveles hormonales. En la mayor parte de los estudios de laboratorio sobre los efectos de la exposición a campos de ELF en los niveles nocturnos de melatonina en voluntarios no se encontró ningún efecto cuando se tuvo cuidado en el control de los posibles factores de confusión.

Del gran número de estudios en animales que investigan los efectos de los campos eléctricos y magnéticos en frecuencias de energía sobre los niveles de la melatonina pineal (en la epífisis) y en el suero, algunos reportaron que la exposición provocaba la supresión nocturna de la melatonina. Los cambios en los niveles de melatonina observados por primera vez en los estudios iniciales de exposición a campos eléctricos de hasta 100 kV m^{-1} no pudieron reproducirse. Los resultados de una serie de estudios más recientes, que mostraban que los campos magnéticos polarizados circularmente suprimían los niveles nocturnos de melatonina, fueron debilitados por las comparaciones inapropiadas entre los animales expuestos y los controles históricos. Los datos de otros experimentos en roedores, que abarcaban niveles de intensidad comprendidos desde unos pocos microteslas a 5 mT, fueron

equívocos, con algunos mostrando depresión de la melatonina, mientras que en otros no se observaron cambios. En animales de reproducción estacional, la evidencia de un efecto de la exposición a campos en frecuencia de energía sobre los niveles de la melatonina y en el estatus reproductivo dependiente de ésta son predominantemente negativas. En un estudio con primates no humanos sometidos a una exposición crónica a campos en frecuencia de energía no se detectó ningún efecto convincente en los niveles de melatonina, aunque en un estudio preliminar en el que se utilizaron dos animales se reporto la supresión de la melatonina en respuesta a una exposición irregular e intermitente.

Los efectos de la exposición a campos de ELF sobre la producción o liberación de melatonina en glándulas pineales aisladas fueron variables, aunque se han realizado relativamente pocos estudios in vitro. Las evidencias que la exposición a campos de ELF interfiere con la acción de la melatonina en las células de cáncer de mama in vitro son complicadas. Sin embargo, este sistema presenta el inconveniente que frecuentemente las líneas celulares muestran deriva genotípica y fenotípica en el cultivo que puede obstaculizar la transferibilidad posibilidad de transferencia entre laboratorios.

No se han observado efectos consistentes en las hormonas relacionadas con el estrés del eje hipófisis-glándulas suprarrenales en diversas especies de mamíferos, con la posible excepción de un estrés de corta duración tras el inicio de la exposición a campos eléctricos ELF de niveles suficientemente altos para poder percibirlos. Similarmente, si bien son pocos los estudios que se han realizado, en la mayoría se han observado efectos negativos o inconsistentes en los niveles de hormona del crecimiento y de las hormonas que intervienen en el control de la actividad metabólica o están asociadas con el control de la reproducción y el desarrollo sexual.

Considerados en conjunto, estos datos no indican que los campos eléctricos y/o magnéticos de ELF afecten al el sistema neuroendocrino de manera que se produzcan efectos adversos en la salud humana, por lo que las pruebas se consideran inadecuadas.

18.1.6 Trastornos neurodegenerativos

Se ha planteado la hipótesis que la exposición a campos de ELF puede estar asociada con varias enfermedades neurodegenerativas. En relación con la enfermedad de Parkinson y la esclerosis múltiple, el número de estudios ha sido pequeño y no hay evidencias de asociación con estas enfermedades. En el caso de la enfermedad de Alzheimer y la esclerosis lateral amiotrófica (ELA), se han publicado más estudios. Algunos de estos informes parecen indicar que las personas que trabajan en ocupaciones relacionadas con la electricidad podrían tener mayor riesgo de esclerosis lateral amiotrófica (ELA). Hasta ahora no se ha establecido ningún mecanismo biológico que pueda explicar esta asociación, aunque podría haber surgido debido a factores de confusión relacionados con las ocupaciones vinculadas a la electricidad, como los choques eléctricos. En conjunto, se considera que

las pruebas de la asociación entre la exposición a campos de ELF y la esclerosis lateral amiotrófica son (inadecuadas) insuficientes.

Los pocos estudios en los que se ha investigado la asociación entre la exposición a campos ELF y la enfermedad de Alzheimer son contradictorios. Sin embargo, los estudios de mayor calidad que se concentraron en la morbilidad de la enfermedad de Alzheimer más que en la mortalidad no indicaron una asociación. En conjunto, las pruebas de una asociación entre la exposición a campos ELF y la enfermedad de Alzheimer son insuficientes.

18.1.7 Trastornos cardiovasculares

Los estudios experimentales de exposición tanto de corta como de larga duración indican que, si bien el choque eléctrico representa un peligro evidente para la salud, es improbable que se produzcan otros efectos cardiovasculares peligrosos asociados con los campos de ELF a los niveles de exposición ambiental u ocupacional comúnmente encontrados. Aunque se han reportado diversos cambios cardiovasculares en la literatura, la mayoría de los efectos son pequeños y los resultados no han sido consistentes en los estudios y entre ellos. Con una sola excepción, ninguno de los estudios de la morbilidad y mortalidad de las enfermedades cardiovasculares ha mostrado una asociación con la exposición. La posibilidad de que exista una asociación específica entre la exposición y el control autónomo alterado del corazón sigue siendo una mera especulación. En conjunto, las pruebas no respaldan una asociación entre la exposición a campos de ELF y las enfermedades cardiovasculares.

18.1.8 Inmunología y hematología

Las evidencias de los efectos de los campos eléctricos o magnéticos de ELF sobre los componentes del sistema inmunológico en general son inconsistentes. En muchos casos las poblaciones celulares y los marcadores funcionales no fueron afectados por la exposición. Sin embargo, en algunos estudios en seres humanos con campos desde 10 μT a 2 mT se observaron cambios en las células asesinas naturales (citolíticas) , que mostraron tanto un aumento como una disminución de su número, y en la cuenta total de células blancas (leucocitos), sin cambios o con una disminución del número. En estudios en animales, se observó una actividad reducida de las células citolíticas en ratones hembras, pero no en los machos ni en las ratas de ambos sexos. También en la cuenta de células blancas el recuento de leucocitos se obtuvieron resultados inconsistentes, con una disminución o ningún cambio en los distintos estudios. La gama de exposición de los animales fue aún más amplia, de 2 μT a 30 mT. La dificultad para interpretar el impacto potencial de estos datos en la salud radica en las grandes variaciones de las condiciones de exposición y ambientales, el número relativamente pequeño de individuos sometidos a prueba y la amplia variedad de efectos finales.

Son pocos los estudios realizados sobre los efectos de los campos magnéticos de ELF en el sistema hematológico. En los experimentos de evaluación de la cuenta diferencial de células blancas (leucocitos), las exposi-

ciones fueron desde 2 μT a 2 mT. No se han encontrado efectos consistentes de la exposición aguda a campos magnéticos de ELF o a campos eléctricos y magnéticos de ELF combinados ni en los estudios con personas ni con animales.

Por consiguiente, de manera global las evidencias de los efectos de los campos eléctricos o magnéticos de ELF en los sistemas inmunológico y hematológico se consideran insuficientes.

18.1.9 Reproducción y desarrollo

En conjunto, los estudios epidemiológicos no han demostrado que haya una asociación entre resultados adversos en la reproducción humana con la exposición materna o paterna a campos de ELF. Hay algunas evidencias de un aumento del riesgo de aborto asociado con la exposición materna a campos magnéticos, pero son insuficientes.

Se han evaluado exposiciones a campos eléctricos de ELF de hasta 150 kV m^{-1} en varias especies de mamíferos, incluidos estudios con grupos de gran tamaño y exposiciones durante varias generaciones. Los resultados, consistentemente, no mostraron ningún efecto adverso en el desarrollo.

La exposición de mamíferos a campos magnéticos de ELF de hasta 20 mT no da lugar a malformaciones externas, viscerales o esqueléticas graves. Algunos estudios muestran un aumento de pequeñas anomalías esqueléticas, tanto en ratas como en ratones. En estudios teratológicos son relativamente frecuentes las variaciones en el esqueleto, las cuales frecuentemente se consideran biológicamente insignificantes. Sin embargo, no se pueden excluir sutiles efectos de los campos magnéticos en el desarrollo del esqueleto. Se han publicado muy pocos estudios en los que se aborden los efectos en la reproducción, y de ellos no se puede extraer ninguna conclusión.

En varios estudios sobre modelos experimentales no mamíferos (embriones de pollo, peces, erizos de mar e insectos) se han reportado resultados mostrando que los campos magnéticos de ELF a niveles de microteslas pueden alterar el desarrollo inicial. Sin embargo, los resultados de los modelos experimentales no mamíferos en la evaluación global de la toxicidad en el desarrollo tienen un valor menor que los obtenidos en los estudios correspondientes con mamíferos.

En conjunto, las pruebas de efectos en el desarrollo y la reproducción son insuficientes.

18.1.10 Cáncer

La clasificación de la Agencia Internacional de Investigación del Cáncer (IARC) de los campos magnéticos de ELF como “posiblemente carcinogénicos para los seres humanos” (IARC, 2002) se basa en todos los datos disponibles hasta 2001 inclusive. El examen de la literatura en la presente monografía de los Criterios de Salud Ambiental se concentra principalmente en los estudios publicados después de la revisión de la IARC.

Epidemiología

En la clasificación de la IARC influyeron fuertemente las asociaciones observadas en los estudios epidemiológicos sobre la leucemia infantil. La clasificación de esta evidencia como limitada no cambia con la adición de dos estudios sobre leucemia infantil publicados después de 2002. Desde la publicación de la monografía de la IARC, las evidencias de otros casos de cáncer infantil siguen siendo insuficientes.

Con posterioridad a la monografía de la IARC se han publicado varios informes relativos al riesgo de cáncer de mama en mujeres adultas asociado con la exposición a campos magnéticos de ELF. Estos estudios son más amplios que los anteriores y menos susceptibles a sesgos, y en conjunto son negativos. Con estos resultados, la evidencia de una asociación entre la exposición a campos magnéticos de ELF y el riesgo de cáncer de mama en mujeres se debilitan considerablemente y no respaldan una asociación de este tipo.

En el caso del cáncer cerebral y la leucemia en adultos, los nuevos estudios publicados después de la monografía de la IARC no modifican la conclusión de que la evidencia global de una asociación entre los campos magnéticos de ELF y el riesgo de estas enfermedades siguen siendo insuficientes.

Para otras enfermedades y todos los demás tipos de cáncer, las pruebas permanecen insuficientes.

Estudios en animales de laboratorio

En la actualidad no hay ningún modelo animal adecuado para la forma más frecuente de leucemia infantil, la leucemia linfoblástica aguda. Tres estudios independientes de gran escala con ratas no proporcionaron ninguna evidencia de algún efecto de los campos magnéticos de ELF sobre la incidencia de tumores de mama espontáneos. La mayoría de los estudios no reportan ningún efecto de los campos magnéticos de ELF sobre la leucemia o los linfomas en modelos roedores. Varios estudios de gran escala de larga duración en roedores no han mostrado ningún aumento consistente de ningún tipo de cáncer, incluyendo tumores hematopoyéticos, de mama, cerebrales y de piel.

Un número sustancial de estudios examinaron los efectos de los campos magnéticos de ELF sobre tumores de mama inducidos por sustancias químicas en ratas. Se obtuvieron resultados inconsistentes, que pueden deberse totalmente o en parte a diferencias en los protocolos experimentales, tales como el uso de subrazas específicas. La mayoría de los estudios sobre los efectos de la exposición a campos magnéticos de ELF en modelos de leucemia/linfomas inducidos por sustancias químicas o por radiación fueron negativos. Los estudios de lesiones hepáticas preneoplásicas, tumores de piel inducidos por sustancias químicas y tumores cerebrales reportaron resultados predominantemente negativos. Un estudio reporto una aceleración de la tum-

origenesís cutánea inducida por radiaciones ultravioleta (UV) tras la exposición a campos magnéticos de ELF.

Dos grupos han reportado un aumento de los niveles de ruptura de las cadenas de ADN en el tejido cerebral tras la exposición in vivo a campos magnéticos de ELF. Sin embargo, otros grupos, utilizando una variedad de diferentes modelos de genotoxicidad en roedores, no encontraron ninguna evidencia de efectos genotóxicos. Los resultados de los estudios de investigación sobre los efectos no genotóxicos pertinentes al cáncer no son concluyentes.

En conjunto no hay ninguna prueba que la exposición a campos magnéticos de ELF provoque por sí sola la aparición de tumores. La evidencia que la exposición a campos magnéticos de ELF puede potenciar el desarrollo de tumores en combinación con carcinógenos es inadecuada (insuficiente).

Estudios in vitro

En general, los estudios de los efectos de la exposición de células a campos de ELF no han mostrado ninguna inducción de genotoxicidad para campos por debajo de 50 mT. La notable excepción es la evidencia obtenida en estudios recientes en los que se han descrito daños en el ADN con campos de una intensidad de apenas 35 μT; sin embargo, estos estudios todavía están siendo evaluados y la comprensión de estos hallazgos todavía es incompleta. También existe evidencia creciente que los campos magnéticos de ELF pueden interactuar con agentes causantes de daños en el ADN.

No hay ninguna evidencia clara de la activación por campos magnéticos de ELF de genes asociados con el control del ciclo celular. Sin embargo, todavía no se han realizado estudios sistemáticos en los que se analice la respuesta del genoma completo.

Muchos otros estudios celulares, por ejemplo sobre proliferación celular, apoptosis, señalización del calcio y transformación maligna, han dado resultados inconsistentes o no concluyentes.

Conclusión general

Los nuevos estudios en seres humanos, en animales e in vitro, publicados desde la monografía de 2002 de la IARC, no modifican la clasificación global de los campos magnéticos de ELF como posibles carcinógenos para los seres humanos.

18.1.11 Evaluación de los riesgos de salud

Según la Constitución de la OMS, la salud es un estado de completo bienestar físico, mental y social, y no solamente la ausencia de afecciones o enfermedades. La evaluación de riesgo es un marco conceptual para una revisión estructurada de la información pertinente a la estimación de los resultados para la salud o el ambiente. La evaluación de riesgo de salud se puede utilizar como un aporte a la gestión del riesgo que acompaña a todas

las actividades necesarias para adoptar decisiones sobre si una exposición requiere algunas acciones específicas y la aplicación de esas acciones.

En la evaluación de los riesgos para la salud humana, los datos válidos en seres humanos, siempre que se disponga de ellos, generalmente son más informativos que los obtenidos en animales. Los estudios en animales e in vitro pueden respaldar las pruebas procedentes de los estudios en seres humanos, llenar las brechas en la evidencia procedentes de los estudios en seres humanos o utilizarse para adoptar una decisión sobre los riesgos cuando los estudios en seres humanos son insuficientes o no existen.

Todos los estudios, ya sea con efectos positivos o negativos, necesitan ser evaluados juzgados por su propio valor, y luego en conjunto en un sistema basado en el peso de la evidencia. Es importante determinar en qué medida un conjunto de evidencias cambia la probabilidad de que la exposición dé lugar a un resultado. La evidencia de un efecto generalmente es reforzada si los resultados de distintos tipos de estudios (epidemiología y laboratorio) apuntan a la misma conclusión, o cuando estudios múltiples del mismo tipo dan el mismo resultado.

Efectos agudos

Se han establecido los efectos biológicos agudos para la exposición a campos eléctricos y magnéticos de ELF en el rango de frecuencias de hasta 100 kHz que pueden tener consecuencias adversas para la salud. Por consiguiente, se necesitan límites de exposición. Existen recomendaciones internacionales en las que se ha abordado esta cuestión. La observancia de estas recomendaciones proporciona una protección adecuada frente a los efectos agudos.

Efectos crónicos

La evidencia científica que sugiere que la exposición cotidiana crónica a campos magnéticos en frecuencia de energía de baja intensidad (por encima de 0,3–0,4 μT) representa un riesgo para la salud se basa en estudios epidemiológicos que demuestran que hay un patrón consistente de aumento del riesgo de leucemia infantil. Entre las incertidumbres que rodean la evaluación del peligro se incluyen el rol que que podrían desempeñar en la relación observada entre los campos magnéticos y la leucemia infantil el sesgo de selección de los controles y la clasificación errónea de la exposición. Además, virtualmente ninguna de las evidencias de laboratorio y mecanísticas respaldan una relación entre los campos magnéticos de ELF de bajo nivel y los cambios en la función biológica o el estado patológico. Por tanto, en el balance la evidencia no es lo suficientemente fuerte para considerar que hay una relación causal, pero sí para que se mantenga la preocupación.

Aunque no se ha establecido una relación causal entre la exposición a campos magnéticos y la leucemia infantil, se ha calculado el posible impacto en la salud pública suponiendo la existencia de causalidad, a fin de

proporcionar un aporte potencialmente útil a las políticas. Sin embargo, estos cálculos dependen en gran medida de las distribuciones de la exposición y de otras hipótesis, por lo que son muy imprecisos. Suponiendo que la asociación sea causal, se puede estimar que el número de casos de leucemia infantil en todo el mundo que podrían atribuirse a la exposición es del orden de 100 a 2400 al año. Sin embargo, esto representa 0,2 a 4,9% de la incidencia anual total de casos de leucemia, estimados en 49 000 en todo el mundo en el año 2000. Por tanto, en un contexto mundial las repercusiones en la salud pública, si las hay, serían limitadas y dudosas.

Se ha investigado la posible asociación de otras enfermedades con la exposición a campos magnéticos de ELF. Entre ellas están el cáncer tanto en niños como en adultos, la depresión, el suicidio, la disfunción reproductiva, los trastornos del desarrollo, las modificaciones inmunológicas y las enfermedades neurológicas. La evidencia científica que respalda una vinculación entre los campos magnéticos de ELF y cualquiera de estas enfermedades es mucho más débil que para la leucemia infantil, y en algunos casos (por ejemplo en las enfermedades cardiovasculares o el cáncer de mama) la evidencia es suficiente para tener la confianza que los campos magnéticos no son causa de la enfermedad.

18.1.12 Medidas de protección

Es esencial que se apliquen límites de exposición, a fin de proteger contra los efectos adversos establecidos de la exposición a campos eléctricos y magnéticos de ELF. Estos límites de exposición deberían basarse en un examen exhaustivo de toda la evidencia científica relevante.

Solamente se han establecido los efectos agudos, y hay dos recomendaciones internacionales de límites de exposición (ICNIRP, 1998a; IEEE, 2002) destinadas a la protección frente a estos efectos.

Además de estos efectos agudos conocidos, hay incertidumbres acerca de la existencia de efectos crónicos, debido a que las pruebas de una vinculación entre la exposición a campos magnéticos de ELF y la leucemia infantil son limitadas. Por consiguiente, se justifica la utilización de enfoques de precaución. Sin embargo, no se recomienda la reducción de los valores límites de las recomendaciones sobre la exposición a algún nivel arbitrario en aras de la precaución. Dicha práctica socava el fundamento científico en el que se basan los límites y probablemente sea una manera costosa y no necesariamente eficaz de proporcionar protección.

La aplicación de otros procedimientos apropiados de precaución para reducir la exposición es razonable y se justifica. Sin embargo, la energía eléctrica aporta evidentes beneficios a la salud, sociales y económicos, y los enfoques de precaución no deberían comprometer esos beneficios. Además, teniendo en cuenta, por una parte la debilidad de la evidencia de una vinculación entre la exposición a campos magnéticos de ELF y la leucemia infantil y por otra parte el limitado impacto en la salud pública si existe una vinculación, no están claros los beneficios para la salud de una reducción de la exposición. Así pues, los costos de las medidas de precaución deberían ser

muy bajos. Los costos de la aplicación de reducciones de la exposición variarán de un país a otro, por lo que resulta muy difícil formular una recomendación general para alcanzar un equilibrio entre los costos y los posibles riesgos derivados de los campos ELF.

En vista de lo expuesto, se recomienda lo siguiente.

- Los encargados de formular las políticas deberían establecer recomendaciones para la exposición a campos de ELF tanto del público en general como de los trabajadores. La mejor fuente de orientación para los niveles de exposición y los principios aplicables a la revisión científica son las recomendaciones internacionales.
- Los encargados de formular las políticas deberían establecer un programa de protección para los CEM ELF que incluya mediciones de los campos de todas las fuentes, a fin de asegurarse de que no se superen los límites de exposición del público en general o de los trabajadores.
- Siempre que no se pongan en peligro los beneficios para la salud, sociales y económicos de la energía eléctrica, es razonable y se justifica la aplicación de procedimientos de precaución de muy bajo costo para reducir la exposición.
- Los encargados de formular las políticas, los planificadores comunitarios y los fabricantes deberían aplicar medidas de muy bajo costo al construir nuevas instalaciones y diseñar nuevos equipos, incluyendo aparatos eléctricos.
- Se debe estudiar la introducción de cambios en las prácticas de ingeniería para reducir la exposición a campos de ELF procedentes de equipos o dispositivos, siempre que se obtengan otros beneficios adicionales, tales como mayor seguridad o un costo escaso o nulo.
- Cuando se planteen cambios en las fuentes existentes de campos ELF, se debería considerar los aspectos de seguridad, la fiabilidad y los aspectos económicos involucrados.
- Las autoridades locales deberían hacer cumplir las normas sobre las instalaciones eléctricas a fin de reducir corrientes a tierra accidentales cuando se construyan nuevos locales o cuando se renueven las instalaciones eléctricas ya existentes, manteniendo al mismo tiempo la seguridad. Las medidas preventivas para identificar infracciones o problemas existentes en las instalaciones eléctricas resultarían costosas y probablemente no estarían justificadas.
- Las autoridades nacionales deberían aplicar una estrategia eficaz y de comunicación abierta a fin de que todas las partes interesadas puedan adoptar decisiones fundamentadas; debe estar incluida la

información sobre la manera en que las personas pueden reducir su propia exposición.

- Las autoridades locales deben mejorar la planificación de las instalaciones emisoras de CEM ELF, incluyendo el mejoramiento de las consultas entre la industria, los gobiernos locales y los ciudadanos al establecer las principales fuentes de emisión de CEM ELF.
- Los gobiernos y la industria deberían promover programas de investigación para reducir la incertidumbre de la evidencia científica sobre los efectos de la exposición a campos ELF en la salud.

18.2 Recomendaciones para la investigación

La identificación de las brechas en los conocimientos relativos a los posibles efectos en la salud de la exposición a campos de ELF es una parte esencial de la presente evaluación de los riesgos de salud. Como consecuencia, se han formulado las siguientes recomendaciones para investigación adicional (resumidas en la Tabla 1).

Es primordial la necesidad de realizar nuevas investigaciones sobre las frecuencias intermedias (FI), usualmente comprendidas entre 300 Hz y 100 kHz, dada la presente falta de datos en esta área. Es muy escasa la base de conocimientos de la cual se dispone y que se necesita para la evaluación de los riesgos de salud, y en la mayoría de los estudios existentes se han obtenido resultados inconsistentes, que es necesario comprobar ulteriormente. Los requisitos generales para establecer una base de datos de FI que sea suficiente a la hora de evaluar los riesgos de salud incluye la evaluación de la exposición, estudios epidemiológicos, estudios humanos de laboratorio y estudios en animales y celulares (in vitro) (ICNIRP, 2003; ICNIRP, 2004; Litvak et al., 2002).

En los estudios de laboratorio se debe conceder prioridad a las respuestas reportadas (i) para las cuales exista por lo menos alguna evidencia de replicación o confirmación, (ii) que sean potencialmente pertinentes a la carcinogénesis (por ejemplo de genotoxicidad), (iii) que sean suficientemente sólidas para permitir un análisis mecanístico y (iv) que se produzcan en sistemas de mamíferos o seres humanos.

18.2.1 Fuentes, mediciones y exposiciones

La caracterización ulterior de los hogares con un exposición elevada a campos de ELF en los distintos países, a fin de identificar la contribución relativa de las fuentes internas y externas, la influencia de las prácticas de instalación del tendido eléctrico/aterramiento eléctrico y otras características del hogar, puede servir de ayuda para identificar un sistema de medición de la exposición pertinente a la evaluación epidemiológica. Un componente importante de esto es el mejor entendimiento de la exposición fetal e infantil a campos de ELF, especialmente los procedentes de la

exposición residencial a la calefacción eléctrica debajo del piso en los domicilios y de los transformadores en los edificios de viviendas.

Se sospecha que en algunos casos de exposición ocupacional se superan los límites presentes de las recomendaciones sobre campos de ELF. Se necesita más información sobre la exposición (incluso a frecuencias que no son de energía) relacionada con el trabajo, por ejemplo, mantenimiento de líneas con tensión, el trabajo dentro o cerca del núcleo central de las magnetos de los aparatos de IRM (y en consecuencia con los campos de ELF de gradiente conmutada) y el trabajo en sistemas de transporte. Asimismo, se necesitan más conocimientos acerca de la exposición del público general que pueda acercarse a los límites de las recomendaciones, incluyendo fuentes tales como los sistemas de seguridad, los sistemas de desmagnetización de las bibliotecas, las cocinas de inducción y los calentadores de agua.

Se ha propuesto la exposición a corrientes de contacto como una posible explicación de la asociación de los campos magnéticos de ELF con la leucemia infantil. Es necesario realizar investigaciones en países distintos de los Estados Unidos para evaluar la posibilidad de que las prácticas de aterramiento eléctrico residenciales y la ductería de agua potable en las viviendas den lugar a corrientes de contacto. Dichos estudios tendrían prioridad en los países con resultados epidemiológicos importantes con respecto a los campos de ELF y la leucemia infantil.

18.2.2 Dosimetría

La mayor parte de las investigaciones de laboratorio realizadas en el pasado se basaban en corrientes eléctricas inducidas en el cuerpo como métrica básica, de manera que la dosimetría se concentraba en esta cantidad. Sólo en fechas recientes se ha comenzado a explorar la relación entre la exposición externa y los campos eléctricos inducidos. Para comprender mejor los efectos biológicos, se necesitan más datos sobre los campos eléctricos internos en distintas condiciones de exposición.

Se debe realizar un cálculo de los campos eléctricos internos, debido a la influencia combinada de los campos eléctricos y magnéticos externos en distintas configuraciones. Es necesaria la adición vectorial de las contribuciones fuera de fase y con variaciones espaciales de los campos eléctricos y magnéticos para evaluar el cumplimiento de las restricciones básicas.

Son muy pocos los cálculos que se han realizado sobre modelos avanzados de la mujer embarazada y el feto con modelos anatómicos apropiados. Es importante evaluar el posible aumento de la inducción de campos eléctricos en el feto en relación con el tema de la leucemia infantil. En este sentido son importantes la exposición ocupacional materna y residencial.

Existe la necesidad de seguir perfeccionando los modelos microdosimétricos, con el objetivo de tener en cuenta la estructura celular de las redes neurales y otros sistemas suborgánicos complejos identificados como más sensibles a los efectos de los campos eléctricos inducidos. En este proceso de modelamiento también se debe tener presente la influencia en los

potenciales eléctricos de la membrana celular y en la liberación de neurotransmisores.

18.2.3 Mecanismos biofísicos

Existen tres áreas principales en los que son evidentes los límites del entendimiento actual de los mecanismos: el mecanismo par radical, las partículas magnéticas en el cuerpo y la relación señal a ruido en los sistemas multicelulares, tales como las redes neuronales.

El mecanismo par radical es uno de los mecanismos más verosímiles de interacción de bajo nivel, pero todavía no se ha demostrado que es capaz de mediar efectos significativos en el metabolismo y la función celular. Es particularmente importante entender el límite inferior de exposición al cual actúa, de manera que se pueda determinar si puede ser o no un mecanismo importante para la carcinogénesis. Teniendo en cuenta los estudios recientes en los que aumentaron las especies de oxígeno reactivo en células inmunitarias expuestas a campos de ELF, se recomienda el empleo de células del sistema inmunológico que generan especies de oxígeno reactivo como parte de su respuesta inmunitaria como modelos celulares para investigar el potencial del mecanismo par radical.

Aunque, de acuerdo con las evidencias actuales, la presencia de partículas magnéticas (cristales de magnetita) en el cerebro humano no parece conferir sensibilidad a los campos magnéticos de ELF del ambiente, se deberían explorar más enfoques teóricos y experimentales para estudiar si tal sensibilidad puede existir bajo determinadas condiciones. Además, se debería buscar cualquier modificación que pueda introducir la presencia de magnetita en el mecanismo par radical antes mencionado.

Se debe seguir investigando en qué medida actúan mecanismos multicelulares en el cerebro, de manera que mejoren las relaciones señal a ruido, a fin de desarrollar un marco teórico para su cuantificación o para determinar sus posibles límites. Se debe realizar investigación adicional del umbral y la respuesta de frecuencia de las redes neuronales en el hipocampo y en otras partes del cerebro utilizando métodos in vitro.

18.2.4 Neurocomportamiento

Se recomienda que los estudios de laboratorio basados en voluntarios sobre los posibles efectos en el sueño y en la realización de tareas que exijan un esfuerzo mental grande se lleven a cabo utilizando procedimientos metodológicos armonizados. Es necesario identificar las relaciones dosis-respuesta con densidades de flujo magnético superiores a las utilizadas anteriormente y con una gama amplia de frecuencias (es decir, en el rango de los kilohertz).

Los estudios realizados en voluntarios adultos y en animales sugieren que pueden producirse efectos cognitivos agudos con exposiciones de corto plazo a campos eléctricos o magnéticos intensos. La caracterización de tales efectos es muy importante para el desarrollo de orientación sobre la exposición, pero se carece de datos específicos concernientes a efectos

dependientes del campo en niños. Se recomienda la realización de estudios de laboratorio en la cognición y los cambios en los electroencefalogramas (EEG) en personas expuestas a campos de ELF, incluyendo adultos sujetos habitualmente a exposición ocupacional y niños.

Los estudios de comportamiento con animales inmaduros proporcionan un indicador útil de los posibles efectos cognitivos en los niños. Se deben estudiar los posibles efectos de la exposición prenatal y postnatal a campos magnéticos de ELF en el desarrollo del sistema nervioso y la función cognitiva. Sería útil complementar estos estudios con investigaciones sobre los efectos de la exposición a campos magnéticos de ELF y campos eléctricos inducidos en el crecimiento de las células nerviosas, utilizando rebanadas de cerebro o neuronas cultivadas.

Es necesario seguir investigando las consecuencias potenciales en la salud sugeridas por los datos experimentales que muestran respuestas opioides y colinérgicas en animales. Se deberian ampliar los estudios en los que se examina la modulación de las respuestas opioides y colinérgicas en animales y se debería definir los parámetros de exposición y la base biológica de estas respuestas de comportamiento.

18.2.5 Sistema neuroendocrino

La base de datos existente sobre la respuesta neuroendocrina no indica que la exposición a campos de ELF tenga impactos adversos en la salud humana. Por consiguiente, no se formula ninguna recomendación para nuevas investigaciones.

18.2.6 Trastornos neurodegenerativos

En varios estudios se ha observado un aumento del riesgo de esclerosis lateral amiotrófica en las “ocupaciones eléctricas”. Se considera importante realizar más investigación de esta asociación, a fin de descubrir si los campos magnéticos de ELF intervienen como causa de esta rara enfermedad neurodegenerativa. Esta investigación requiere estudios prospectivos de cohortes de gran envergadura con información sobre la exposición a campos magnéticos de ELF, a choques eléctricos así como exposición a otros posibles factores de riesgo.

Sigue siendo discutible si los campos magnéticos de ELF constituyen un factor de riesgo para la enfermedad de Alzheimer. Los datos disponibles en la actualidad no son suficientes, por lo que habría que estudiar más esta asociación. Tiene particular importancia el uso de datos sobre la morbilidad más que sobre la mortalidad.

18.2.7 Trastornos cardiovasculares

No se considera prioritaria la realización de investigaciones adicionales sobre la asociación entre los campos magnéticos de ELF y el riesgo de enfermedades cardiovasculares.

18.2.8 Inmunología y hematología

Los cambios observados en los parámetros inmunológicos y hematológicos en adultos expuestos a campos magnéticos de ELF mostraron inconsistencias, y esencialmente no se dispone de datos de investigación sobre niños. Por consiguiente, se recomienda la realización de estudios sobre los efectos de la exposición a campos de ELF en el desarrollo de los sistemas inmunológicos y hematopoyético en animales jóvenes.

18.2.9 *Reproducción y desarrollo*

Existen algunas evidencias de un aumento del riesgo de aborto asociado con la exposición a campos magnéticos de ELF. Teniendo en cuenta las repercusiones potencialmente elevadas de dicha asociación para la salud pública se recomienda la realización de nuevas investigaciones epidemiológicas.

18.2.10 Cáncer

La máxima prioridad de las investigaciones en esta área corresponde a la solución del conflicto entre los datos epidemiológicos (que muestran una asociación entre la exposición a campos magnéticos de ELF y un aumento del riesgo de leucemia infantil) y los datos experimentales y mecanísticos (que no respaldan esta asociación). Se recomienda la colaboración de epidemiólogos y científicos experimentales en este sentido. Para que los nuevos estudios epidemiológicos sean ilustrativos, se deben concentrar en nuevos aspectos de la exposición, en la interacción potencial con otros factores o en grupos muy expuestos, o bien introducir alguna otra innovación en esta esfera de investigación. Además, se recomienda también la actualización de los análisis combinados existentes, añadiendo datos de estudios recientes y aplicando nuevos conocimientos dentro del análisis.

En los estudios sobre el cáncer cerebral infantil se han obtenido resultados inconsistentes. Al igual con la leucemia infantil, el análisis de los estudios combinados sobre el cáncer cerebral infantil sería muy informativo, por lo que se recomienda. Un análisis de este tipo puede proporcionar sin grandes gastos mayor y mejor información sobre los datos existentes, incluyendo la posibilidad del sesgo de selección, y si los estudios son suficientemente homogéneos puede ofrecer la mejor estimación de riesgo.

En el caso del cáncer de mama en adultos, estudios más recientes han mostrado de manera convincente que no existe ninguna asociación con la exposición a campos magnéticos de ELF. Por consiguiente, la investigación adicional sobre esta asociación debe ser objeto de una prioridad muy baja.

En relación con la leucemia y el cáncer cerebral en adultos, se recomienda la actualización de las cohortes de gran envergadura existentes de personas expuestas ocupacionalmente. Los estudios ocupacionales, los análisis combinados y los metaanálisis para la leucemia y el cáncer cerebral han sido inconsistentes y no concluyentes. Sin embargo, posteriormente se han publicado nuevos datos que deberían utilizarse para actualizar estos análisis.

Se ha de conceder prioridad al abordar las evidencias epidemiológicas, mediante el establecimiento de modelos in vitro y animales apropiados para las respuestas a campos magnéticos de ELF de bajo nivel que sean ampliamente transferibles entre laboratorios.

Se deben desarrollar modelos de roedores transgénicos para la leucemia infantil, a fin de disponer de modelos de animales experimentales apropiados para estudiar los efectos de la exposición a campos magnéticos de ELF. De otra manera, para los estudios existentes en animales el peso de la evidencia es que no existen efectos carcinogénicos provenientes de los campos magnéticos de ELF actuando por sí solos. Por consiguiente, se debe conceder máxima prioridad a los estudios in vitro y en animales en los que se evalúen rigurosamente los campos magnéticos de ELF como cocarcinógenos.

Con respecto a otros estudios in vitro, se deben repetir los experimentos en los que se reportan los efectos genotóxicos de una exposición intermitente a campos magnéticos de ELF.

18.2.11 Medidas de protección

Se recomienda la realización de investigaciones sobre la formulación de políticas de protección de la salud y su aplicación en sectores con incertidumbre científica, en concreto sobre el uso del principio de precaución, su interpretación y la evaluación del impacto de las medidas de precaución para campos magnéticos de ELF y otros agentes clasificados como "posibles carcinógenos para los seres humanos". Cuando existen incertidumbres acerca del riesgo potencial para la salud que un agente plantea para la sociedad, medidas de precaución que pueden estar justificadas, a fin de asegurar la protección adecuada del público y los trabajadores. Son limitadas las investigaciones que se han realizado sobre este tema para campos magnéticos de ELF y, debido a su importancia, es necesario seguir investigando. Esto puede ayudar a los países a integrar el principio de precaución en sus políticas de protección de la salud.

Se aconsejan nuevas investigaciones sobre la percepción y comunicación del riesgo orientadas específicamente a los campos electromagnéticos. Se han investigado ampliamente los factores psicológicos y sociológicos que influyen en la percepción del riesgo en general. Sin embargo, han sido limitadas las investigaciones para analizar la importancia relativa de estos factores en el caso de los campos electromagnéticos o para identificar otros factores específicos de dichos campos. En estudios recientes se ha sugerido que las medidas de precaución que transmiten mensajes de riesgo implícitos pueden modificar la percepción del riesgo, aumentando o disminuyendo la preocupación. Por consiguiente, está justificada una investigación más profunda sobre este tema.

Se debe realizar la investigación sobre el desarrollo de un análisis de costo-beneficio / costo-efectividad para la mitigación de los campos magnéticos de ELF. El empleo del análisis de costo-beneficio y costo-efectividad para evaluar si una opción en materia de políticas es beneficiosa para la

sociedad se ha investigado en muchos sectores de las políticas públicas. Es necesario formular un marco que permita identificar qué parámetros son necesarios a fin de realizar este análisis para campos magnéticos de ELF. Debido a las incertidumbres en la evaluación, se necesitará incorporar parámetros cuantificables y no cuantificables.

Tabla 1. Recomendaciones para nuevas investigaciones

Fuentes, mediciones y exposiciones	**Prioridad**
Caracterización ulterior de los hogares con exposición elevada a campos magnéticos de ELF en distintos países	Media
Identificar las brechas en el conocimiento acerca de la exposición ocupacional a campos de ELF, tales como en las IRM	Alta
Evaluación de la capacidad de las instalaciones eléctricas residenciales fuera de los Estados Unidos para inducir corrientes de contacto en los niños	Media
Dosimetría	
Dosimetría computacional adicional de la relación de los campos eléctricos y magnéticos externos con los campos eléctricos internos, en particular con respecto a la exposición a campos eléctricos y magnéticos combinados en distintas orientaciones	Media
Cálculo de los campos eléctricos y las corrientes inducidos en las mujeres embarazadas y en el feto	Media
Mayor perfeccionamiento de los modelos microdosimétricos, teniendo en cuenta la estructura celular de las redes neurales y otros sistemas suborgánicos complejos	Media
Mecanismos biofísicos	
Mayor estudio de los mecanismos par radical en las células inmunitarias que generan especies de oxígeno reactivo como parte de su función fenotípica	Media
Nuevos estudios teóricos y experimentales de la posible función de la magnetita en la sensibilidad a campos magnéticos de ELF	Baja
Determinación de las respuestas umbral a campos eléctricos internos inducidos por campos de ELF en sistemas multicelulares, tales como las redes neurales, utilizando enfoques teóricos e in vitro	Alta
Neurocomportamiento	
Estudios de la función cognitiva, el sueño y el electroencefalograma (EEG) en voluntarios, con inclusión de niños y personas ocupacionalmente expuestas, utilizando un amplio rango de frecuencias de campos de ELF con densidades de flujo elevadas	Media
Estudios de la exposición prenatal y postnatal en la función cognitiva posterior en animales	Media
Nuevos estudios de las respuestas opioides y colinérgicas en animales	Baja

Trastornos neurodegenerativos	
Estudios adicionales del riesgo de esclerosis lateral amiotrófica en ocupaciones eléctricas y en relación con la exposición a campos magnéticos de ELF y de la enfermedad de Alzheimer en relación con la exposición a dichos campos	Alta
Inmunología y hematología	
Estudios de las consecuencias de la exposición a campos magnéticos de ELF sobre el desarrollo del sistema inmunitario y hematopoyético en animales jóvenes	Baja
Reproducción y desarrollo	
Further study of the possible link between miscarriage and ELF magnetic field exposure Estudio adicional de la posible vinculación entre el aborto y la exposición a campos magnéticos de ELF	Baja
Cáncer	
Actualización de los análisis combinados existentes de la leucemia infantil con nueva información	Alta
Análisis combinados de los estudios existentes sobre los tumores cerebrales infantiles	Alta
Update existing meta-analyses of adult leukaemia and brain tumour studies and of cohorts of occupationally exposed individuals Actualización de los meta análisis existentes de los estudios sobre la leucemia y los tumores cerebrales en adultos y de las cohortes de personas expuestas ocupacionalmente	Media
Desarrollo de modelos de leucemia infantil en roedores transgénicos para su utilización en estudios sobre los campos de ELF	Alta
Evaluación de los efectos cocarcinogénicos utilizando estudios *in vitro* y en animales	Alta
Intento de reproducción de estudios de genotoxicidad *in vitro*	Media
Medidas de protección / precautorias / prevención	
Investigación sobre la formulación de políticas de protección de la salud y su aplicación en sectores con incertidumbre científica	Media
Nuevas investigaciones sobre la percepción y la comunicación del riesgo orientadas a los campos electromagnéticos	Media
Desarrollo de un análisis costo-beneficio/costo efectividad para la mitigación de los campos de ELF	Media

Electromagnetic fields act *via* activation of voltage-gated calcium channels to produce beneficial or adverse effects

Martin L. Pall *

Professor Emeritus of Biochemistry and Basic Medical Sciences, Washington State University, Portland, OR, USA

Received: January 8, 2013; Accepted: May 20, 2013

Abstract

The direct targets of extremely low and microwave frequency range electromagnetic fields (EMFs) in producing non-thermal effects have not been clearly established. However, studies in the literature, reviewed here, provide substantial support for such direct targets. Twenty-three studies have shown that voltage-gated calcium channels (VGCCs) produce these and other EMF effects, such that the L-type or other VGCC blockers block or greatly lower diverse EMF effects. Furthermore, the voltage-gated properties of these channels may provide biophysically plausible mechanisms for EMF biological effects. Downstream responses of such EMF exposures may be mediated through Ca^{2+}/calmodulin stimulation of nitric oxide synthesis. Potentially, physiological/therapeutic responses may be largely as a result of nitric oxide-cGMP-protein kinase G pathway stimulation. A well-studied example of such an apparent therapeutic response, EMF stimulation of bone growth, appears to work along this pathway. However, pathophysiological responses to EMFs may be as a result of nitric oxide-peroxynitrite-oxidative stress pathway of action. A single such well-documented example, EMF induction of DNA single-strand breaks in cells, as measured by alkaline comet assays, is reviewed here. Such single-strand breaks are known to be produced through the action of this pathway. Data on the mechanism of EMF induction of such breaks are limited; what data are available support this proposed mechanism. Other Ca^{2+}-mediated regulatory changes, independent of nitric oxide, may also have roles. This article reviews, then, a substantially supported set of targets, VGCCs, whose stimulation produces non-thermal EMF responses by humans/higher animals with downstream effects involving Ca^{2+}/calmodulin-dependent nitric oxide increases, which may explain therapeutic and pathophysiological effects.

Keywords: intracellular Ca^{2+} ● voltage-gated calcium channels ● low frequency electromagnetic field exposure ● nitric oxide ● oxidative stress ● calcium channel blockers

Introduction

An understanding of the complex biology of the effects of electromagnetic fields (EMFs) on human/higher animal biology inevitably must be derived from an understanding of the target or targets of such fields in the impacted cells and tissues. Despite this, no understanding has been forthcoming on what those targets are and how they may lead to the complex biological responses to EMFs composed of low-energy photons. The great puzzle, here, is that these EMFs are comprised of low-energy photons, those with insufficient energy to individually influence the chemistry of the cell, raising the question of how non-thermal effects of such EMFs can possibly occur. has found that there is a substantial literature possibly pointing to the direct targets of such EMFs and it is the goal of this study to review that evidence as well as review how those targets may lead to the complex biology of EMF exposure.

The role of increased intracellular Ca^{2+} following EMF exposure was already well documented more than 20 years ago, when Walleczek [1] reviewed the role of changes in calcium signalling that were produced in response EMF exposures. Other, more recent studies have confirmed the role of increased intracellular Ca^{2+} following EMF exposure, a few of which are discussed below. His review [1] included two studies [2, 3] that showed that the L-type voltage-gated channel blocker, verapamil could lower or block changes in response to EMFs. The properties of voltage-gated calcium channels (VGCCs) have been reviewed elsewhere [4]. Subsequently, extensive evidence has been published clearly showing that the EMF exposure can act to produce excessive activity of the VGCCs in many cell types [5–26] suggesting that these may be direct targets of EMF exposure. Many of these studies implicate specifically the L-type VGCCs such that various L-type calcium channel blockers can block responses to EMF exposure (Table 1). However, other studies have shown lowered responses produced by other types of calcium channel blockers including N-type, P/Q-type, and T-type blockers (Table 1), showing that other VGCCs may have important roles. Diverse responses to EMFs are reported to be blocked by such calcium channel blockers (Table 1), suggesting that most if not all EMF-mediated responses may be produced through VGCC stimulation. Voltage-gated calcium channels are essential to the responses produced by extremely low frequency (including 50/60 Hz) EMFs and also to microwave frequency range EMFs, nanosecond EMF pulses, and static electrical and magnetic fields (Table 1).

In a recent study, Pilla [27] showed that an increase in intracellular Ca^{2+} must have occurred almost immediately after EMF exposure, producing a Ca^{2+}/calmodulin-dependent increase in nitric oxide occurring in less than 5 sec. Although Pilla [27] did not test whether VGCC stimulation was involved in his study, there are few alternatives that can produce such a rapid Ca^{2+} response, none of which has been implicated in EMF responses. Other studies, each involving VGCCs, summarized in Table 1, also showed rapid Ca^{2+} increases following EMF exposure [8, 16, 17, 19, 21]. The rapidity of these responses rule out many types of regulatory interactions as being involved in producing the increased VGCC activity following EMF exposure and suggests, therefore, that VGCC stimulation in the plasma membrane is directly produced by EMF exposure.

Possible modes of action following VGCC stimulation

The increased intracellular Ca^{2+} produced by such VGCC activation may lead to multiple regulatory responses, including the increased nitric oxide levels produced through the action of the two Ca^{2+}/calmodulin-dependent nitric oxide synthases, nNOS and eNOS. Increased nitric oxide levels typically act in a physiological context through increased synthesis of cGMP and subsequent activation of protein kinase G [28, 29]. In contrast, in most pathophysiological contexts, nitric oxide reacts with superoxide to form peroxynitrite, a potent non-radical oxidant [30, 31], which can produce radical products, including hydroxyl radical and NO_2 radical [32].

Therapeutic bone-growth stimulation *via* Ca^{2+}/nitric oxide/cGMP/protein kinase G

An example of a therapeutic effect for bone repair of EMF exposure in various medical situations includes increasing osteoblast differentiation and maturation and has been reviewed repeatedly [33–44]. The effects of EMF exposure on bone cannot be challenged, although there is still considerable question about the best ways to apply this clinically [33–44]. Our focus, here, is to consider possible mechanisms of action. Multiple studies have implicated increased Ca^{2+} and nitric oxide in the EMF stimulation of bone growth [44–49]; three have also implicated increased cGMP and protein kinase G activity [46, 48, 49]. In addition, studies on other regulatory stimuli leading to increased bone growth have also implicated increased cGMP levels and protein kinase G in this response [50–56]. In summary, then, it can be seen from the above that there is a very well-documented action of EMFs in stimulating osteoblasts and bone growth. The available data, although limited, support the action of the main pathway involved in physiological responses to Ca^{2+} and nitric oxide, namely Ca^{2+}/nitric oxide/cGMP/protein kinase G in producing such stimulation.

Ca^{2+}/nitric oxide/peroxynitrite and pathophysiological responses to EMF exposures: the example of single-strand DNA breaks

As was noted above, most of the pathophysiological effects of nitric oxide are mediated through peroxynitrite elevation and consequent oxidative stress. There are many reviews and other studies, implicating oxidative stress in generating pathophysiological effects of EMF exposure [see for example 57–64]. In some of these studies, the rise in oxidative stress markers parallels the rise in nitric oxide, suggesting a peroxynitrite-mediated mechanism [64–67].

Peroxynitrite elevation is usually measured through a marker of peroxynitrite-mediated protein nitration, 3-nitrotyrosine (3-NT). There are four studies where 3-NT levels were measured before and after EMF exposure [66, 68–70]. Each of these studies provides some evidence supporting the view that EMF exposure increases levels of peroxynitrite and therefore 3-NT levels [66, 68–70]. Although these cannot be taken as definitive, when considered along with the evidence on oxidative stress and elevated nitric oxide production in response to EMF exposure, they strongly suggest a peroxynitrite-mediated mechanism of oxidative stress in response to EMFs.

Table 1 EMF responses blocked or lowered by calcium channel blockers

Ref. no.	EMF type	Calcium channel	Cell type or organism	Response measured
2	Pulsed magnetic fields	L-type	Human lymphocytes	Cell proliferation; cytokine production
3	Static magnetic field (0.1 T)	L-type	Human polymorphonuclear leucocytes	Cell migration; degranulation
5	ELF	L-type	Rat chromaffin cells	Differentiation; catecholamine release
6	Electric field	L-type	Rat and mouse bone cells	Increased Ca^{2+}, phospholipase A2, PGE2
7	50 Hz	L-type	Mytilus (mussel) immunocytes	Reduced shape change, cytotoxicity
8	50 Hz	L-type	AtT20 D16V, mouse pituitary corticotrope-derived	Ca^{2+} increase; cell morphology, premature differentiation
9	50 Hz	L-type	Neural stem/progenitor cells	*In vitro* differentiation, neurogenesis
10	Static magnetic field	L-type	Rat	Reduction in oedema formation
11	NMR	L-type	Tumour cells	Synergistic effect of EMF on anti-tumour drug toxicity
12	Static magnetic field	L-type	Myelomonocytic U937 cells	Ca^{2+} influx into cells and anti-apoptotic effects
13	60 Hz	L-type	Mouse	Hyperalgesic response to exposure
14	Single nanosecond electric pulse	L-type	Bovine chromaffin cells	Very rapid increase in intracellular Ca^{2+}
15	Biphasic electric current	L-type	Human mesenchymal stromal cells	Osteoblast differentiation and cytokine production
16	DC & AC magnetic fields	L-type	β-cells of pancreas, patch clamped	Ca^{2+} flux into cells
17	50 Hz	L-type	Rat pituitary cells	Ca^{2+} flux into cells
18	50 Hz	L-type, N-type	Human neuroblastoma IMR32 and rat pituitary GH3 cells	Anti-apoptotic activity
19	Nanosecond pulse	L-type, N-type, P/Q-type	Bovine chromaffin cells	Ca^{2+} dynamics of cells
20	50 Hz	Not determined	Rat dorsal root ganglion cells	Firing frequency of cells
21	700–1100 MHz	N-type	Stem cell–derived neuronal cells	Ca^{2+} dynamics of cells
22	Very weak electrical fields	T-type	Sharks	Detection of very weak magnetic fields in the ocean
23	Short electric pulses	L-type	Human eye	Effect on electro-oculogram
24	Weak static magnetic field	L-type	Rabbit	Baroreflex sensitivity
25	Weak electric fields	T-type	Neutrophils	Electrical and ion dynamics
26	Static electric fields, 'capacitive'	L-type	Bovine articular chondrocytes	Agrican & type II collagen expression; calcineurin and other Ca^{2+}/calmodulin responses

EMF: electromagnetic field; ELF: extremely low frequency.

Such a peroxynitrite-mediated mechanism may explain the many studies showing the single-stranded breaks in DNA, as shown by alkaline comet assays or the similar microgel electrophoresis assay, following EMF exposures in most such studies [71–89], but not in all [90–97]. Some of the factors that are reported to influence whether such DNA single-strand breaks are detected after EMF exposure include the type of cell studied [79, 86], dosage of EMF exposure [78] and the type of EMF exposure studied [73, 77]. Oxidative stress and free radicals have roles, both because there is a concomitant increase in oxidative stress and because antioxidants have been shown to greatly lower the generation of DNA single-strand breaks following EMF exposure [72, 75, 81, 82] as has also been shown for peroxynitrite-mediated DNA breaks produced under other conditions. It has also been shown that one can block the generation of DNA single-strand breaks with a nitric oxide synthase inhibitors [82].

Peroxynitrite has been shown to produce single-strand DNA breaks [98–100], a process that is inhibited by many but not all antioxidants [99, 100]. It can be seen from this that the data on generation of single-strand DNA breaks, although quite limited, support a mechanism involving nitric oxide/peroxynitrite/free radical (oxidative stress). Although the data on the possible role of peroxynitrite in EMF-induced DNA single-strand breaks are limited, what data are available supports such a peroxynitrite role.

Discussion and conclusions

How do EMFs composed of low-energy photons produce non-thermal biological changes, both pathophysiological and, in some cases, potentially therapeutic, in humans and higher animals? It may be surprising that the answer to this question has been hiding in plain sight in the scientific literature. However, in this era of highly focused and highly specialized science, few of us have the time to read the relevant literature, let alone organize the information found within it in useful and critical ways.

This study shows that:

1 Twenty-three different studies have found that such EMF exposures act *via* activation of VGCCs, such that VGCC channel blockers can prevent responses to such exposures (Table 1). Most of the studies implicate L-type VGCCs in these responses, but there are also other studies implicating three other classes of VGCCs.

2 Both extremely low frequency fields, including 50/60 cycle exposures, and microwave EMF range exposures act *via* activation of VGCCs. So do static electric fields, static magnetic fields and nanosecond pulses.

3 Voltage-gated calcium channel stimulation leads to increased intracellular Ca^{2+}, which can act in turn to stimulate the two calcium/calmodulin-dependent nitric oxide synthases and increase nitric oxide. It is suggested here that nitric oxide may act in therapeutic/potentially therapeutic EMF responses *via* its main physiological pathway, stimulating cGMP and protein kinase G. It is also suggested that nitric oxide may act in pathophysiological responses to EMF exposure, by acting as a precursor of peroxynitrite, producing both oxidative stress and free radical breakdown products.

4 The interpretation in three above is supported by two specific well-documented examples of EMF effects. Electromagnetic fields stimulation of bone growth, modulated through EMF stimulation of osteoblasts, appears to involve an elevation/nitric oxide/protein kinase G pathway. In contrast to that, it seems likely that the EMF induction of single-stranded DNA breaks involves a Ca^{2+}/elevation/nitric oxide/peroxynitrite/free radical (oxidative stress) pathway.

It may be asked why we have evidence for involvement of VGCCs in response to EMF exposure, but no similar evidence for involvement of voltage-gated sodium channels? Perhaps, the reason is that there are many important biological effects produced in increased intracellular Ca^{2+}, including but not limited to nitric oxide elevation, but much fewer are produced by elevated Na^{+}.

The possible role of peroxynitrite as opposed to protein kinase G in producing pathophysiological responses to EMF exposure raises the question of whether there are practical approaches to avoiding such responses? Typically peroxynitrite levels can be highly elevated when both of its precursors, nitric oxide and superoxide, are high. Consequently, agents that lower nitric oxide synthase activity and agents that raise superoxide dismutases (SODs, the enzymes that degrade superoxide) such as phenolics and other Nrf2 activators that induce SOD activity [101], as well as calcium channel blockers may be useful. Having said that, this is a complex area, where other approaches should be considered, as well.

Although the various EMF exposures as well as static electrical field exposures can act to change the electrical voltage-gradient across the plasma membrane and may, therefore, be expected to stimulate VGCCs through their voltage-gated properties, it may be surprising that static magnetic fields also act to activate VGCCs because static magnetic fields do not induce electrical changes on static objects. However, cells are far from static. Such phenomena as cell ruffling [102,103] may be relevant, where thin cytoplasmic sheets bounded on both sides by plasma membrane move rapidly. Such rapid movement of the electrically conducting cytoplasm, may be expected to influence the electrical charge across the plasma membrane, thus potentially stimulating the VGCCs.

Earlier modelling of electrical effects across plasma membranes of EMF exposures suggested that such electrical effects were likely to be too small to explain EMF effects at levels reported to produce biological changes (see, for example [22]). However, more recent and presumably more biologically plausible modelling have suggested that such electrical effects may be much more substantial [104–109] and may, therefore, act to directly stimulate VGCCs.

Direct stimulation of VGCCs by partial depolarization across the plasma membrane is suggested by the following observations discussed in this review:

1 The very rapid, almost instantaneous increase in intracellular Ca^{2+} found in some studies following EMF exposure [8, 16, 17, 19, 21, 27]. The rapidity here means that most, if not all indirect, regulatory effects can be ruled out.

2 The fact that not just L-type, but three additional classes of VGCCs are implicated in generating biological responses to EMF

Journal of Cellular and Molecular Medicine Published by Foundation for Cellular and Molecular Medicine/Blackwell Publishing Ltd

exposure (Table 1), suggesting that their voltage-gated properties may be a key feature in their ability to respond to EMFs.

3 Most, if not all, EMF effects are blocked by VGCC channel blockers (Table 1).

4 Modelling of EMF effects on living cells suggests that plasma membrane voltage changes may have key roles in such effects [104–109]. Saunders and Jefferys stated [110] that 'It is well established that electric fields … or exposure to low frequency magnetic fields, will, if of sufficient magnitude, excite nerve tissue through their interactions with … voltage gated ion channels'. They further state [110] that this is achieved by direct effects on the electric dipole voltage sensor within the ion channel.

One question that is not answered by any of the available data is whether what is known as 'dirty electricity' [111–113], generated by rapid, in many cases, square wave transients in EMF exposure, also acts by stimulating VGCCs. Such dirty electricity is inherent in any digital technology because digital technology is based on the use of such square wave transients and it may, therefore, be of special concern in this digital era, but there have been no tests of such dirty electricity that determine whether VGCCs have roles in response to such fields, to my knowledge. The nanosecond pulses, which are essentially very brief, but high-intensity dirty electricity do act, at least in part, *via* VGCC stimulation (Table 1), suggesting that dirty electricity may do likewise. Clearly, we need direct study of this question.

The only detailed alternative to the mechanism of non-thermal EMF effects discussed here, to my knowledge, is the hypothesis of Friedman *et al.* [114] and supported by Desai *et al.* [115] where the apparent initial response to EMF exposure was proposed to be NADH oxidase activation, leading to oxidative stress and downstream regulatory effects. Although they provide some correlative evidence for a possible role of NADH oxidase [114], the only causal evidence is based on a presumed specific inhibitor of NADH oxidase, diphenyleneiodonium (DPI). However, DPI has been shown to be a non-specific cation channel blocker [116], clearly showing a lack of such specificity and suggesting that it may act, in part, as a VGCC blocker. Consequently, a causal role for NADH oxidase in responses to EMF exposure must be considered to be undocumented.

In summary, the non-thermal actions of EMFs composed of low-energy photons have been a great puzzle, because such photons are insufficiently energetic to directly influence the chemistry of cells. The current review provides support for a pathway of the biological action of ultralow frequency and microwave EMFs, nanosecond pulses and static electrical or magnetic fields: EMF activation of VGCCs leads to rapid elevation of intracellular Ca^{2+}, nitric oxide and in some cases at least, peroxynitrite. Potentially therapeutic effects may be mediated through the Ca^{2+}/nitric oxide/cGMP/protein kinase G pathway. Pathophysiological effects may be mediated through the Ca^{2+}/nitric oxide/peroxynitrite pathway. Other Ca^{2+}-mediated effects may have roles as well, as suggested by Xu *et al.* [26].

United States Department of the Interior

OFFICE OF THE SECRETARY
WASHINGTON, D.C. 20240

FEB - 7 2014

In Reply Refer To: (ER 14/0001) (ER 14/0004).

Mr. Eli Veenendaal
National Telecommunications and Information
Administration
U.S. Department of Commerce
1401 Constitution Avenue, N.W.
Washington, D.C. 20230

Dear Mr. Veenendaal:

The Department of the Interior (Department) has reviewed the above referenced proposal and submits the following comments and attachment for consideration. Because the First Responder Network Authority (FirstNet) is a newly created entity, we commend the U.S. Department of Commerce for its timely proposals for NEPA implementing procedures.

The Department believes that some of the proposed procedures are not consistent with Executive Order 13186 Responsibilities of Federal Agencies to Protect Migratory Birds, which specifically requires federal agencies to develop and use principles, standards, and practices that will lessen the amount of unintentional take reasonably attributed to agency actions. The Department, through the Fish and Wildlife Service (FWS), finds that the proposals lack provisions necessary to conserve migratory bird resources, including eagles. The proposals also do not reflect current information regarding the effects of communication towers to birds. Our comments are intended to further clarify specific issues and address provisions in the proposals.

The Department recommends revisions to the proposed procedures to better reflect the impacts to resources under our jurisdiction from communication towers. The placement and operation of communication towers, including un-guyed, unlit, monopole or lattice-designed structures, impact protected migratory birds in two significant ways. The first is by injury, crippling loss, and death from collisions with towers and their supporting guy-wire infrastructure, where present. The second significant issue associated with communication towers involves impacts from non-ionizing electromagnetic radiation emitted by them (See Attachment).

In addition to the 147 Birds of Conservation Concern (BCC) species, the FWS has listed an additional 92 species as endangered or threatened under the Endangered Species Act. Together with the bald and golden eagle, this represents 241 species of birds whose populations are in trouble or otherwise merit special protection, according to the varying criteria of these lists. The Department suggests that FirstNet consider preparing a programmatic environmental impact statement (see attachment) to determine and address cumulative impacts from authorizing FirstNet projects on those 241 species for which the incremental impact of tower mortality, when

added to other past, present, and reasonably foreseeable future actions, is most likely significant, given their overall imperiled status. Notwithstanding the proposed implementing procedures, a programmatic NEPA document might be the most effective and efficient method for establishing best management practices for individual projects, reducing the burden to individual applicants, and addressing cumulative impacts.

Categorical Exclusions
The Department has identified 13 of the proposed categorical exclusions (A-6, A-7, A-8, A-9, A-10, A-11, A-12, A-13, A-14 A-15, A-16, A-17, and A-19) as having the potential to significantly affect wildlife and the biological environment. Given this potential, we want to underscore the importance of our comments on FirstNet's procedural guidance under Environmental Review and Consultation Requirements for NEPA Reviews and its list of extraordinary circumstances in Appendix D.

Environmental Review and Consultation Requirements for NEPA Reviews
To ensure there are no potentially significant impacts on birds from projects that may otherwise be categorically excluded, the Department recommends including the Migratory Bird Treaty Act and the Bald and Golden Eagle Protection Act to the list of requirements in this section.

Extraordinary Circumstances
To avoid potentially significant impacts on birds from projects that may otherwise be categorically excluded, the Department recommends including species covered under the Migratory Bird Treaty Act and the Bald and Golden Eagle Protection Act to the list of environmentally sensitive resources. Additionally, adding important resources to migratory birds such as sites in the Western Hemisphere Shorebird Reserve Network and Audubon Important Bird Areas to the paragraph on areas having special designation or recognition would help ensure their consideration when contemplating use of a categorical exclusion.

Developing the Purpose and Need
The Department recommends inclusion of language that would ensure consideration of all other authorities to which NEPA is supplemental as opposed to simply the FirstNet mission. As currently written, the procedures are limited to ensuring the purpose and need considers the FirstNet mission. If strictly applied, this approach would severely limit the range of reasonable alternatives, and likely preclude consideration of more environmentally benign locations or construction practices.

Environmental Review Process, Apply NEPA Early in the Process, Where Action is by Non-Federal Entity
The Department recommends that FirstNet be required to coordinate with federal agencies having jurisdiction by law or special expertise on construction and lighting of its network of towers.

Thank you for the opportunity to comment on the draft document. If you have any questions concerning the comments, please contact Diana Whittington, NEPA Migratory Bird lead, at (703) 358-2010. If you have any questions regarding Departmental NEPA procedures, contact Lisa Treichel, Office of Environmental Policy and Compliance at (202) 208-7116.

Sincerely,

Willie R. Taylor
Director, Office of Environmental Policy
and Compliance

Enclosure A

Background

The placement and operation of communication towers, including un-guyed, unlit, monopole or lattice-designed structures, impact protected migratory birds in two significant ways.

The first is by injury, crippling loss, and death from collisions with towers and their supporting guy-wire infrastructure, where present. Mass mortality events tend to occur during periods of peak spring and fall songbird bird migration when inclement weather events coincide with migration, and frequently where lights (either on the towers and/or on adjacent outbuildings) are also present. This situation has been well documented in the U.S. since 1948 in the published literature (Aronoff 1949, see Manville 2007a for a critique). The tallest communication towers tend to be the most problematic (Gehring *et al.* 2011). However, mid-range (~400-ft) towers as proposed by the First Responder Network Authority (FirstNet, a newly created entity under the Department of Commerce) can also significantly impact protected migratory birds, as can un-guyed and unlit lattice and monopole towers (Gehring *et al.* 2009, Manville 2007a, 2009, 2013a). Mass mortalities (more than several hundred birds per night) at unguyed, unlit monopole and lattice towers were documented in fall 2005 and 2011 in the Northeast and North Central U.S. (*e.g.*, Manville 2007a). It has been argued that communication towers including "short" towers do not impact migratory birds, including at the population level (*e.g.*, Arnold and Zink 2011), but recent findings have contradicted that assertion (Manville 2007a, 2013a, Longcore *et al.* 2012, 2013).

The second significant issue associated with communication towers involves impacts from non-ionizing electromagnetic radiation emitted by these structures. Radiation studies at cellular communication towers were begun circa 2000 in Europe and continue today on wild nesting birds. Study results have documented nest and site abandonment, plumage deterioration, locomotion problems, reduced survivorship, and death (*e.g.*, Balmori 2005, Balmori and Hallberg 2007, and Everaert and Bauwens 2007). Nesting migratory birds and their offspring have apparently been affected by the radiation from cellular phone towers in the 900 and 1800 MHz frequency ranges – 915 MHz is the standard cellular phone frequency used in the United States. However, the electromagnetic radiation standards used by the Federal Communications Commission (FCC) continue to be based on thermal heating, a criterion now nearly 30 years out of date and inapplicable today. This is primarily due to the lower levels of radiation output from microwave-powered communication devices such as cellular telephones and other sources of point-to-point communications; levels typically lower than from microwave ovens. The problem, however, appears to focus on very low levels of non-ionizing electromagnetic radiation. For example, in laboratory studies, T. Litovitz (personal communication) and DiCarlo *et al.* (2002) raised concerns about impacts of low-level, non-thermal electromagnetic radiation from the standard 915 MHz cell phone frequency on domestic chicken embryos – with some lethal results (Manville 2009, 2013a). Radiation at extremely low levels (0.0001 the level emitted by the average digital cellular telephone) caused heart attacks and the deaths of some chicken embryos subjected to hypoxic conditions in the laboratory while controls subjected to hypoxia were unaffected (DiCarlo *et al.* 2002). To date, no independent, third-party field studies have been conducted in North America on impacts of tower electromagnetic radiation on migratory birds. With the European field and U.S. laboratory evidence already available,

independent, third-party peer-reviewed studies need to be conducted in the U.S. to begin examing the effects from radiation on migratory birds and other trust species.

Discussion

Collision Deaths and Categorical Exclusions

Attempts to estimate bird-collision mortality at communication towers in the U.S. resulted in figures of 4-5 million bird deaths per year (Manville 2005, 2009). A meta-review of the published literature now suggests, based on statistically determined parameters, that mortality may be 6.8 million birds per year in Canada and the U.S.; the vast majority in the United States (Longcore *et al.* 2012). Up to 350 species of birds have been killed at communication towers (Manville 2007a, 2009). The Service's Division of Migratory Bird Management has updated its voluntary, 2000 communication tower guidelines to reflect some of the more recent research findings (Manville 2013b). However, the level of estimated mortality alone suggests at a minimum that FirstNet prepare an environmental assessment to estimate and assess the cumulative effects of tower mortality to protected migratory birds.

A second meta-review of the published mortality data from scientific studies conducted in the U.S. and Canada (Longcore *et al.* 2013) strongly correlates population effects to at least 13 species of Birds of Conservation Concern (BCC, USFWS 2008). These are mortalities to BCC species based solely on documented collisions with communication towers in the U.S. and Canada, ranging from estimated annual levels of mortality of 1 to 9% of their estimated total population. Among these where mortality at communication towers was estimated at over 2% annually are the Yellow Rail, Swainson's Warbler, Pied-billed Grebe, Bay-breasted Warbler, Golden-winged Warbler, Prairie Warbler, and Ovenbird. Longcore *et al.* (2013) emphasized that avian mortality associated with anthropogenic sources is almost always reported in the aggregate, *i.e.*, "number of birds killed," which cannot detect species-level effects necessary to make effective and meaningful conservation assessments, including determining cumulative effects. These new findings strongly suggest the need for at least an environmental assessment by FirstNet, or more likely, an environmental impact statement.

Radiation Impacts and Categorical Exclusions

There is a growing level of anecdotal evidence linking effects of non-thermal, non-ionizing electromagnetic radiation from communication towers on nesting and roosting wild birds and other wildlife in the U.S. Independent, third-party studies have yet to be conducted in the U.S. or Canada, although a peer-reviewed research protocol developed for the U.S. Forest Service by the Service's Division of Migratory Bird Management is available to study both collision and radiation impacts (Manville 2002).

As previously mentioned, Balmori (2005) found strong negative correlations between levels of tower-emitted microwave radiation and bird breeding, nesting, and roosting in the vicinity of electromagnetic fields in Spain. He documented nest and site abandonment, plumage deterioration, locomotion problems, reduced survivorship, and death in House Sparrows, White Storks, Rock Doves, Magpies, Collared Doves, and other species. Though these species had historically been documented to roost and nest in these areas, Balmori (2005) did not observe these symptoms prior to construction and operation of the cellular phone towers. Balmori and Hallberg (2007) and Everaert and Bauwens (2007) found similar strong negative correlations

among male House Sparrows. Under laboratory conditions, DiCarlo *et al.* (2002) raised troubling concerns about impacts of low-level, non-thermal electromagnetic radiation from the standard 915 MHz cell phone frequency on domestic chicken embryos – with some lethal results (Manville 2009). Given the findings of the studies mentioned above, field studies should be conducted in North America to validate potential impacts of communication tower radiation – both direct and indirect – to migratory birds and other trust wildlife species.

ABSTRACT

The response of cells to different types of electromagnetic fields can be induced by low-level (athermal) high frequency (HF) electromagnetic fields (EMFs) exposure associated with mobile phone technologies. There are many examples of biological effects involving the epigenome. EMFs could trigger protein activation mediated by ligands, such as Ca^{2+}, that alter the conformation of binding proteins, especially the NADPH plasmic membrane oxidase, so inducing increased formation of reactive oxygen species (ROS) that may alter proteomic functions. Classical anti-apoptotic and procarcinogenic signaling pathways that are commonly found activated in human malignancies and in inflammation mainly involve the transcription factor NF-κB. The microenvironment that exists during chronic inflammation can contribute to cancer progression. The data support the proposition that long term HF-EMF exposure associated with improper use of cell phones can potentially cause cancer.

Keywords: Cell Membrane; Chronic Inflammation; EMF Exposure; Gene Expression; Cancer; Carcinogenesis; NF-κB

1. INTRODUCTION

Global system for mobile communication (GSM), which being used in most of the countries, has a frequency of either 900 or 1800 MHz. This low-energy (non-thermal) radiation is emitted not only by cell phones themselves, but also by the base stations. There are many examples of biological effects resulting from low-level (athermal) EMF exposure [1-4].

The environment is a well-established source of damaging or disrupting influences on cellular function. In the past, studies of the mechanisms by which such disruptions occur have focused largely on either direct toxic effects on cellular function at the protein or cell signaling level, or mutagenic effects that impact the genome [4]. In recent years there has been a growing appreciation for the potential for environmental influences to disrupt the epigenome and mechanisms of epigenetic regulation within the cell. Indeed, because of the inherent lability of the epigenome, this represents a primary target for environmentally induced disruption [5].

Chronic inflammation has long been associated with the development of cancer [6-8]. Although inflammation is part of the defense response, paradoxically it can lead to important health disorders. Since it was discovered in the 19th century, chronic inflammation has been proven to be involved both at the initiation/promotion and progression phases of carcinogenesis [9]. This is mainly due to the fact that inflammatory response is followed by a proliferative cellular effect in tissus (basal cell hyperplasia, papillary elongation) [10].

An office workers cohort with high EMF exposure showed a cancer increase, with a high risk of malignant melanoma. School teachers exposed to a type of Radio-frequency radiation (RFR) had increased incidence of malignant melanoma and thyroid cancer [11]. Pooling of data from Nordic countries and part of the UK yielded a significantly increased risk of glioma and a significantly increased risk of acoustic neurinoma related to use of mobile phones for a period of 10 years or more on the side of the head where the tumour developed [12,13]. In an Israeli study, where study subjects tended to report

*Corresponding author.

substantially heavier use of mobile phones, results suggest a possible relation between heavy mobile phone use and risk of parotid gland tumours [14]. Several reports have indicated that EMFs enhance free radical activity in cells particularly via the Fenton reaction [15,16].

2. CELL RESPONSES

Duckweed growth and peroxidase activity was evaluated after exposure in a Gigahertz Transversal Electromagnetic (GTEM) cell to electromagnetic fields of frequencies 400, 900, and 1900 MHz. Growth of plants exposed for 2 h to 23 V/m electric field of 900 MHz significantly decreased in comparison with the control, while an electric field of the same strength but at 400 MHz did not have such effect. At both frequencies a longer exposure mostly decreased the growth and the highest electric field (390 V/m) strongly inhibited the growth. Exposure of plants to lower field strength (10 V/m) for 14 h caused significant decrease at 400 and 1900 MHz while 900 MHz did not influence the growth. Peroxidase activity in exposed plants varied, depending on the exposure characteristics. Observed changes were mostly small, except in plants exposed for 2 h to 41 V/m at 900 MHz where a significant increase (41%) was found. Therefore, the effects of EMFs strongly depended on the characteristics of the field exposure [17].

Exposure of tomato plants to non-thermal high frequency electromagnetic field (HF-EMF, 900 MHz, 5 $V \cdot m^{-1}$) for 10 min led to show a direct relationship between HF-EMF exposure and responses at the level of gene expression [1]. There was no direct link between the amplitude of the stimulation and the amplitude of the plant response, which suggested the concept of an "all-or-nothing" response with a threshold of induction [18]. The energy used in the electromagnetic exposure (900 MHz, 5 $V \cdot m^{-1}$, 10 min) was very low (close to 0.1 W dissipated in 200 m^3) and did not produce any thermal effect [1,18]. The genesis and/or transmission of the informative signal were rapid and strongly dependent upon calcium. Expression of Hsp70 [19], and tumor suppressor p53 [20] are also affected by microwave irradiation.

Electromagnetic irradiation emitted from mobile phones (frequency 900 MHz) induces expression of proteins in various cells [21-23]. The specific absorption rate (SAR) level to which cells were exposed was 2.8 W/kg. The effects observed were not caused by bulk heating of the cells [22]. Among the proteins whose expression is induced by mobile phone irradiation are transcription factors [21]. The proteomes of the same cell type (endothelium) but derived from different vascular beds (umbilical vein and brain microvasculature) differ widely in their expression. The effect is frequency-dependent. When cells were exposed for 1 h at an average SAR of 2.0 W/kg and examined immediately thereafter, 1800 MHz GSM radiation exposure had only very limited effect on the proteome of human endothelial cell line EA.hy926, as compared with the effect of 900 MHz GSM radiation [24]. Mobile phone radiation might alter protein expression in human skin, with a SAR of 1.3 W/kg induced in the skin, below the ICNIRP (International Commission on Non-Ionizing Radiation Protection) safety guidelines (2.0 W/kg), for one hour [25].

Paulraj and Behari [26] indicated DNA single strand break and decrease in level of protein kinase at 2.45 GHz [27]. More recently, Kesari and Behari [28] reported that microwave (2.45 GHz) exposure cause infertility by decreasing sperm count and an increase in apoptosis.

Tkalec *et al*. [29] showed that non-thermal exposure to the radiofrequency fields can induce mitotic aberrations in root meristematic cells of *A. cepa*. The observed effects were markedly dependent on the field frequencies (400 and 900 MHz) applied as well as on field strength and modulation. They also indicate that mitotic effects of RF-EMF could be due to impairment of the mitotic spindle.

Microwave (MW) exposure at the water resonance frequency, *i.e*. exposure to radiofrequencies between about 1 GHz and 300 GHz, was able to induce alteration of the mitotic apparatus and apoptosis as a function of the applied power densities (5 and 10 mW/cm^2), together with a moderate reduction in the rate of cell division. After an exposure time of 15 min the proportion of aberrant spindles and of apoptotic cells was significantly increased, while the mitotic index decreased as well, as compared to the untreated V79 cells. Ballardin *et al*. [30] hypothesised that short-time MW exposures at the water resonance frequency cause, in V79 cells, reversible alterations of the mitotic spindle, this representing, in turn, a pro-apoptotic signal for the cell line.

Another mechanism that could be involved in the formation of aberrant spindles concerns the polar protein structures**.** Microtubule fibers represent extremely dynamic structure which functioning depends on dynamical instability that is continuously binding and releasing of free tubule proteins. One can reasonably assume that the external EM radiation might interact with polar cytoskeletal structure. This structure greatly contributes to the balance between internal physiological electrostatic forces. Depending on the dipole moment, an external electric field could theoretically disturb the equilibrium [31] and increase the number of free cytoplasmatic tubulin proteins following a mechanism of depolarization of tubulins involved in the formation of the mitotic apparatus. Recently, it has been shown that electromagnetic field (90 V/m at 835 MHz) exposure can induce significant increases of mitotic disturbances in human-hamster hybrid cells [32].

3. EMF-TARGET MOLECULE INTERACTIONS

Energy transfer of Microwaves (MW) is conducted through two mechanisms, dipole rotation and ionic conduction [33]. Blank and Soo [34] examined the EMF effects on electron transfer and concluded that EMF accelerate all linked redox reactions. Blank [35] considered examples of direct effects of electric and magnetic fields on charge transfer in biological systems, and reported the structural changes driven by such effects. He concluded that conformational changes arising from alterations in charge distribution play a key role in membrane transport proteins, including ion channels. Thus, weak EMFs can control and amplify biological processes through their effects on charge distribution [3].

EMFs could interact with moving charges or charged species [36] which are implicated in various biological processes. Moreover, HF-EMF may lead to ion movement, directly or indirectly, and particularly near the plasma membrane [37] and this could initiate the biological response. Ligands, such as Ca^{2+}, alter the conformation of proteins and hence control their receptor function. EMF exposure produces changes in binding probability of the ligand. Occupation of one protein site by a ligand changes its conformation. This suggests that EMF could trigger a transition from a random array to an ordered array of phase transition in proteins [38]. Calcium has been well recognised as a signaling factor involved in the regulation of a wide range of cellular processes involving cell proliferation.

Panagopoulos *et al*. [39] have suggested that oscillating ions during forced vibration will also exert mechanical force-pressure on the plasma membrane able to upset the membrane electrochemical balance, under certain conditions, by opening or closing mechanically gated channel proteins, like some Ca influx channels. The irregular gating of ion channels caused by the forced vibration of the free ions, induced by external oscillating EMFs, is a fact that could upset the electrochemical balance of the plasma membrane and, consequently, the whole cell function.

4. TRANSDUCTION SIGNALS AND ONCOGENE EXPRESSION

Currently, cancer is recognized as a disease associated with both genetic and epigenetic alterations, and both of these components cooperate and complement each other to initiate and promote cancer development and progression [40]. The carcinogenic process can be associated to a modification of gene expression regulation; the modification of the signal cascade into the cell can induce the dysregulation of transcription factor activities (overexpression, activation, uninhibition…) through the activation of specific cellular messengers. Free radicals play an essential role in the activation of certain signaling pathways [6]. The effects of reactive oxygen species (ROS) on cell proliferation occurred exclusively at low or transient concentrations of radicals that can stimulate proliferation and enhanced survival in a wide variety of cell types [41]. ROS can play a very important physiological role as secondary messengers. This includes regulation of the cytosolic calcium concentration, which itself regulates biological activities, regulation of protein phosphorylation and activation of certain transcription factors such as Nuclear Factor NF-κB and the AP-1 family factors [41-43].

In general, the balance between the production and scavenging of ROS leads to homeostasis. Disturbance of this equilibrium can alter normal cellular processes; it often occurs in tumour cells [44]. The cumulative production of ROS through either endogenous or exogenous insults is termed oxidative stress and is common for many types of cancer with altered redox regulation of cellular signaling pathways [45]. A sustained oxidative stress has been associated with several steps of carcinogenesis, including malignant transformation and achievement of a metastatic phenotype [46]. Thornber *et al.* [47] have shown that, in large cell lymphoma the nucleophosmin-anaplastic lymphoma kinase (NPM-ALK) induces the production of reactive oxygen species (ROS) by a pathway involving the arachidonic acid-metabolizing enzymes of the lipoxygenase (LOX) family. The NPM-ALK chimeric gene encodes a constitutively activated tyrosine kinase that has been shown to be a potent oncogene.

Several MAPkinases, signal transducers and activators of transcription, Akt/protein kinase B and phospholipase D-signaling pathways are all activated by ROS [48,49] but in some cases, activation is indirect [50].

Cadmium (Cd) is a toxic metal causing nephrotoxicity, immunotoxicity, osteotoxicity and tumors after prolonged exposure. Cd-generated ROS are often accompagnied by activation of redox sensitive transcription factors, such as NF-κB, and alteration of ROS-related gene expression. Acquired Cd tolerance with aberrant gene expression plays important roles in chronic Cd toxicity and carcinogenesis [51]. Chronic inflammation induced by biological, chemical and physical agents, is associated with increased risk of tumors development in various organs and tissues. Association of cancer with chronic inflammation has been described, in particular, in pathological processes in organs of the digestive system, where the risk of carcinogenesis increases as much as chronic inflammation occurs (esophagitis, gastritis, hepatitis etc.). Mediators of inflammation, which contribute to the process of malignant transformation, affect many aspects of cancer cell behavior, including pro-

liferation, differentiation and apoptosis. Inflammation contributes to initiation and promotion, *i.e*. to malignant transformation of normal cells and to tumor progression due to production of both proinflammatory cytokines and various forms of reactive oxygen and nitrogen species. Significant activation of NF-κB can stimulate malignant transformation and progression, providing antiapoptotic and proliferative signals.

Developmental signaling pathways that regulate normal stem cell self-renewal have been shown to be active in numerous human cancers [52]. Inflammatory breast cancer (IBC) is an uncommon disease accounting for 1% - 5% of all breast cancers [53,54]. Experimental evidence now solidly validates the HER2 oncogene hypothesis and etiologically links amplification of the HER2 gene locus with human cancer pathogenesis [55]. HER2 protein overproduction is not only seen in breast cancer but also uncommonly in cancers of the esophagus, stomach, ovaries and endometrium. Mutations in the HER2 gene are found rarely in these cancers but overexpression appears to be the principal mechanism by which HER2 mediates tumorigenesis in these cancers [56].

5. SIGNAL TRANSDUCTION AND EMF SIGNALING PATHWAYS

Mitogen-activated-phospho-kinase (MAPK) family pathway control cell proliferation, metabolism and cell survival in response to tissue injury, infection, malignancy and other diseases. Activation of the MAPK cascades leads to phosphorylation of transcription factors that bind to the upstream regulatory elements on the gene promoter, relative to the transcription initiation site. Three out of four MAPK cascades are differentially activated by Extremely Low Frequency (ELF EMF) (ELF-EMF) [57].

The signaling pathways and stress responses are activated by EMF. Friedman *et al.* [58] have shown that the initial step in transmitting extracellular EMF information from the plasma membrane to the nucleus of the cell occurs when NADH oxidase rapidly generates ROS. These ROS stimulate matrix metalloproteinases, and then activate the extracellular signal regulated kinase (ERK-1/2) cascade. These changes in activity of the protein kinases pathways can consequently regulate the physiological response of the exposed cells and organisms, and therefore are major regulators of the effects of electromagnetic fields at mobile phone frequencies.

Data indicate that, prior to the stress responses, mobile phone irradiation induces an immediate intracytoplasmic effect which activates ERK signalling to induce further transcription of a variety of genes [59]. The fact that the stress-related cascades, which are known to be activated by heat or other related stressors, were not activated, in the time course of Friedman *et al.* [58] experiments, indicates that the activation of ERKs is induced by other mechanisms. It has been reported that within 10 min of cell phone exposure, two MAPKinase cascades, p38 and ERK1/2, are activated [60].

Both ELF and RF radiations can upregulate the HSP70 gene and induce elevated levels of the Hsp70 protein. This effect on RNA transcription and protein stability is controlled by specific protein transcription factors that are elements of the mitogen MAPK cascade. EMF can also stimulate serum response factor which binds to the serum response element (SRE) through ERK MAPK activation and is associated with injury and repair *in vivo* and *in vitro*. The SRE site is on the promoter of an early response gene, c-fos, which under specific cellular circumstances has oncogenic properties. The c-fos promoter is EMF-sensitive [61,62].

Activation of NF-κB and AP-1, the downstream of the MAPK or PI3K-Akt signaling pathways, are involved in many pathological processes, such as inflamemation, cancer cell adhesion, invasion, migration, and angiogenesis [63,64]. NF-κB and AP-1 transcription factors function as crucial regulators of inflammatory and immune responses as well as of cell survival. They have been implicated in cellular transformation and tumorigenesis. The NF-κB pathway is required for the development of tumours in a mouse model of lung adenocarcinoma [65]. Elevated P13K/PDK/Akt or NF-κB signaling (or both) have been correlated with advanced tumor progression and poor prognosis in patients with breast cancer [66,67].

NF-κB is maintained in the cytoplasm through interactions with an inhibitor of NF-κB (IκB), but upon dissociation, it moves into the nucleus and promotes cancer cells proliferation, angiogenesis, and metastasis. Carcinogens and tumour promoters involving toxic metals, UV radiation, phobol esters, asbestos, alcohol and benzo (α) pyrene are among the external stimuli that activate NF-κB [68]. Hepatitis B viral proteins (HBx) have oncogenic properties by activation of different promoter elements and then trigger activation of transcription factors such as AP-1 and NF-κB [45,69].

In fact NF-κB is a transcriptional factor that regulates a battery of genes that are critical to innate and adaptive immunity, cell proliferation, inflammation, and tumor development [70]. Increasing evidence suggests that the physiological NF-κB-associated pathways are dysregulated in numerous malignancies [66,71-74]. The activation of NF-κB-dependent anti-apoptotic genes may promote IBC tumorigenesis and, other inflammation-associated tumor types [75]. The NF-κB pathway appears to play a major role in IBC, possibly contributing to the unusual phenotype and aggressiveness of this form of breast cancer [76]. DNA microarrays studies of

IBC have shown abnormal expression of several NF-κB target genes [77,78]. Activated NF-κB translocates to the nucleus and binds to the DNA to initiate expression of genes that enhances cell proliferation and survival [67, 73,79].

Indeed, activation of the transcription factor NF-κB, one of the most investigated nuclear transcription factors, has been found to control multiple cellular processes in cancer including inflammation, transformation, proliferation, angiogenesis, invasion, metastasis, chemoresistance and radioresistance. NF-κB is constitutively active in most cancer cells, and its suppression inhibits the growth of tumor cells, leading to the concept of "NF-κB addiction" in cancer cells. As NF-κB is the key transcription factor involved in inflammation, and inflammation is frequently associated with cancers, many of the signaling pathways implicated in cancer are likely to be networked to the activation of NF-κB. NF-κB interacts with many transcription factors and transcriptional regulators [80].

Chronic inflammation has been associated with the development of cancer. Molecular biology studies have shown that there are genes, which when "activated" (oncogenes) or "inactivated" (tumour suppressor genes) contribute to the clonal expansion of an initiated stem cell. Cancer would thus be a disease of homeostasis [45]. Any exposure, including prolonged low-intensity ELF and RF exposures that result in increased free radical production may be considered a plausible biological mechanism for carcinogenesis [6].

6. CONCLUSIONS: HYPOTHETIC MODELISATION

Oncogenesis is suggested to be mediated by a sustained and not a transient ERK activation [58] that could be an explanation for the possible increased cancer risk that may be associated with base station antenna. RF field studies have shown that RFF exposure is followed by the stimulation of cell proliferation and activation of stress proteins [57]. In the present overview, production of ROS by mobile phone irradiation, a process that has already been evidenced in previous studies [81,82], is suggested to be induced by the activation of NADH oxidase, which appears to be an early target of mobile phone irradiation. These events appear to occur within seconds and could initiate subsequent activation of pathways that lead to phosphorylation of ERKs. Several components of the proposed model (**Figure 1**) have been implicated in activation of the ERK cascade in different cellular systems.

Microwave effects have been always mainly observed in stem cells. This result suggests both significant misbalance in double strand break (DSB) repair and severe

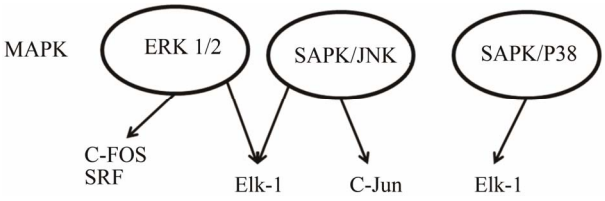

Figure 1. The mitogen activated protein kinase (MAPK) signaling cascades identified to date are: extracellular signal regulated kinase 1/2 (ERK), c-Junterminal kinase (JNK), p38-MAPK and stress activated protein kinase (SAPK). Elements of the three MAPkinase pathways that have been identified as activated by EMF are shown in the shaded circles, according to Weisbrot *et al*. [57].

stress responses. Findings that stem cells are most sensitive to microwave exposure and react more strongly to EMF than do differentiated cells may be important for cancer risk assessment and indicate that stem cells are the most relevant model for studying mobile-induced intracellular communication signals [83].

Brain cell cultures of mice were exposed to 10.715 GHz with specific absorbtion rate (SAR) of 0.725 W/kg signals for 6 h in 3 days at 25˚C to access the changes in the micronucleus (MNi) assay and in the expression of 11 proapoptotic and antiapoptotic genes. It was found that MNi rate increased 11-fold and STAT3 expression decreased 7-fold in the cell cultures exposed to RF. Cell phones which spread RF may damage DNA and change gene expression in brain cells. The data support the proposition that cell phones may have a potential to cause hazardous effects on the genome; however, in *in vivo* conditions, the duration of exposure and the capacity of DNA repair may prevent the development of cancer [84].

An interesting question raised in studies is what could be the early molecular target of mobile phone irradiation. Results of Friedman *et al*. [58] indicated that the early target could be NADH oxidase, which is localized in the plasma membrane and converts EMF irradiation into ROS.

However, the earliest target receptor of HF-EMF could be calcium ions stored on the external surface of cell membrane. The proposed HF-EMF induction pathway is resumed in **Figures 2** and **3**. Near the plasma membrane, EMFs could induce Ca^{++} ion movement, directly or indirectly, and activate NAD(P)H oxydase, a calcium-dependent enzyme. Its activity leads to the production of superoxide ion and hydrogene peroxide. Alternatively, the production of ROS would also activate several calcium channels, then enhancing the calcium ion concentration that is required for signal transduction. ROS can function as cellular second messengers that are likely to modulate the action of many different proteins, so leading to a variety of responses. The nuclear trans-

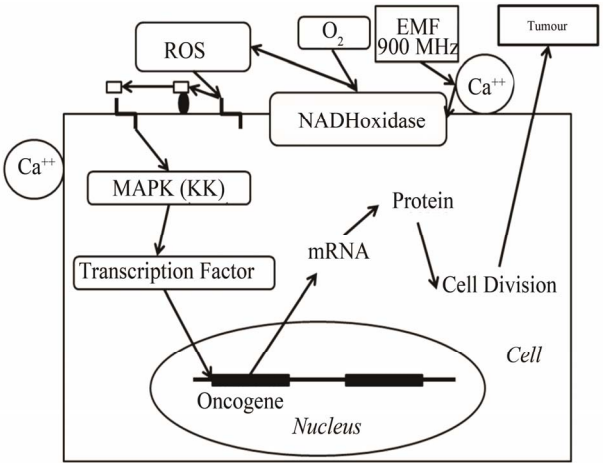

Figure 2. Cell survival after EMF stimuli. Schematic representation of proposed mechanism that mediates the phosphorylation of transcription factors upon mobile phone irradiation. EMFs (900 MHz) could shift calcium ions that trigger changes in the nearby enzyme NAD(P)H oxidase. The enzyme generates ROS that can induce membrane proteins which in formation of the signal message. Signal transduction could activate calciproteins, then MAP kinases and transcription factors that would activate oncogene expression. In turn, EMFs (900 MHz) could activate calcium channels that would allow the induction of the cell transduction signal cascade.

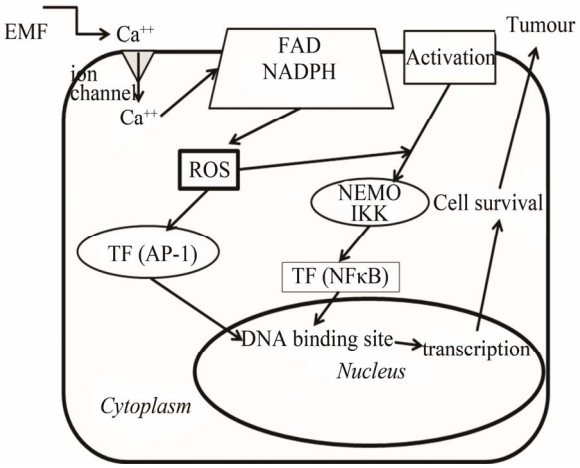

Figure 3. Cell transduction signal after EMF stimuli. Following targeting various agents (activation) on cell membrane, IκB proteins are phosphorylated by a protein kinase complex (IKK) and a regulation element (NEMO), then IκB is ubiquitinated. Proteasomal degradation is proceeded allowing the translocation of the NF-κB complexes in the nucleus where they bind to the gene promoters which are invoved in cell response [91]. EMF can activate a cell membrane calcium channel which allows triggering of membrane NADPH oxidase. The latter enzyme is part of a mechanism producing reactive oxygen species (ROS) that can activate transcription factors (TF) such as AP-1 and/or NF-κB. Oxidizing stimuli in the cytosol lead to post-translational transcription factor modification that facilitates translocation to the nucleus. The transcription factor can bind to the DNA site of oncogene promoters that trigger cell survival and tumour development.

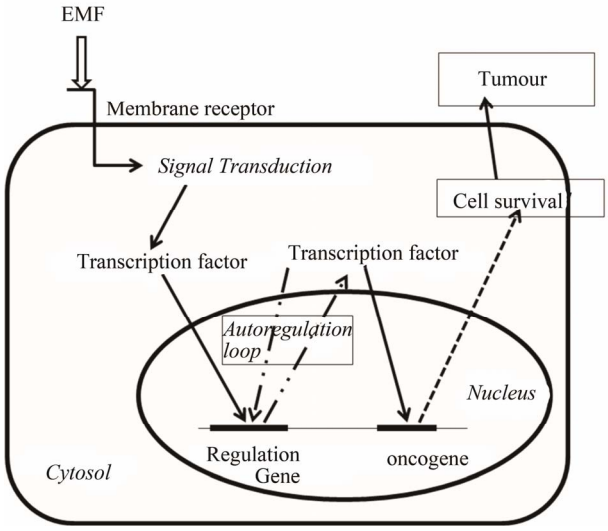

Figure 4. Cell survival homeostasis after EMF stimuli. EMF could trigger cell signal transduction through membrane receptor. Activated transcription factors would allow the expression of genes involved in cell survival together with transcription factor genes resulting in permanent cell survival and tumour development.

cription factor, NF-κB, is maintained in the cytoplasm through interactions with its inhibitor of IκB, but upon dissociation, as previously indicated, it moves into the nucleus and promotes cancer cell proliferation, angiogenesis, and metastasis (**Figure 2**). In addition, EMF could activate ion movements thus allowing the activation of calcium channels, activating NAD(P)H oxidase and inducing signal transduction for oncogene expression (**Figure 3**). Consequently a modelling of cell survival homeostasis following EMF stimuli can be proposed (**Figure 4**). The EMF stimuli might trigger the expression of transcription factors that could develop some type of permanent loop of gene expression. Transcription factors could thus induce the permanent expression of oncogenes involved in survival and proliferation of cancer cells (**Figure 4**).

The microenvironment that is associated with chronic inflammation can contribute to cancer progression [7,85]. Macrophages are key mediators of the interaction between inflammation, immunity and cancer. The role of macrophages in cancer has recently received special attention due to the discovery of their tumor-promoting effects [86-88]. Inhibition in macrophages activity during tumorigenesis at certain check points may interfere with host-suppressive effects on metastasis formation, and suggests that timing and cell specificity may be key determinants of the impact of specific NF-κB inhibitors used as cancer therapy [89]. Tumor growth increases inflammation and recent data have indicated that in cancer, high oxidative stress can be detected [7].

Panagopoulos and Margaritis [90] showed that GSM

900 MHz radiation is slightly more bioactive than Digital Cellular System (DCS) 1800 MHz radiation, at the same exposure durations and under equivalent radiation intensities. Exposure to mobile telephony radiation may have adverse health effects and thus mobile telephony use should be restricted within more rigorous defined limits of exposure. Since radiation intensity in their experiments was 45 and 90 times lower than the current exposure limits for 900 and 1800 MHz, respectively, this suggests the need for a significant reduction of the current exposure limits.

Animal Magnetism: How the magnetic field influences animal navigation

Tricia Edgar
decodedscience.com
Sun, 30 Nov 2014 15:40 CET

The migration of the monarch butterfly seems like it's magic, but it's actually guided by the magnetic field.
Sometimes, ecology is quite visible. When an owl catches a mouse, we see that connection very clearly. When a river floods, we see how water shapes a landscape.

Ecology can also be less visible. The soil is a good example of this: There is so much life in that brown material beneath our feet, but since we live on top of it, soil life can be difficult for us to visualize.

Sometimes, ecology is invisible.

What forces guide monarch butterflies as they migrate to a place they've never seen? When animals interact with the Earth's magnetic field, these invisible influences play a big role in animals' behavior.

Many animals can sense the Earth's magnetic field

How do you navigate through your everyday life? You likely use landmarks such as street signs or buildings. If you're not relying on a device to keep time, you could use the sun's position in the sky to tell you the time of day, and unless you live near the Arctic Circle, the presence of light or dark tells you whether it's day or night.

Humans use many environmental cues to tell them when and where to move, and for a long time, scientists thought that animals relied on similar environmental cues to find their way around.

However, in 1957, a Frankfurt scientist named Hans Fromme noticed that the robins he'd placed in a cage were getting restless. It was fall, and they kept on moving to the southwest part of the cage. Why were they doing this? Yes, the robins in Germany migrate to Spain to the winter, but their behavior puzzled him: these robins were in a closed room, without the sun or the stars to guide them.

They could not tell that it was fall, and they could not use the position of the sun and the stars to tell where Spain was. He decided that they must be using the Earth's magnetic field to guide them in their attempted migration.

How animals navigate

Just as we might use street signs, a GPS, and a map to navigate our way around a city, animals use multiple means of navigation. They use environmental clues such as temperature, light levels, and the availability of food sources to trigger migration. **They use the sun, moon, and stars to help them make their way to breeding grounds.**

Some animals use landmarks to show where they should go, while others such as salmon use the smell of a particular river to guide them home. While they usually use it together with other navigational methods, animals also use the earth's magnetic field as their compass.

© Gracey.

What's behind the amazing navigational abilities of birds? While they use the sun and the stars to navigate, birds also use the Earth's magnetic field.
How does the magnetic field influence animal behavior?

Since Fromme's time, many experiments on animal behavior have determined that organisms as diverse as bacteria and hamsters can detect the intensity of the Earth's magnetic field and the angle at which it intersects with the Earth.

The most visible interaction between animals and the magnetic field comes every year as animals migrate from cold to warm climates and back again. To navigation-challenged humans, animal migration can seem almost magical.

How do animals like salmon, leatherback turtles, butterflies, and hummingbirds manage to migrate thousands of miles? It turns out that it's not magic at all: **it's an invisible ecological**

interaction.

An inner compass is very important to migrating animals, particularly on days when it's overcast and hard to navigate using the sun or the stars.

In a 2014 study of monarch butterflies, researchers from the University of Massachusetts Medical School discovered that migrating monarchs orient themselves to the south - even in the absence of cues from the sun. This means that even when it's overcast, butterflies can continue moving southward to their winter home.

An alignment with the magnetic field can also help organisms move within their immediate environment. According to Kirschvink and Diaz-Ricci's work published in the *Bioeletromagnetics Supplement*, magnetotactic bacteria align with the Earth's magnetic field to seek out the area between mud and water in their aquatic environments. This is the best place for the bacteria to live.

Animal magnetoception: Where is this built-In compass?

When humans use a compass, it's visible in our hands. If animals have a compass, where is it? For a long time, studies of animal behavior showed animals aligning themselves with the earth's magnetic field, but no one knew exactly how they managed to figure it out. However, **research has discovered that many species contain small quantities of magnetite, the same material used in the ancient lodestones that humans used to guide their journeys.**

In 2012, research published in the *Proceedings of the National Academy of Sciences* discovered that rainbow trout have a good nose for figuring out directions. In their olfactory system, the trout have some cells that contain tiny quantities of magnetite. Researchers isolated these cells by looking for cells that aligned with the magnetic field and discovered that the cells contained magnetic components.

While people have not studied the magnetoreceptor anatomy of all animals that migrate, **many organisms - including humans - contain particles of magnetite within their bodies.** In the case of the magnetic bacteria, the bacteria contain magnetosomes, particles of magnetite or iron sulfide tucked into their cells.

It seems that animals that use the magnetic field to navigate may come with a built-in compass, **but there may be more than one type of compass. The bodies of animals such as birds and the fruit fly contain proteins called cryptochromes. When these proteins are exposed to blue light, they form molecules with electrons that spin in specific ways depending on the earth's magnetic field.** Researchers think that these cryptochromes could help some animals navigate.

© Muvuca.

Although it’s controversial, some scientists think that electromagnetic interference from humans could interfere with animal migration.

Human impacts on the Earth's magnetic field

Humans have an impact on so many aspects of the earth's ecology. While wrangling with the magnetic field might seem like an activity that is out of our reach, **human-induced electromagnetic noise could be a concern for migrating animals.**

In a 2014 study published in the journal *Nature*, laboratory studies on robins showed birds that were exposed to background electromagnetic noise had trouble discerning which way was south.

While other studies have not seen the same impact from everyday background noise, **it's prudent to be aware that human-induced electromagnetic disturbances could have an impact on some animals' highly-tuned sensory systems.**

Animal navigation: Migration and the Earth's magnetic field

Animal navigation has long fascinated humans. We enjoy watching the geese migrate overhead as fall approaches, but for a long time, no one knew how they managed to find their way.

While it's not completely clear how all animals navigate using the Earth's magnetic field, recent investigations of animal anatomy have drawn us closer to the answer to this perplexing question.

Cancer Trends During the 20th Century

Örjan Hallberg,[a] M.Sc. e.e., consultant and
Olle Johansson,[a] Assoc. Professor

Abstract

Purpose: To review development trends and possible relations between different cancers in Sweden and in other countries to better understand causing mechanisms.

Materials and methods: We used publicly available databases on cancer incidence and mortality to highlight trends and trend breaks. The data were used for correlation studies between different forms of cancers as reported from different counties within Sweden, and from other countries.

Results: Some cancer forms correlate to malignant melanoma while others, like leukaemia, do not relate to melanoma at all. Asthma is a disease that has a sharp trend break just as these cancers show around 1955.

Conclusions: There is a common environmental stress that accelerates several cancer forms such, as colon cancer, lung cancer, breast cancer, bladder cancer and malignant melanoma. Every effort should be taken to identify and eliminate this stress.

Introduction

There are a number of cancers that still are lacking good explanations as to their cause. The cancer report from *Socialstyrelsen* 1997[1] states that the causing mechanisms behind bladder-, breast-, colon- and prostate cancers still are unknown. Considerable doubt rests also with the popular explanation that sunburn is causing the drastic increased incidence in skin melanoma and death rates since 1955. Another problem that has not been solved is why we see such an explosive increase of asthma and allergies from about the same time.

In this paper, we will take a closer look at the statistics of all these diseases in an attempt to narrow down the range of possible causing mechanisms.

Methods

We used databases on cancer incidence and mortality for Sweden as well as for other countries to derive cancer trends over time.[1-3] We also combined results from a death-cause register and a cancer incidence register in Sweden to investigate if people who died from lung cancer or breast cancer had earlier in life suffered from skin melanoma.[4] Correlation characteristics were calculated between different cancer types, both within Sweden and between different countries.

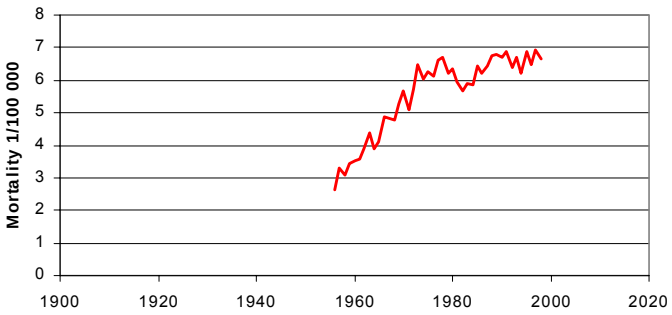

Figure 1. Mortality due to bladder cancer in Sweden since 1956.

Results

Bladder, prostate, melanoma, colon and breast cancers

Figure 1 shows the development of bladder cancer since 1955. In 1979 this disease had a reduction in the numbers dying annually, but since 1982 the rate is increasing again. Due to lack of data we can only see the development from 1955.

Figure 2 gives the drastic increase in Sweden in prostate cancer since 1951. Increasing trends can be noticed in 1955, 1970 and 1982, while a period of decreasing numbers started in 1979, just as for bladder cancer.

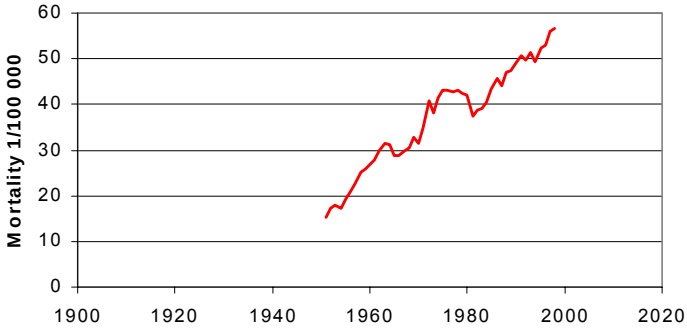

Figure 2. Development of prostate cancer death rates in Sweden since 1951.

Figure 3 shows the mortality for skin melanoma in Sweden. Data before 1955 is not published by the authorities, but was retrieved from a library.[5] The raw data shows that the 'natural' death rate increased from about 30 per year in 1912 to 50 in 1954. This gives an increase of 0.5 more victims per year. From 1955 it increased to 325 in 1996, which gives an increase by almost 7 victims per year, i.e. 14 times more than before 1955.

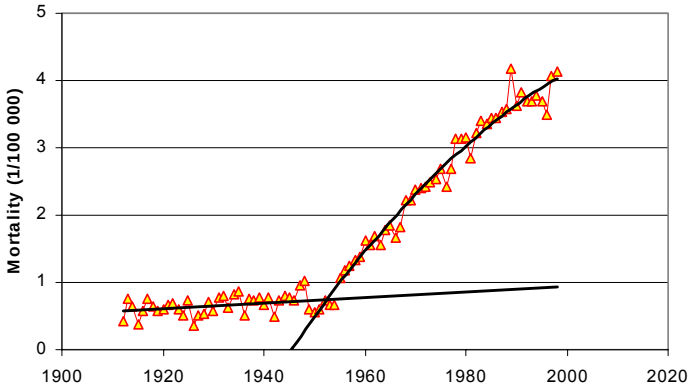

Figure 3. Skin melanoma mortality in Sweden since 1912.

Figure 4 gives the development of lung cancer death rate in Sweden.

Figure 5 gives the development of female breast cancer deaths in Sweden. Breast cancer screening started after 1975 to be gradually introduced in the country, which might explain part of the stabilisation. Better treatment in general is also altering these types of graphs. It should be noticed that breast cancer incidence has not levelled off, but continues to increase. This means that the causing mechanism behind breast cancer has not been properly addressed, but only methods of treatment and early diagnostics.

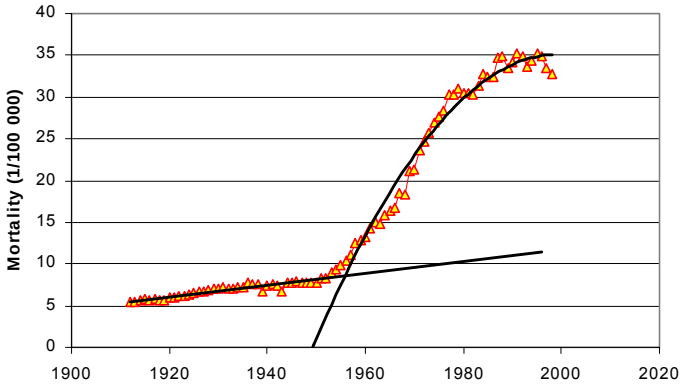

Figure 4. Lung cancer death rates in Sweden.

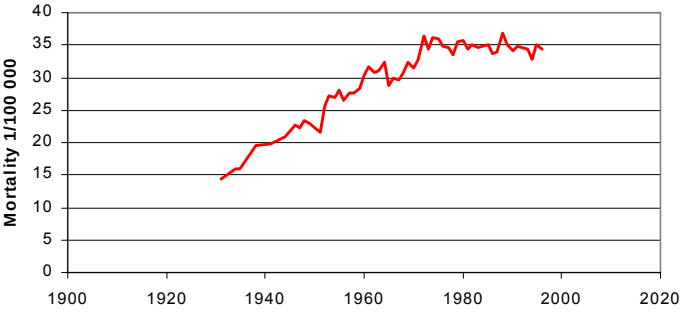

Figure 5. Development of female breast cancer mortality.

Figure 6 gives the development of colon cancer mortality since 1931. The mortality is increasing between 1920-1940 and starts to increase again around 1955 and 1969. A reduction is noticed from 1979.

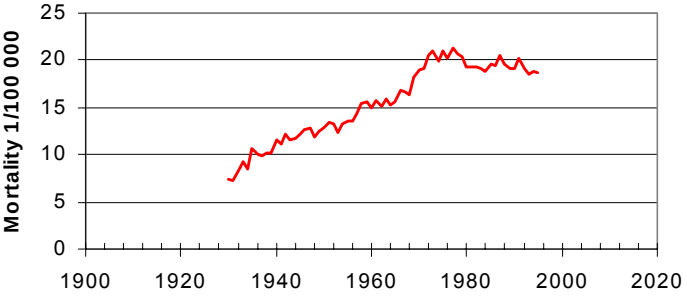

Figure 6. Mortality due to colon cancer in Sweden.

Asthma

Figure 7 shows the prevalence of asthma among 18-year-old males in Sweden.[6] The same graph also gives the percentage of 18-year-old males in Finland who were rejected at the military conscription test due to asthma.[7] These data are only available up to 1989. Before 1960 this level was essentially zero or at a very low level. Again, the graph indicates that a drastic change was made to the environmental conditions around 1960 or before 1960.

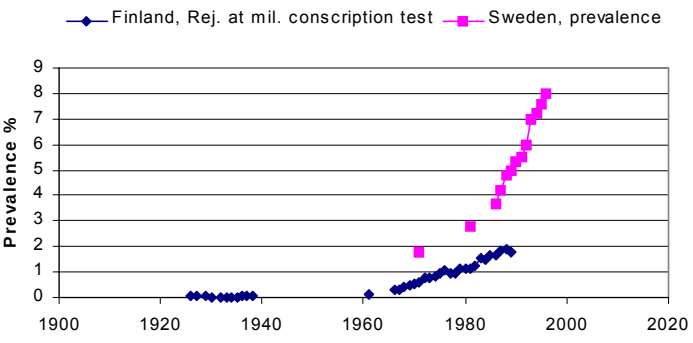

Figure 7. Asthma prevalence among Swedish 18-year-old males and the rejection rate at military conscription test due to asthma in Finland.[6,7]

Figure 8 gives the general asthma prevalence in the Swedish population according to a number of studies, summarised in ref. 8.

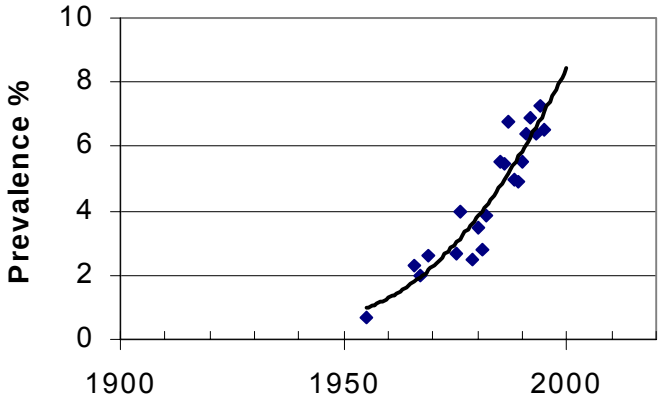

Figure 8. General asthma prevalence in the Swedish population.[8]

International cancer correlations

According to a recent study,[9] breast and prostate cancers are correlated. References 2 and 9 give the incidences from different regions in the world. People who move from low- to high-incidence countries also increase their incidence.[9] Figure 9 is a plot of prostate cancer mortality versus breast cancer mortality in a number of countries (Age standardised rates adjusted).

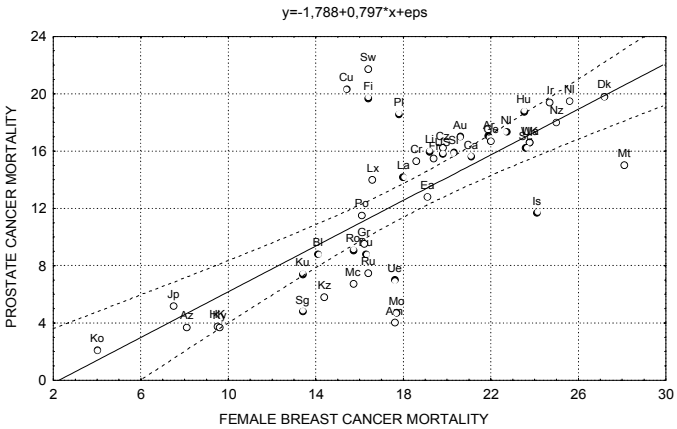

Figure 9. Breast and prostate cancer mortalities correlate. b=0.74; p<0.00001

Since we see a correlation between breast cancer and prostate cancer, it might be of interest to see if other cancers correlate. Figure 10 is a plot of melanoma and breast cancer incidences from 40 countries.[2] Here an association is also evident. Each dot is a specific country. See also Table 1.

Swedish cancer death rates

Figure 11 shows the development of different cancer death rates in Sweden, expressed as a percentage of reported rates in 1996. The graph also includes breast cancer incidence expressed in the same way. It is obvious that the graphs are quite similar, with a major trend break around 1955 and a short period of improvement around 1980. Colon cancer starts to increase already after 1920 and has a very clear reduction around 1980.

From Figure 11 it is clear that these cancer forms have a very similar development, although colon mortality seems to have been triggered already in 1920. The average development for the rest of the cancers

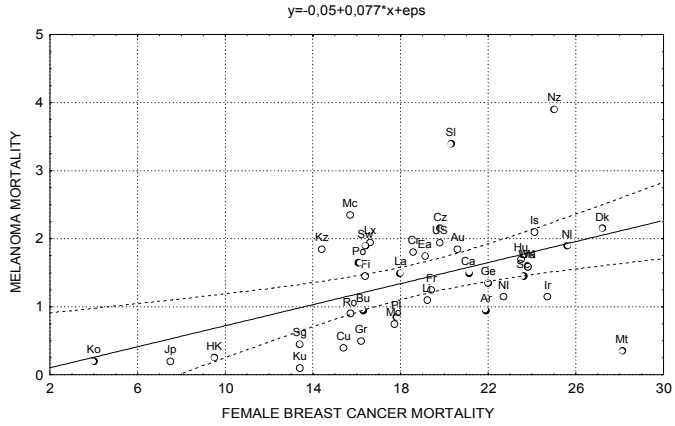

Figure 10 An association is noticed between breast cancer and skin melanoma mortality. b=0.49; p=0.00151

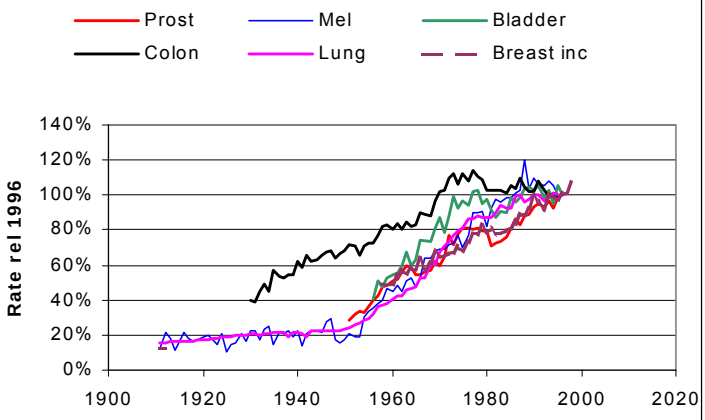

Figure 11. Cancer death rates and breast cancer incidence in Sweden expressed as a percentage of their values in 1996.

11 is given in Figure 12. In the same graph the number of persons per year who have been registered as sick for more than one year is also plotted. Again, 1979 seems to be a magic year of health improvement, while 1997 looks to be another year of disaster. It may predict that the cancer mortality for 1999 and onwards will also increase.

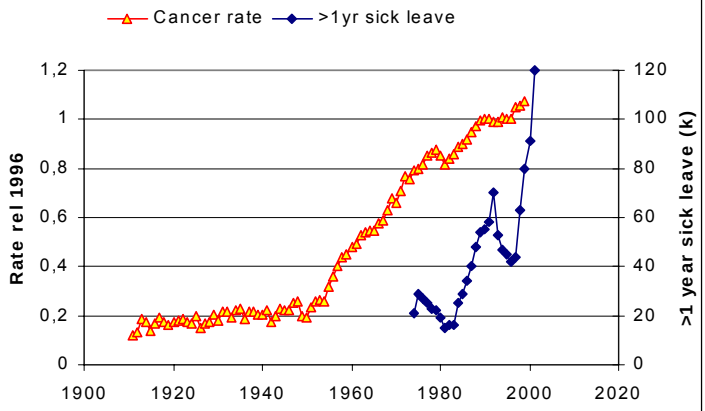

Figure 12. The average cancer rate relative to 1996 for bladder, melanoma, prostate, lung and breast cancers and the number of persons on sick leave for more than one year.

Figure 13 gives a similar graph where the 'illness factor' in Sweden has been plotted since 1955. There is obviously a clear relationship between this factor and cancer mortality.

Discussion

The authorities never publish the drastically increasing cancer mortality as shown in figures 11-13. First of all, data before 1955 has always been locked out from publicly available databases. Secondly,

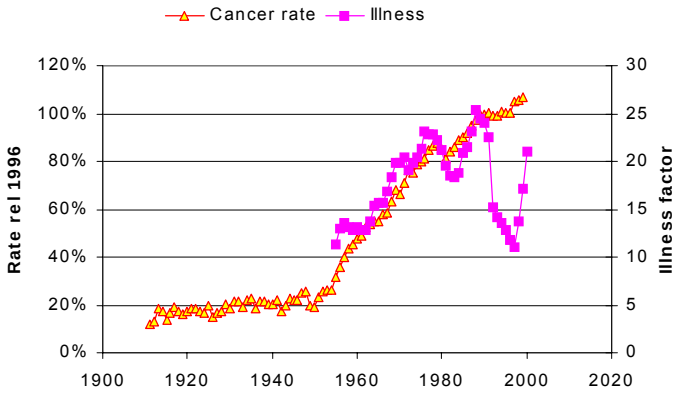

Figure 13. The similarity between the 'illness factor' and cancer mortality for the cancers analysed. Since 1997 the illness factor has increased drastically and continues to do so in 2001.

and even worse, trends for obviously exposure-time-dependent cancers are effectively neutralised by use of age-standardised ratios (ASR). This procedure assumes that the increasing cancer incidence is a natural effect of growing old and thus the age standardised mortality will stay the same although the population gets older. By doing this, the responsible institutions can show to the authorities that the mortality is in control and in effect not increasing at all despite the fact that it is. Furthermore, several cancer mortalities are not published before 1969, which makes it difficult to notice the sharp trend breaks that are present at that year. The responsible authorities do not agree that there is any trend break of interest at all.[13] Nothing speaks for either a trend break in cancer incidence or that a large number of cancers would depend on electromagnetic fields.

Figure 5 shows that breast cancer deaths started to increase long ago, maybe in 1920. This curve has an almost linear increase that flattens out around 1975. But since death rates are influenced by improvements in the medical treatment, it may be better to look at incidence data (rate of people getting ill per year) rather than on death rates.

Figure 14 shows that the incidence rate continues to grow even though the mortality levelled off after 1975. This implies that we have improved the treatment but not at all addressed the cause of this disease. It is interesting to note that breast cancer incidence also shows an improvement in 1979 and a few years onwards, just as the prostate, bladder and colon cancer death-rate graphs do.

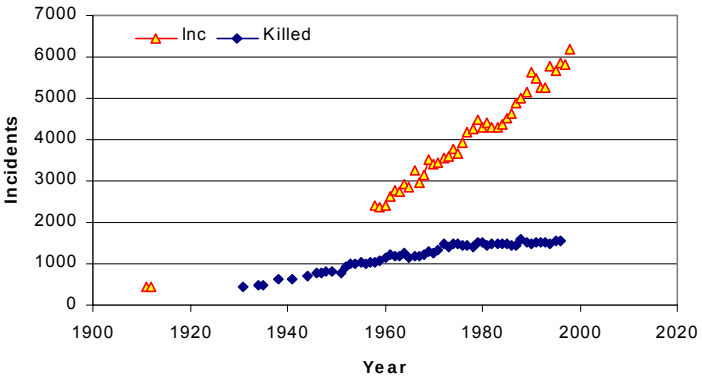

Figure 14. Development of female breast cancer cases in Sweden.

Skin melanoma is a cancer that started to explode in 1955 (see Figure 3). It is interesting to note that a similar steep increase in melanoma mortality was also reported from Queensland, Australia, when comparing 1951-1959 with 1964-1967.[10] This increase was related to the introduction of high power TV broadcasting transmitters. Skin melanoma has also been associated with the expansion of broadcasting networks in Sweden, Norway, Denmark and USA.[11] Lung cancer has an almost identical development, as melanoma has had in Sweden with a scale factor of 10 (see Figures 3 and 4).

Augustsson and Stierner[14, 15] presented statistics on the location of

moles, melanocytes and melanoma on the human body. Figure 15 is a summary picture of all these moles. Figure 16 gives the dot density for different parts of the body. It is interesting to note the similarity to induced vertical currents in the body due to radio frequent electromagnetic fields (RF) as has been presented in ref. 16 (see Figure 17).

Augustsson and Stierner[14, 15] noticed that the largest mole density

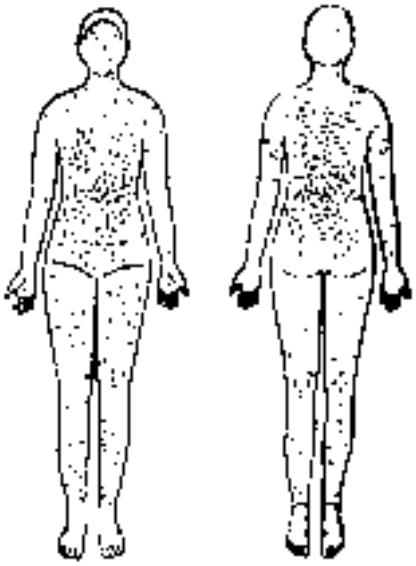

Figure 15. The combined distribution of dysplastic naevi and melanoma ('dots') over the human body.[14-15]

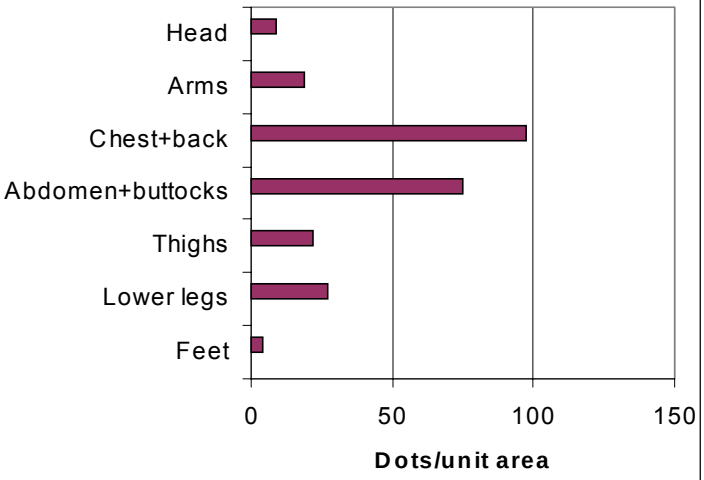

Figure 16. The number of 'dots' per unit skin area according to Figure 15.

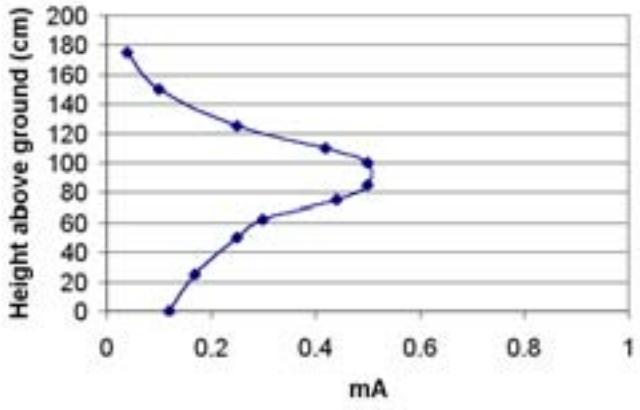

Figure 17. Induced vertical1 current distribution for isolated, shoe-wearing, grounded or ground-topped human model at 27.12 MHz under near-field exposure conditions.[16]

was found in areas that were not normally exposed to sunshine. Thus, they concluded that intermittent or minimal exposure to UV radiation was more dangerous than continuous exposure. We think that the explanation is quite different from that. The induced currents from RF exposure are largest at these parts of the body so the mole density should be expected to follow the same pattern.

Cancers in the Swedish counties

Figure 18 shows the correlation between a number of cancers and melanoma in the 26 different Swedish counties. Table 2 gives the respective beta-values. It is worth noticing that leukaemia does not correlate to these cancer types at all.

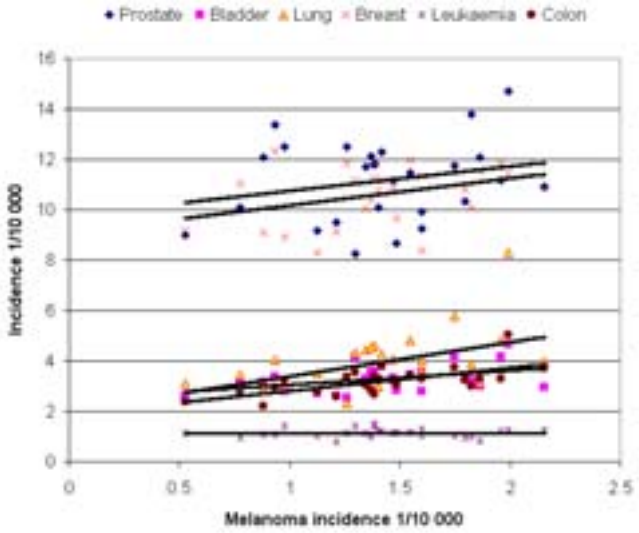

Figure 18. Several cancers correlate with skin melanoma in the 26 different Swedish counties, but leukaemia does not.

A closer look at the lung cancer mortality shows a development very similar to skin melanoma (see Figures 3-4). The average consumption of cigarettes in Sweden has decreased from 1,946 cigarettes per year per capita in 1980 to 1,200 in 1995, although the mortality has continued to increase; however, the increase has been lower than that for skin melanoma.

In Figure 19 we plotted the annual melanoma deaths vs. lung deaths in Sweden for each year from 1912 to 1996 (beta = 0,982).

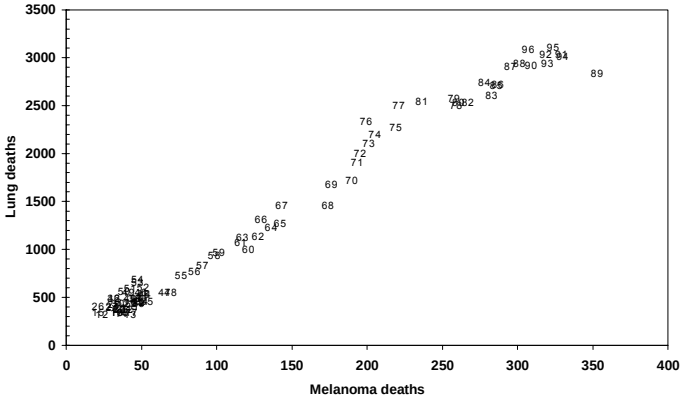

Figure 19. Melanoma and lung cancer deaths for different years.

In order to test by other means if lung cancer and breast cancer are related to skin melanoma, we combined two databases: the Swedish Cancer Register and the Death Cause Register of Sweden.[4] The records of those who died from breast cancer or lung cancer were searched for any treatment for skin melanoma earlier in their lives. As a reference, all other death causes except breast, lung or melanoma cancers were also searched for the same. A specific, non-cancer death

cause was ischemic heart disease, which also was searched for any melanoma treatment.

The data was collected over the time period 1970-1998. The results show the fraction (%) of the deceased who earlier in life had been treated against skin melanoma:

All death causes: ... 0.21% (>2.5 millions deaths)
Breast cancer: ..... 0.37% (42,610 deaths)
Lung cancer: ..... 0.33% (71,956 deaths)
Heart Disease: ..... 0.24% (821,367 deaths)

We conclude that breast cancer and lung cancer are linked to skin melanoma, since people who died due to breast or lung cancer had an increased melanoma incidence by a factor of 1.67 (0.35/0.21). This was further underscored by the strong geographical relationship between melanoma incidence and lung, breast or colon cancer incidence. The large numbers involved in this analysis exclude the possibility that the results are just a matter of coincidence.

Figures 20 and 21 show that colon cancer relates to skin melanoma and that lung cancer and bladder cancer are strongly correlated. Figures 22 and 23 show that cigarette consumption is not a strong common factor for these cancers. See Table 2, data is from 1989-1993.

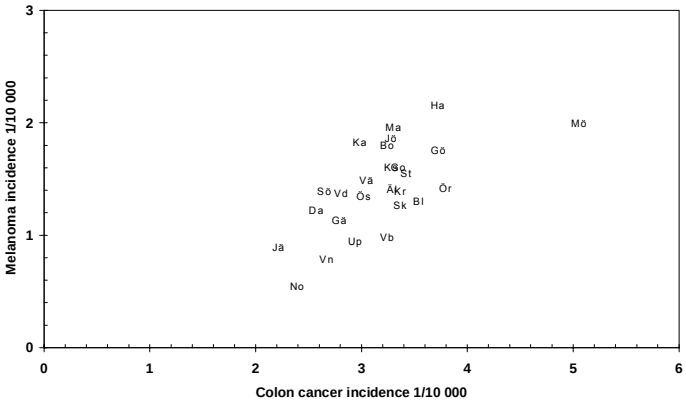

Figure 20. Melanoma incidence versus colon incidence in the 26 counties of Sweden. b=0.655; p=0.000207. R^2=0.43

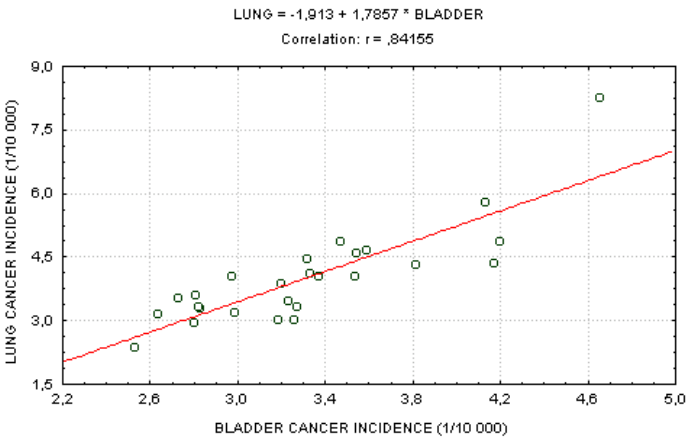

Figure 21. Lung cancer and bladder cancer incidence in the Swedish counties are strongly correlated. b=0.842; p<0.00001. R^2=0.71

A multi-regression analysis of lung cancer mortality in 22 different countries showed a relation to both cigarette consumption and melanoma mortality. Cig-beta=0.679 and Mel-beta=0.528 with p=0.00212.

Finally, we looked at all cancer deaths reported since 1912 and plotted the result in Figure 24. Trend-breaks are quite visible in 1920, 1955, 1970 and in 1979.

In 1920 we got MW radio, in 1955 we got FM radio and TV1, in 1969-70 we got TV2 and colour TV and in 1978 several of the old AM broadcasting transmitters were disrupted, all according to ref. 12.

Improvements in prostate cancer deaths have been reported in

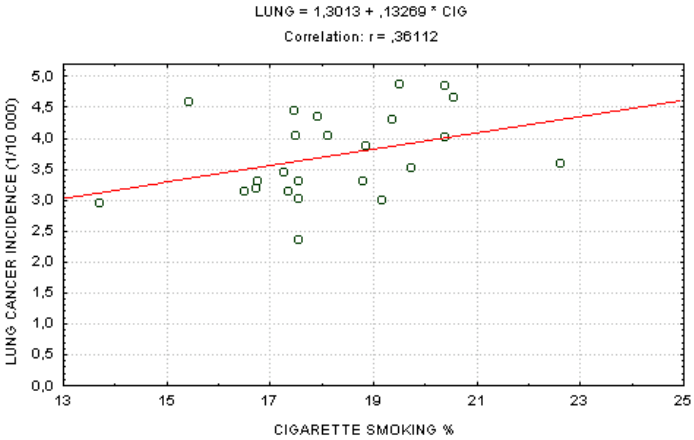

Figure 22. The correlation between lung cancer incidence and cigarette consumption (% of the population that is smoking cigarettes) is weak in the Swedish counties. R^2=0.13.

Figure 23. Bladder cancer incidence does not correlate well to cigarette consumption in Sweden. R^2=0.07

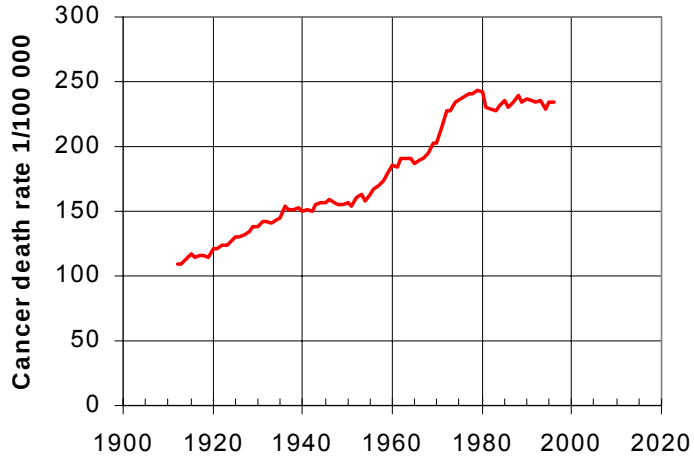

Figure 24. The mortality shows clear trend-breaks in 1920, 1955, 1970 and in 1979.

USA. Figure 25 gives the number of prostate cancer deaths and the number of AM stations still active. Since 1990 the number of active AM stations has been steadily decreasing.

Figure 26 gives the development of cancer mortalities in different countries.

Conclusions

1. Breast, bladder, prostate, lung, colon and cutaneous melanoma cancers are all associated with each other. Figures 15-17 and ref. 11 relate melanoma to radio-frequency EMF.

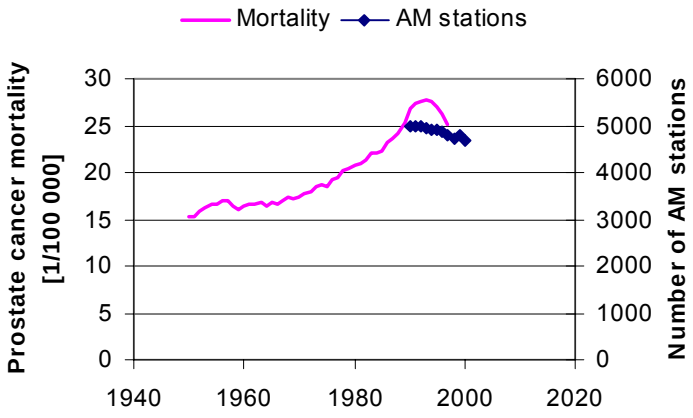

Figure 25. A sharp decline in number of men killed by prostate cancer has been noticed in USA since 1990. At the same time the number of AM stations have started to decline.

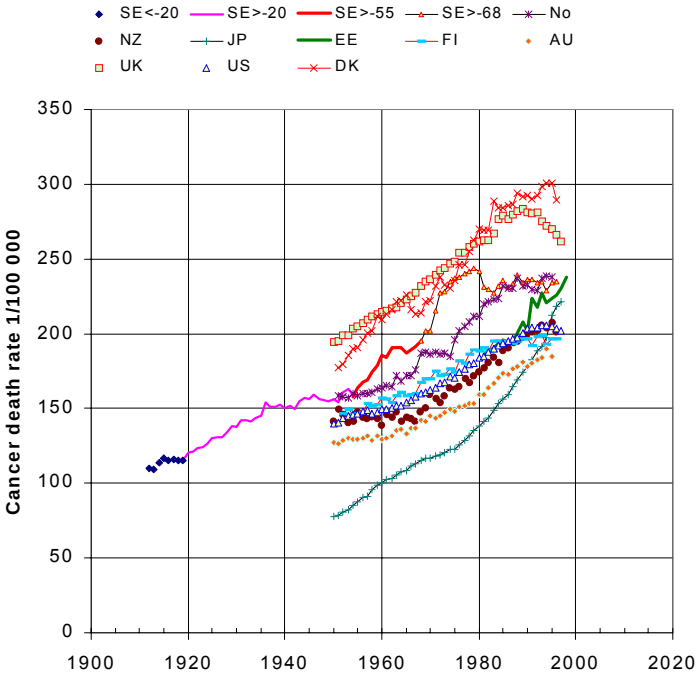

Figure 26. Cancer mortality development in several countries since 1950.

2. Figure 18 indicates that leukaemia has nothing to do with melanoma. Somewhat more unexpected is the strong relation between melanoma and colon cancer and between lung cancer and bladder cancer.
3. Since the cancer mortality trend-breaks coincide with expansion or disruption of public broadcasting in Sweden, studies regarding the influence from electromagnetic fields on cancer and asthma development cannot be further delayed.
4. Lung cancer mortality has a multiple correlation to both cigarette consumption and skin melanoma mortality.
5. Since closing down of public radio transmitters seems to have a strong effect in reducing cancer mortality, public air radio transmission should be avoided.
6. Age-standardised ratios should be used with care when presenting cancer rates that are dependent on exposure times.

Similar trend-breaks as found in Sweden can be noticed for other countries. Figure 26 shows, for example, that Estonia (EE) had a steep increase in the cancer mortality in 1991, the year that the 'western' FM radio-frequencies were allowed and introduced all over the country.

Acknowledgements

This study was financially supported by the Swedish Cancer and Allergy Foundation (Cancer och Allergifonden). We are grateful to Charlotte Björkenstam at the Epidemiological Centre of Sweden, EpC, for support in extracting death and incidence data from the public databases.

We thank Ms Margareta Krook-Brandt at the Karolinska Institute for expert support with the statistical evaluations.

Woman Cuts Family Off From WiFi Over Health Concerns

May 5, 2015 11:17 PM By Lisa Sigell

LOS ANGELES (CBSLA.com) — A local mother's health concerns prompted her to cut her family off from wireless and wants more research conducted into the safety of WiFi.

In the Lawson household, cassette tapes are still in use, as are landline telephones.

Not in use, however, are cellphones, iPads, iPods nor absolutely no wireless connections to the outside world.

"You're just thinking, 'I want to live,' " said Anura Lawson, a mother and teacher.

Lawson says she started feeling sick in 2012 soon after the Los Angeles Department of Water and Power installed a wireless smart meter on her home.

There are 52,000 of these smart meters being tested in L.A., and the DWP says they're safe.

But some people claim the radio waves they emit trigger health problems.

"I began to feel dizzy at first," Lawson said. "Migraines. Heart palpitations."

Lawson's daughter, Amira, 22, also experienced trouble.

"My brain was running slower, and I was like, 'I don't know what's going on,' " she said.

"There is a syndrome called electromagnetic hypersensitivity," said Robert Nagourney, an oncologist in Long Beach and professor at UC Irvine.

"There are two kinds of radiation we speak about. One is ionizing, and one is nonionizing," Nagourney said. "In ionizing radiation, clearly, there's a great risk of DNA damage, mutation and cancer."

This danger has not been proven with nonionizing radiation, which is the type emitted by cellphones, smart meters and WiFi.

But with our 21st century explosion of wireless, Nagourney says "we're bathed in this type of radiation."

"Does it cause medical illnesses? Great question. Difficult to answer," the doctor said.

For the Lawson family, who consider themselves sensitive to electromagnetic fields, the smart meter had to go.

Once they got their analogue meter back, Lawson said they felt better healthwise.

But a 1 ½ years later, Lawson says her symptoms returned.

“I began to have migraines. I began to have the heart palpitations,” she said.

It coincided with a change at work as Lawson is an eighth-grade English teacher at Johnnie Cochran Middle School.

In March 2014 to facilitate its iPad program, Lawson says, the “LAUSD decided to install WiFi within my school site.”

With her health deteriorating, Lawson testified before the Board of Education.

“I’m the parent of six children. I want to be around to see them grow up,” she had said. “When I am in the WiFi classroom, I don’t feel good at all.”

“There were a lot of people that were concerned about putting WiFi in the classroom,” said Bill Piazzi, the LAUSD’s environmental assessment coordinator, whose job it is to make sure classrooms are safe.

Where there are WiFi access points, Piazza says, they use a very sophisticated piece of equipment, which measures radio-frequency output.

“We looked very hard at the potential exposures in the classroom,” he said. “No matter where we went, it’s all low.”

Piazza showed CBS2 an emissions report from a classroom that had WiFi.

“These are 30 kids streaming in a classroom, and these are the exposures that they’re getting,” he said “Look how low that is.”

Still, the board in September agreed to turn off the WiFi in Lawson’s classroom.

Now, she is believed to be the first public school teacher in the U.S. granted a health accommodation for electromagnetic hypersensitivity.

“I think the district did a very good job in making a reasonable accommodation for her,” Piazza said.

Lawson’s accommodation applies to her classroom only. To keep her children away from WiFi exposure, her four youngest are being educated at home.

The Lawson’s have Internet at home, but it’s only through a wired connection.

Over the past three years, Lawson says, she has encountered plenty of doubters, which Nagourney says is too bad.

“People are of different sensitivities. We know that one person can get a bee sting and nothing happens. Another person goes into anaphylactic shock. It’s the same bee sting. Different reaction,” he said.

Nagourney says the likelihood of WiFi emissions causing illness is small, “but the chance is not zero.”

Lawson says she would like to see the issue thoroughly researched and believes the newness of wireless makes it impossible to fully understand now how it might one day affect one’s health.

Thus, she’s keeping her kids away from it for as long as she can.

“Teaching doesn’t have to involve a device,” she said. “I think that our students unfortunately are the Guinea pigs, and I don’t think that’s right.”

The LAUSD says it is continuing to study all safety data with respect to WiFi. To view the most recent reports, click **here**.

Lawson has started an online petition to get WiFi out of California classrooms. For more information, click **here**. To reach Nagourney, click **here**.

Electromagnetic Cover-Up

Attempts to water down a US Government report linking exposure to electromagnetic fields to cancer have provoked charges of a cover-up.

A two-year study commissioned by the US Environmental Protection Agency (EPA) has concluded that there is a significant link between exposure to extremely low frequency (ELF) radiation and the occurrence of human cancer. The study group's report *An Evaluation of the Potential Carcinogenicity of Electromagnetic Fields*, was made available in June amid much publicity.[1] However, it has emerged that the conclusions of the EPA assessors have been watered down significantly in the published version of the report, prompting charges of a cover-up.

Early drafts of the report, which were leaked to various sections of the American media, recommended that ELF electromagnetic fields (EMFs) be classified as "probable human carcinogens".[2] The EPA assessors also recommended that radio-frequency and microwave radiation be designated as "possible" carcinogens.[3]

As originally drafted, the summary of the report stated that although the biological mechanisms by which non-ionizing radiation might cause cancer in humans are unknown, animal tests and epidemiological studies "are suggestive of a causal relationship". According to the New York-based newsletter *Microwave News*, the following paragraph concluded the draft summary — until it was deleted in mid-March by Dr William Farland, Director of EPA's Office of Health and Environmental Assessment, the body which prepared the report:

> "Concerning exposure to fields associated with 60 Hz electrical power distribution, the conclusion reached in this document is that such exposure is a 'probable' carcinogen risk factor, corresponding to 'B1' degree of evidence that it is a risk factor. This conclusion is based on 'limited' evidence of carcinogenicity [in] humans which is supported by laboratory research indicating that the carcinogenic response observed in humans has a biological basis, although the precise mechanisms [are] only vaguely understood."[4]

As published, however, the report concludes that studies of leukaemia, lymphoma and brain cancer in children and adults occupationally exposed to extremely low frequency EMFs, "show a consistent pattern of response that suggests, but *[does] not prove*, a causal link." The recommendation that ELF radiation be classified as a "probable human carcinogen" has also been deleted from the officially-released version, as has the recommendation on classifying radio-frequency and microwave radiation as "possible" carcinogens. The deletions were made by Farland because there was, in his judgement, an absence of both a mechanism of interaction and an observed dose-response relationship.

Positive Association

Despite the deletions ordered by Farland, other sections in the report underline the original conclusions. For example, after evaluating the 28 studies of occupational exposure to EMFs, the report states:

> "The occupational studies seem to suggest the likelihood that there exists a positive association of leukaemia and central nervous system cancer with employment in jobs that have a high potential for exposure to EMFs."

And assessing six studies of childhood cancer and EMFs, the report concludes:

> "The case-control studies of children residentially exposed to magnetic fields provide evidence of a positive association of a risk of certain types of cancer, namely leukaemia, central nervous system cancers and lymphoma. Because these measured risks are low in all of these studies the possibility that some unknown confounder is responsible cannot be eliminated. However, because of the consistent positive findings and suggested site concordance, chance is not likely to be the explanation."

Referring to the work of both the Polish researcher Szmigielski, and Dr Bill Guy at the University of Washington, on the effects of radio-frequency radiation, it is stated that:

> "The clear positive findings of Szmigielski et al. show that radio-frequency fields without low frequency components stimulate the growth of tumours and indicate that they may act as a tumour promoter, or a modifying factor in the development of tumours, the role of tissue heating as a mechanism for this effect is not clear."

Comments such as these are the strongest yet made by a US government agency on the connection between human cancer and chronic exposure to electromagnetic fields from sources such as powerlines, visual display units, household appliances, radio broadcast and microwave systems. It is reported that the question of how to deal with EMFs is being debated at the highest levels of the Bush Administration. Indeed, the White House was briefed in early March by EPA officials on the report's original recommendations.

Simon Best

Notes and References

1. Copies of the report can be obtained from: The Environmental Protection Agency, 401 Main Street SW, Washington, DC 20460, USA. Tel: (202) 382-5898. Currently, there are five independent studies on the link between childhood cancer and EMFs being carried out in Europe and North America.

CONTENT

Introduction

The primary natural source of RF fields is the sun. Human-made sources, however, emit the majority of fields in the immediate environment of the community, home or the workplace. Most RF fields found in the environment are due to commercial radio and TV broadcasting and to telecommunications facilities (Table 1). RF sources in the home include microwave ovens, DECT telephones and Wi-Fi routers. In the workplace, there are a number of industrial processes which use RF fields: dielectric heaters used for wood lamination and the sealing of plastics; industrial induction heaters and microwave ovens, medical diathermy equipment to treat pain and inflammation of body tissues and electrosurgical devices for cutting and welding tissues.

Table 1: RF range: frequencies and type of device or service (adapted from Mathes)

Frequency Range	Frequency	Type of Device or Service
30 - 300 kHz	LF (low)	LF broadcast and long range radio
300 - 3000 kHz	MF (medium)	AM radio, radio navigation, ship to shore
3 - 30 MHz	HF (high)	CB radio, amateurs, HF radio communications and broadcast
30 - 300 MHz	VHF (very high)	FM radio, VHF TV, emergency services
300 - 3000 MHz	UHF (ultra high)	UHF TV, paging, mobile telephones, amateur radios, DECT
3 -30 GHz	SHF (super high)	Microwaves, satellite communications, radar, point to point microwave communications, Wi-Fi
30 - 300 GHz	EHF (extremely high)	Radar, radio, astronomy, short link microwave communications

Today the largest source of RF for the general public is the use of mobile telephones. Except when phones are used in a hands-free position or used to send data, mobile telephones are generally held against the head when a call is being made and the antenna receives and sends the signal. The head of the user is in the near field of the source because of the distance of the antenna to the head is typically a few centimetres. Due to this close proximity, most of the RF energy is absorbed in the brain hemisphere on the side where the phone is used, mainly (50ï 60%) in the temporal lobe. The average relative SAR is highest in the temporal lobe (6ï 15%, depending on frequency, of the spatial peak SAR in the most exposed region of the brain) and the cerebellum (2ï 10%) and decreases very rapidly with increasing depth, particularly at higher frequencies(Cardis et al. 2008).

Occupational exposures, on the other hand, can differ from mobile phone exposures in a number of important respects:

- They may occur for more prolonged periods. For example, working next to an industrial heater may expose the subject to radiation for eight hours a day, five days a week, over a number of years.
- They may expose larger areas of the body. Mobile phones tend to expose on a small area of the body adjacent to the ear; whereas some pieces of industrial machinery may expose the entire body to radiation.

This is the third and final report on epidemiological studies of health effects of RF fields. The first two reports focused on new literature published during the project period of EMF-NET, whereas

the final report will make an assessment of the totality of the available epidemiological scientific evidence. Included in the assessment are scientific studies that have been published primarily in peer reviewed scientific journals. The studies have been identified through systematic searches in PubMed, ISI Web of Science, scrutinizing reference lists of published papers and reports, and through participation in scientific conferences focused on biological effects of electromagnetic fields.

Evaluation

Whereas the original objective of WP3 was to evaluate the epidemiological evidence for health effects of EMF exposure, an evaluation of the effects of RF was not possible within the lifespan of the EMF-Net project because of delays in publication of the results of the international analyses within INTERPHONE, the largest epidemiological study to date. The International Agency for Research on Cancer (IARC) and World Health Organization (WHO) evaluations have likewise not yet taken place because of this delay.

The current report is therefore limited to a critical review of the evidence to date. It is, at present, premature to draw conclusions concerning the presence or absence of health effects from RF at ñathermal levelsò.

Where available studies existed, the following outcomes have been reviewed:

1. Cancer outcomes
    a. Brain and CNS tumours in adults
    b. Other tumours
2. Fertility and pregnancy outcome
3. Cardiovascular effects
4. Other possible health effects

The list is based on the ñKey Issueò list of Main Task 1 (MT1) of EMF-NET, and corresponds to the endpoints evaluated in WP2.1 Laboratory studies, for which evidence from epidemiological studies of RF are available.

Exposure assessment

As there is at present no known biophysical interaction mechanism for potential health effects of athermal, levels of RF it is not obvious which aspect of exposure is the most relevant.

Where efforts have been made to use an exposure metric, studies have generally focused on estimates of the amount of RF energy absorbed, measured by SAR (the specific energy absorption rate i.e. energy absorption rate per unit mass (measured in W kgī 1)) in mobile phone studies, or on the total RF electromagnetic field exposure.

Residential exposure

As discussed below, most residential studies in relation to RF transmitters are of ecological design. Exposure assessment methods in these studies are generally very crude, based on the measured distance between a house and nearby RF sources. Spot measurements have, however, been used in two recent case-control studies to validate exposure prediction models (Ha et al. 2007;Merzenich et al. 2008), showing a better correlation between measurements and the models than between measurements and distance from the source.

A number of studies have also considered RF exposure from cordless telephones at home (Hardell et al. 2006c;Hardell et al. 2006b;Schuz et al. 2006a;Schuz et al. 2006b). Information on the use of

these telephones has been obtained, together with information on mobile phone use, from questionnaires and include dates of start and stop of use, type of cordless phone and, in the German study, location of the base station in the house or apartment.

Integrated measurements over longer time periods (1-7 days) have also been made in recent RF exposure assessment studies (Thomas et al. 2008;Röösli et al. 2008;Viel et al. 2008) with the use of personal RF meters. These meters allow estimation of exposure in most of the frequency bands of concern for environmental exposure (including TV, radio, mobile phones ï handsets and base stations -, Wifi and DECT routers). These instruments have not, however, yet been used in any of the analytical epidemiological studies published to date.

Occupational exposure

Occupational studies are also characterized by rather crude exposure assessment, sometimes limited to investigations of disease risk associated with individual job titles, or to grouping of occupational titles thought to be exposed to RF. In some of the studies, workers in the groupings considered were also exposed to ELF and it is difficult to separate RF and ELF exposed workers.

Recent studies (Karipidis et al. 2007;Berg et al. 2006) have used detailed occupational history, in conjunction with assessments by occupational hygienists and, in the Karipidis study, linkage with an EMF Job-Exposure Matrix (JEM) to infer exposure levels.

Mobile phones

Most studies to date have been based on historical use of mobile phones rather than any estimate of RF ñexposureò.

Information collected in cohort studies has been limited ï the fact of having a subscription, and, in some instances, the date of start of the subscription and the type of network.

Case-control studies have provided the opportunity of collecting much more detailed information at the individual level. Exposure variables generally collected include: ever having been a regular user (this variable was defined differently in different studies ï within INTERPHONE, it was defined a priori as at least one call per week on average for a period of 6 months or more), time (years) since first regular use, cumulative number of calls, and cumulative duration of calls. For analyses of cancer risk, exposure variables were generally censored some time (often 1 year) before the reference date. Cumulative number and cumulative duration of calls have also been analyzed, generally excluding use with hands-free devices. Use in different time windows has also been analysed in some papers.

Because the absorption of RF energy from phones is localized, if a risk exists it is likely to be greatest for tumours in regions with greatest energy absorption. Most (97ï 99% depending on frequency) appears to be absorbed in the brain hemisphere on the side where the phone is used, mainly in the temporal lobe. The average relative SAR is highest in the temporal lobe and the cerebellum and decreases very rapidly with increasing depth, particularly at higher frequencies. Analyses of risk by location of tumour are therefore essential for the interpretation of results studies of brain tumours in relation to mobile phone use (Cardis et al. 2008).

Major efforts are therefore underway to evaluate the amount of RF energy at the site of the tumour in case-control studies of brain and central nervous system (CNS) tumours.

In the glioma analyses of the Japanese INTERPHONE study (Takebayashi et al. 2008), the maximum amount of RF energy absorbed inside the tumour was estimated. Within INTERPHONE; efforts are underway at the international level to develop an RF ñexposure

gradientò to estimate the amount of RF energy absorbed at the location of the probably origin of the tumour, taking into account the subject´s mobile phone use history as well as historical characteristics of phones (including radiation pattern) and networks in participating countries. This gradient is not yet available, however, in the studies published to date.

An important issue in the interpretation of results of case-control studies that rely on self-reported history of mobile phone use is the potential for errors and biases in recall of amount of phone use. Within INTERPHONE; validation studies have been conducted to evaluate potential error in the recall of phone, indicating that phone use was subject to moderate systematic and substantial random error (Berg et al. 2005;Vrijheid et al. 2006;Vrijheid et al. 2008a;Hours et al. 2007b;Parslow et al. 2003;Hepworth et al. 2006;Samkange-Zeeb et al. 2004;Tokola et al. 2008). Errors appear to be larger for duration of calls than for number of calls, and phone use appears to be under-estimated by light users and over-estimated by heavy users. Comparison of a sample of cases and controls in three countries showed little evidence for differential recall errors overall or in recent time periods, but apparent overestimation by cases in more distant time periods (Vrijheid et al. 2008a).

Laterality of phone use is also subject to recall error and to differential reporting between cases and controls. Hence reported increases in the risk of some tumour types for ipsilateral use in long-term users that are described below, are currently difficult to interpret. These could reflect a real association (since, as indicated above, RF energy absorption is very localised) or an artefact related to laterality recall bias.

Studies of health effects from environmental sources of RF other than phones

Point sources (broadcasting towers and mobile phone base stations)

Epidemiological studies completed so far have mostly looked at cancer incidence broadcasting towers, using an ecological design. Only two case-control studies have been conducted to date. Ecologic studies are subject to a number of methodological problems, which limit their usefulness for studies of low levels of RF (Cardis and Estève 1991;Goldberg and Cardis 1994). It is difficult to ensure an adequate choice of the geographical areas to be compared: the choice of boundaries of the study regions may exaggerate or diminish the apparent significance of an association. Information on levels of exposure, on confounding factors and population movements is rarely available. In the best of cases, crude estimates of exposure by sub-regions may be available, or sub-regions may be classified as a function of their distance (which may not be a good surrogate for exposure level) from a source of exposure. Because individual exposures are not determined, a causal relationship is not easy to infer and studies are subject to the "ecological fallacy" – the failure of group level data to properly reflect individual level associations – (Greenland and Morgenstern 1989;Piantadosi et al. 1988). In most instances therefore, a "negative" ecological study (i.e. a study in which no increase in risk is observed) cannot be interpreted to mean that no risk exists, and can only provide an upper bound for the risk estimate. A "positive" correlation study, on the other hand, may be difficult to interpret because of potential biases and confounding. Reported clusters (rather than actual epidemiological studies) are even more difficult to interpret as they may suffer a number of methodological limitations (including completeness of case ascertainment and validation of diagnoses) in addition to those of formal ecological studies (Gavin and Catney 2006).

Case-control studies

In Korea, a case-control study of childhood leukaemia and brain cancer (0-14 years) was conducted (Ha et al. 2007) in order to investigate the possible relation with RF exposure from AM radio broadcasting tower, previously reported in an ecological study (Ha et al. 2003;Park et al. 2004). Controls were individually matched to the cases on age and sex and were chosen among patients with a respiratory illness. The study included 1,928 leukaemia cases and 956 brain cancer cases from 14 South Korean hospitals using the South Korean Medical Insurance Data System, and 3,082 controls. A prediction program incorporating a geographic information system was used to estimate total and peak RF exposure at the subjectsô home address from 31 AM radio transmitters with a power of 20 kW or more. An elevated OR was seen for all types of leukaemia combined (OR 2.15, 95% CI 1.00, 4.67) among children who resided within 2 km of the nearest AM radio transmitter as compared with those resided more than 20 km from it. The corresponding OR for lymphocytic leukaemia was 1.69 (95% CI 0.69, 3.72). In analyses by level of RF exposure, no association was found for brain cancer. A significantly increased risk of lymphocytic leukaemia was found in the highest quartile of peak RF exposure (OR 1.40, 95% CI 1.04, 1.88; peak exposure > 0.6 V/m) for lymphocytic, but not for myelocytic leukaemia (Ha et al. 2008). In this corrected analysis, no association was found, however, with total RF exposure, contrary to the results originally published (Ha et al. 2007).

A case-control study was conducted in West Germany to evaluate the possible link between RF from broadcasting towers and the risk of leukaemia in children (0-14 years) (Merzenich et al. 2008). Analyses included 1,959 cases diagnosed between 1984 and 2003, registered in the German Childhood Cancer Registry and living in municipalities near Germanyôs strongest emitting television and radio broadcasting towers. Individual exposure to RF at the subjectsô home address 1 year before diagnosis was estimated with a field strength prediction program. The OR for leukaemia was 1.04 (95% confidence interval: 0.65, 1.67) among children living within 2 km of the nearest broadcast transmitter compared with those living at a distance of 10-<15 km. It was 1.31 (95% CI 0.80, 2.15) when analyses were restricted to lymphoid leukaemia and 1.56 (95% CI 0.77, 3.16) when further restricted to AM transmitters. No association was found, however, between the estimated level of RF exposure and the risk of leukaemia. The OR for leukaemia (all types combined) was 0.86 (95% confidence interval: 0.67, 1.11) when upper (>/=95%/0.701 V/m) and lower (<90%/0.504 V/m) quantiles of the RF distribution were compared. An analysis of AM and FM transmitters separately did not show increased risks of leukaemia. Validation of the field strength prediction programme, show a better correlation of spot measurements with field strength predictions than with distance from the broadcasting towers.

A combined analysis of the lymphocytic leukaemia results from Korea and Germany found no association with total RF exposure (Schuz and Ahlbom 2008). ORs for living within 2 km of broadcasting towers are of similar magnitude in both studies, however.

Ecological studies

In the USA, spatial clustering of childhood cancer around a large microwave tower was studied in the city of San Francisco, over the period 1973-88. The study included 51 leukaemia, 35 brain cancers and 37 lymphatic cancers and found no association between risk of these diseases and distance from the tower (Selvin et al. 1992).

In the USA, a case-control study was conducted to evaluate the etiology of a cluster of childhood acute leukaemia on the Waianae Coast, Hawaii. The study included 12 cases diagnosed between 1979 and 1990 and 48 controls. Children who lived within 4.2km of the radio towers (median distance) had a non-significantly increased risk of leukaemia (OR 2.0, 95% CI 0.06-8.3) (Maskarinec et al. 1994).

A study of cancer incidence and mortality among residents in the ñinnerò (three municipalities close to the towers) and ñouterò areas (six municipalities which were more distant) around the television towers in Northern Sydney (Australia) was carried out (Hocking et al. 1996). An increased incidence and mortality of childhood leukaemia in the inner area was observed. These data were reanalysed by municipality by (McKenzie et al. 1998) after adding other municipalities close to the towers. The excess of childhood leukaemia was restricted to one of the inner area municipalities. When this municipality was excluded, there was no increased incidence and mortality for childhood leukaemia.

A geographical study of cancer incidence was conducted around the Sutton Coldfield television and FM radio transmitter in the West Midlands, England, following a report of a cluster of leukaemias and lymphomas (Dolk et al. 1997b). The risk of adult leukaemia within 2 km was 1.83 (95% confidence interval 1.22-2.74), and there was a significant decline in risk with distance from the transmitter (p = 0.001). These findings appeared to be consistent over the periods 1974-1980, 1981-1986. A further, more comprehensive study, carried out around 20 television and radio transmission towers in the UK, found no increased risk of adult or childhood leukaemia for persons residing within 2 km (O/E ratio=0.97, 95% CI 0.8-1.2, based on 79 cases) or 10 kms of transmitters. A small significant decline in risk of adult leukaemia with distance from transmitters was seen, however, in the 2-10 km range (Dolk et al. 1997a).

In Italy, a study of childhood leukaemia incidence and adult and adolescent leukaemia mortality was conducted around the powerful Vatican Radio broadcast transmitters in a northern suburb of Rome (Michelozzi et al. 2002). The study covered a 10-km area around the transmitter, with a population of around 50,000. Overall, 40 adult and adolescent leukaemia deaths and 8 childhood leukaemia cases were observed in the study area during the study period (1987-1998 for mortality, 1987-1999 for incidence), compared to 37.4 and 6.5 expected, respectively. For childhood leukaemia, a non-significantly increased risk (SIR 6.1, 95% CI 0.4, 27.5) was seen for residence within 2 km of the transmitter, based on one case, as well as a significant trend of increasing SIR with decreasing distance (p=0.036). Among adolescents and adults, two deaths were reported among men living within 2 km of the transmitter (SMR 2.9, 95% CI 0.5, 9.0) and none in women, and there was a trend of increasing SMR with decreasing distance, which was statistically significant only in men (p=0.03). Results of this study are based on very small numbers of cases.

An ecological study of cancer incidence was conducted in South Korea (Ha et al. 2003) in areas close to 42 AM radio transmitters (11 high-power transmitters ï 100-1500 kW ï and 31 low-power transmitters). Incidence rates were calculated for all cancers, leukaemia, malignant lymphoma, brain and breast cancer in 2km-radius areas around each transmitter, as well as in control areas for the period 1993-1996. Slightly increased rates were seen in high-power transmitter areas compared to low transmitter areas, for all of the outcomes studied; they were significantly increased only for all cancers combined (based on 1,636 cases in high-power areas) and for brain cancer in women (based on about 20 cases). In analyses of individual transmission sites, significant increases of total cancer incidence were observed in 9 out of 11 high-power sites, of leukaemia incidence in 2 and of brain cancer in one; there was no evidence for a relation between the incidence ratio and power level of the transmitter. Numbers of cases for individual cancer types were small, however, particularly when considering individual areas.

An ecological study of cancer mortality was also conducted, in 1994-1995, in South Korea (Park et al. 2004) in 10 RF-exposed areas (defined as regions that included AM radio broadcasting towers of over 100 kW), and in 40 control areas. All cancer mortality was found to be significantly higher in the exposed areas (directly standardised mortality rate ratio (MRR) 1.29, 95%CI = 1.12, 1.49). There was no apparent trend in MRR by electrical power level, however. Mortality from virtually all specific types of cancers considered was also increased (although not statistically significantly

so) in the exposed areas compared to the control areas, in men as well as in women, raising the issue of comparability of the populations in the exposed and control areas. In analyses by age at death, leukaemia mortality was found to be significantly elevated in exposed areas among children (MRR 2.29, 95% CI 1.05, 5.98, based on 11 deaths in the exposed areas) and in adolescents and young adults (MRR 2.44, 95% CI 1.07, 5.24 based on 11 deaths in the exposed areas).

A cross-sectional study of randomly selected inhabitants living in urban and rural areas for near to 10 selected base stations was conducted in Austria to evaluate the possible effect of base stations on subjective symptoms and cognitive performance (Hutter et al. 2006). Cognitive tests were performed on 365 subjects, and their wellbeing and sleep quality were assessed. Field strength of high-frequency electromagnetic fields was measured in bedrooms of 336 households, and the maximum exposure from the base station was computed. Significant relations were found for a number of symptoms, particularly headaches, after adjustment for age, sex, region, mobile phone use and fear of adverse health effects of base stations. No clear difference was found in sleep quality or cognitive performance, although a slightly faster reaction in perceptual speed was associated with higher exposure level.

A cross-sectional health study was conducted in Cyprus in two villages near the Akrotiri salt lake site (part of the UK Sovereign Base Areas Administration, containing a military air base and a large antenna array) and in one control village about 15 km away from the site (Preece et al. 2007). The objective was to compare electromagnetic profile and health status of the population in these villages. The population in the villages totalled about 800 and 350 in Akrotiri and Asomatos (the two villages near the site) and 1,000 in the control village. The prevalence of specific symptoms and diseases was investigated using specifically designed questionnaires, a risk perception survey and collection of health and mortality data from available registry and other sources. The questionnaires were distributed to each household, with response rates of 87%, 77% and 92% respectively in Akrotiri, Asomatos and the control village. Spot RF measurements were also made at a number of places in each village using Delta-T multichannel loggers and portable Narda EMR 20C meter. Overall, during military transmissions, the field strengths were higher in the exposed villages than in the control area (average readings 0.5-0.6 V/m versus <0.01 V/m), though the contribution of the frequencies used by the military antennae (17.6 MHz) was only 10-20% (the dominant sources of RF were cell phone and national broadcast systems). The frequency of reported migraine, headache and dizziness was significantly higher in the exposed villages than in the control village (ORs 2.7, 3.7 and 2.7 respectively ï p<0.001 for each), and higher in Akrotiri than in Asomatos, where, despite similar levels of exposure, the antennae visibility and the aircraft noise are less important. No significant difference was seen in relation to pregnancy, child birth, diabetes, asthma, respiratory problems and most infections. The residents of the exposed village generally had a poorer view of their health status than those of the control village; they also had a higher level of perceived risk, particularly in Akrotiri, from noise and electromagnetic ñpollutionò. These differences could account for the higher reported frequency of migraine, headache and dizziness.

Cordless telephones

Cordless phones have been used extensively in homes since the 1980´s, relying on an analogue system emitting in the 800-900 MHz range, since the late 1990´s however, DECT (Digital Enhanced Cordless Technology) phones, relying on a digital system emitting in the 1900 Mhz range have rapidly taken over the market.

The possible association between the use of cordless telephones and brain tumours has been assessed in studies in Sweden and in Germany

Associations between the use of cordless phones (type unspecified) have been reported in the Swedish studies (Hardell et al. 2006b;Hardell et al. 2006a;Hardell et al. 2005c) for malignant brain tumours, acoustic neurinomas and T-cell lymphomas. Risk appeared to increase with latency and amount of use. The German study did not, however, report an association between the risk of glioma or meningioma and the use of DECT telephones (at home or at work) or with location of the DECT base station close to the bed (Schuz et al. 2006a;Schuz et al. 2006b).

Studies of health effects from occupational sources of RF

The relation between cancer risk and occupation involving RF or microwave (MW) radiation exposure as been studied both in cohort and case-control studies. They are summarised in the sections below. Results of the most informative studies are given in Table 1: the studies in which no effort was made to separate RF from lower frequency radiation are not reported here.

All cancers

The most widely publicised study of the potential effects of microwave radiation was the study of 1827 embassy employees (and their dependants) who lived and worked in the United States Embassy in Moscow between 1953 and 1976 (Lilienfeld et al. 1978). Workplace measurements between 1963 and 1975 detected microwave radiation of maximum 0.05 W/m^2 lasting 9 hours per day at frequencies between 0.5 and 10 Ghz. Cancer mortality was compared to that of 2561 employees from other US embassies in East European countries as well as to that of the US population. Results showed no differences in health status between those who worked or lived in the Moscow embassy and the comparison groups (see Table 1 for comparison with US population). The small number of cancer deaths (17 in total, including two leukaemia), however, makes the study non-informative.

A cohort study of over 40,000 US enlisted naval personnel and aviation workers exposed to microwave radiation during the Korean War (1950-1954) was carried out by (Robinette et al. 1980). Approximately half were chosen among personnel with ñlow exposureò (radiomen, radarmen and aviation electricianôs mates) and half with ñhigh exposureò (electronics technicians, fire-control technicians and aviation electronics technicians). Potential exposure to microwave radiation was assessed in terms of environmental measurements, occupational duties, length of time in occupation and power of equipment at the time of exposure for all deaths from disease, homicide or suicide and for a 5% sample of the cohort. Mortality and morbidity data were obtained from military records. No difference in all cause or cancer mortality or morbidity was seen among the high exposure and low exposure groups or among workers categorised by level of potential exposure after a 20 year follow-up (Robinette et al. 1980) and no difference in mortality rates after 40 years of follow-up (Groves et al. 2002).

A large study of 128,000 Polish military career personnel serving at any time during the period 1971-1985 was followed for cancer morbidity over the same time period using data from military hospital records (Szmigielski 1996). Data on exposure of personnel to RF/MW, obtained from measurements of RF/MW field intensities at and around service posts, served to classify personnel as exposed or non-exposed. A significantly elevated SIR was found for the exposed group compared to non-exposed group for all cancers (Table 1). This result is difficult to interpret, however, as the methods are not clearly described and the authors appear to have invested more effort into finding exposures among the cancer cases than among the personnel that had not been diagnosed with cancer, which could lead to bias.

The bias introduced by this kind of procedure will inevitably lead to findings of increased cancer risks, even if no such associations exist; and no weight can be given these studies in an evaluation of the scientific evidence regarding this question

An investigation of cancer mortality in amateur radio operators in Washington State and California was conducted by linking the US Federal Communications Commission Amateur Radio Station and/or Operator licence file (n=67,829) with the death files in those two states for 1979-1984 (Milham S Jr 1988a). A significantly decreased SMR was found for all cancers, based on a very large number of deaths (2 485) (Table 1). No information about levels of RF exposure was available in this study. When the analyses were carried out by license class (which partly reflect number of years of use), SMRôs were also below 1 (Milham S Jr 1988b).

An investigation of cancer among Norwegian female radio and telegraph operators working at sea was conducted by linking the Norwegian Telecom cohort (2 619) with the Cancer Registry of Norway for 1961-91 (Tynes et al. 1996). No information about individual exposures to RF was provided ï the exposed group was defined as the entire cohort. Workplace RF spot measurements were performed in the radio rooms of the ships; exposure levels varied with location; at the operatorôs desks, however, they were below the detection level. A slight non-significant increase in all cancer incidence was observed compared to the general Norwegian population (Table 1).

A retrospective cohort study of cancer incidence among 22,197 male police officers employed in Ontario (Canada) police departments was conducted by linking the police employee records with the Ontario Cancer Registry for 1964-95 (Finkelstein 1998). No information about individual exposures to radar emissions was provided - the exposed group was defined as the entire cohort. No increased incidence was seen for all cancers compared to the general population of Ontario (Table 1).

The mortality of a cohort of Italian plastic-ware workers exposed to radiofrequency (RF)-electromagnetic fields generated by dielectric heat sealers was investigated over the period 1962-92 (Lagorio et al. 1997). Workers were classified into 3 groups based on their job title and period of assignment: RF-sealer operators (302 women and 4 men), other labourers and white collar workers. Only the first group was considered to be exposed to RF and findings of a survey in the mid 1980´s showed that in that period, before procedures were adopted to limit exposures, recommended IRPA-ICNIRP limits of 10 W/m^2 were frequently exceeded. Analyses were restricted to women workers (481 in total) because of the small number of men RF-sealer operators. The SMR for all malignant neoplasms was 2.0 (95% CI 0.7, 4.3, based on 6 deaths). One leukaemia death was observed among RF-sealers, compared to 0.2 expected. The small number of subjects in this study limits the interpretation of these results.

Cancer mortality was studied in the cohort of all US Motorola workers employed between 1976 and 1996 (Morgan et al. 2000). This cohort was of interest because of the relatively high prevalence of RF exposure of the employees who are involved in designing, manufacturing and testing of wireless devices. A job-exposure matrix allowed the categorisation of workers into four groups on the basis of their likely level of RF exposure (background, low, moderate and high, with average score values of 0, 1, 6 and 100 W respectively). The cohort included 195,775 workers who contributed 2.7 million person-years (PYs) of follow-up during the period 1976-1996. For peak exposure, the moderate and high RF exposure categories included 12,911 and 11,710 workers, respectively, and 7.2% and 6.5% of the total PYs of follow-up. (When usual exposure was considered, the numbers were smaller 8,097 and 8,907 workers, respectively, and 4.3 and 4.9% of the total PYs of follow-up).A substantial healthy worker effect was observed in this cohort, though the SMR for all cancer deaths is not given. Numbers of deaths by specific types of cancer were small among the workers classified as moderately or highly exposed based on their peak exposure: 7 CNS deaths, 21 deaths from neoplasm of the lymphatic and haematopoietic system (Table 1).

Brain cancer

Results of brain cancer analyses in relation to occupations involving RF/MW field exposures were also reported in all the cohort studies described above. The number of brain cancer cases in all but three studies (Milham S Jr 1988a;Finkelstein 1998;Groves et al. 2002) was very small (<=10). These studies do not therefore provide information on the risk of brain cancer from RF exposure. In the Milham study, a small, non-significant increased risk was seen (Table 1). When analyses were carried out by licence class, elevated SMRôs were found among general and advanced class license holders (SMR 1.8, based on 11 cases in each group ï confidence interval not given), two groups thought by the authors to be long term users (Milham S Jr 1988b). In the Finkelstein study, police officers had a slightly reduced brain cancer incidence than the general population, although this was not statistically significant. In the Groves study, subjects in the high-exposure stratum also had a non-significantly reduced risk of brain tumours.

Brain cancer in relation to occupations involving RF/MW field exposures was also studied in two case-control studies (Grayson 1996;Thomas et al. 1987). (Grayson and Lyons 1996) carried out a case-control study nested within a cohort of male air force workers. The study included 230 cases and 920 controls matched on year of birth and race. A complete lifetime occupational history was obtained by questionnaire. A job title-time exposure matrix utilising potential intensity scores was used to estimate potential exposure to RF/MW fields. Results showed a small excess risk of brain tumours for workers ever exposed to RF/MW fields after adjustment for age, race and military rank based on 94 exposed cases (Table 1); no association was seen between level of exposure and brain cancer risk, however.

A case-control study of brain and CNS tumours was carried out in three states in the US (Thomas et al. 1987). The study included 435 cases and 386 controls, matched on age and year of death and area of residence. Lifetime occupational histories were obtained from interviews and occupations were classified with respect to MW/RF radiation by industrial hygienists. The relative risk for all brain tumours, adjusted for education level, was elevated among men ever exposed to MW/RF radiation, based on 69 exposed cases and was significantly elevated among men exposed for 20 or more years. The excess risk for MW/RF radiation-exposed was restricted to workers with electrical or electronic jobs, however, while no excess was seen for other MW/RF exposed workers. It is noted that an excess was also seen for workers who had electrical or electronic jobs not involving MW/RF exposure. It is thus unlikely that the observed increased risk among MW/RF exposed workers is related to the MW/RF exposure.

The effects of occupational exposure to radiofrequency EMF on brain tumours were assessed in the German Interphone study (Berg et al. 2006). Information from the core INTERPHONE questionnaire (which included information on the subjectôs occupational history and history of working with selected sources of exposure to ELF and RF) was used to classify subjectôs degree and likelihood of occupational exposure to RF, based on a review of the literature and on the opinion of industrial hygienists. The study included 381 meningioma and 366 glioma cases with 1494 controls (Berg et al. 2006). No significant association between occupational exposure to RF and risk of brain tumours was found. For glioma, the OR for highly exposed subjects (22 cases and 37 controls) was 1.22 (95% CI 0.69, 2.15), it was 1.39 (95% CI 0.67, 2.88 ï 13 cases and 20 controls) when restricted to high exposure for 10 years or more. For meningioma, the corresponding ORs were 1.34 (95% CI 0.61, 2.96 ï 11 cases and 17 controls ï for high exposure) and 1.55 (0.52, 4.62 ï 6 cases and 8 controls ï for high exposures for 10 years or more). These results are based on small numbers of subjects and need to be verified in further studies with higher sample size.

The possible relation between RF exposure and glioma was evaluated in the framework of a case-control study in Australia (Karipidis et al. 2007). The study included 416 cases of glioma

diagnosed between 1987 and 1991 in Melbourne and 422 controls matched by age, sex and postcode of residence. A detailed occupational history was obtained for each subject. Exposure to RF was assessed using a Finnish job exposure matrix (FINJEM), self-reports and expert hygienist review. 18 cases and 17 controls were classified as having been exposed to RF. No association was found between RF and risk of glioma (ORs respectively: 0.57 95%CI 0.16, 1.96; 1.80 95% CI 0.53, 6.13; and 0.89 95% CI 0.28, 2.81 in the lowest, middle and highest tertiles of exposures). Numbers of exposed subjects were small however in each of these exposure categories, with only 6 cases and 6 controls in the highest tertile of exposure (>52 W/m^2 years).

Lymphatic and haematopoietic cancers

Lymphatic and haematopoietic cancers (including leukaemia) were also analysed in relation to occupations involving RF/MW field exposures was also studied in the cohort studies described above. The number of cases in the Lilienfield and Tynes studies was very small (n=2) ï these studies do not therefore provide information on the risk of these tumours from RF exposure.

In the Milham study, a small, non-significant increased risk for leukaemia and for all lymphatic and haematopoietic cancers was seen (Table 1); the increase was significant for acute myeloid leukaemia (SMR 1.8, 95% CI 1.0-2.9, based on 15 cases); a non-significant increase was also seen for acute unspecified leukaemia. When analyses were carried out by licence class, elevated SMRôs were found among general (SMR 1.2, based on 26 cases ï confidence interval not given), and technician (SMR 1.6, based on 18 cases) class license holders, two groups thought by the authors to be long term users (Milham S Jr 1988a).

In the Szmigielski study, there was a large significant increased incidence of lymphatic and haematopoietic cancers was seen for military workers who worked in areas with high levels of pulse-modulated RF/MW radiation (Table 1). Among these malignancies, the increase was largest for chronic myelocytic leukaemia (SIR=13.9), acute myeloblastic leukaemia (SIR=8.6) and non-Hodgkin lymphomas (SIR=5.8) (Milham S Jr 1988a). As described above for all cancers, these results are difficult to interpret because of the unclear methodology used in this study.

In the second follow-up of Korean War Navy technicians (Groves et al. 2002), significantly elevated RRs were seen for leukaemia as a whole (Table 1) as well as for non-lymphocytic leukaemia (RR 1.82, 95% CI 1.05, 3.14 based on 20 deaths). Non-significantly increased RRs were also seen for ac. The risk was greatest (though not statistically significant) for acute non-lymphocytic leukaemia (RR 1.87, 95% CI 0.98, 3.58) and non significant increases were also seen for acute and chronic myeloid leukaemia (RR respectively 1.81 and 1.55 based on 11 and 5 cases respectively. In the Finkelstein study a non-significant reduction in risk of leukaemia was observed among police officers.

The study of US Motorola workers included 21 deaths from neoplasms of the lymphatic and haematopoietic system in workers classified on the basis of their peak exposure as moderately or highly exposed (10 in the highly exposed), 11 from leukaemia, 6 from NHL and 3 from HD (Morgan et al. 2000). No increased risk of these neoplasms was seen in comparison with workers with no exposure. The small numbers of cases limits, however, the exposure response analyses that can be done and their interpretation.

Other tumour types

Increases in risk of other specific tumours types (colorectal, breast, testicular, oesophageal/stomach) were also reported, but only in single studies (Table 1). Considering the number of tumour types examined in these studies, some of the significant results observed may have been due to chance.

Fertility and adverse pregnancy outcomes

Two studies of physiotherapists have been carried out to investigate the relationship between use of specialised equipment during pregnancy and the risk of adverse pregnancy outcomes.

In one study, members of the American Physical Therapy Association (n=42,403) were queried by mail as to pregnancy history and the use of microwave or radio frequency diathermy. (Ouellet-Hellstrom and Stewart 1993). A total of 1,753 reported miscarriages were compared to the same number of ñcontrolò pregnancies (any non-ectopic pregnancy, regardless of outcome). Women who reported use of microwave diathermy in the 6 months prior to conception and the first trimester of pregnancy were at increased risk of miscarriage (RR 1.28, 95% CI: 1.0-1.6). The risk increased with numbers of use of the equipment per month. It is noted that the information about miscarriage and exposure was self-reported, which may introduce a bias in the results.

A cohort study of delivery outcomes of 2,043 infants born to 2,018 physiotherapists in Sweden was conducted by linking the Medical Birth Register with the file of registered physiotherapists (Kallen et al. 1982). All 37 cases of major malformations and perinatal deaths were matched to two controls for maternal age, parity and time of delivery (n=74). Information on occupational exposures (including equipment used during pregnancy) was obtained from mothers by mail questionnaire. None of the mothers of cases used microwave equipment during pregnancy.

A cross-sectional study of employees of the Norwegian Navy (civilians and military, on ships and ashore) was conducted in 2002 through the use of a mail questionnaire (Mageroy et al. 2006). The overall response rate ws 58% (2,265 out of 3,878). Service aboard a missile torpedo boat, with HF, VHF and UHF transmitters in radars was associated with an increased prevalence ratio of congenital malformations (PR 4.0, 95% CI 1.9, 8.6) and still born and perinatal deaths (PR 4.1, 95% CI 1.7, 8.9) in offspring. These results are based on very small numbers ï 8 cases of congenital anomalies and 6 of stillbirths and deaths within 1 week of birth among the offspring of persons who had served on this boat. Further analyses restricted to military men who had completed their compulsory military service showed an increased risk of infertility among telecommunication (OR 1.72, 95% CI 1.04, 4.09) and radar/sonar (OR 1.18, 95%CI 1.27, 4.09) workers(Møllerløkken and Moen 2008).

A record linkage study was conducted in Norway to assess potential associations between paternal occupational exposure to RF and adverse pregnancy outcomes including birth defects (Mjøen et al. 2006). Information on occupation was obtained from census and an expert panel constructed an exposure classification (possible and probable exposure) based on job title. Data on reproductive outcomes was derived from the Medical Birth Registry of Norway. Among the 1.1 million births recorded in the period 1976-1995, information on paternal identity and occupation was available only for about 49%. No increased risks of congenital malformations as a group were observed. In the offspring of fathers most likely to have been exposed, an increased risk was observed for preterm birth (OR 1.08 95% CI 1.03, 1.15) and a decreased risk for cleft lip (OR 0.63 95% CI 0.41, 0.97). In the medium exposed group, an increased risk was observed for a category of ñother defectsò (OR 2.40 95% CI 1.22, 4.70), and a decreased risk for a category of ñother syndromesò (OR 0.75, 95% CI 0.56, 0.99) and upper gastrointestinal defects (OR 0.61, 95% CI 0.40, 0.93).

Heart disease

A cross-sectional survey of 5,187 male physiotherapists was carried out using a mailed questionnaire on personal health history, including use of diathermy (Hamburger et al. 1983). The prevalence of a number of health conditions was compared among groups classified into high and low exposure categories ï based on length of employment and frequency of treatment ï for exposure to various types of diathermy modalities (ultrasound, microwave, short-wave, infrared).

A significant association was seen between heart disease and frequent use of microwave (OR 2.5, 95% CI:1.1-5.8) diathermy. The response rate in the study was low (58%) however and information about health condition and exposure was self-reported, which may introduce a bias in the results.

Other

A questionnaire survey of subjective symptoms and health status was conducted in Sweden among RF plastic sealer operators (Wilen et al. 2004). The study included 35 sealers and 37 controls. A neurophysiological examination and 24 hour ECG were also conducted. Measurements showed that the RF operators were exposed to rather high electric and magnetic fields. RF sealers appeared to have a lower heard rate and more episodes of bradicardia than controls, to have a higher prevalence of fatigue, headaches and warmth sensation in the hands and a slightly disturbed discrimination ability compared to the control group. Numbers of subjects in this study are small and it is not clear from the methods how the controls were chosen and whether they might differ with respect to age, sex or other variables of importance for the endpoints studied.

Studies of health effects from mobile phones

Descriptive epidemiological studies

A number of descriptive studies have been conducted to assess the potential impact of mobile phone use on the risk of tumours either through analyses of time trends of brain and other types of tumours - see for example (Cook et al. 2003;Lahkola et al. 2007;Lonn et al. 2004b;Klaeboe et al. 2005;Roosli et al. 2007) or through analyses of distribution of laterality of tumours. While these studies did not identify any increases that could be correlated with increases in mobile phone use in these countries, such ecological analyses are limited in their ability to reveal potentially small increases in risk for diseases with a long latency period.

Cohort studies

Up to now, two cohort studies of mobile telephone studies have been conducted, one in the US and one in Denmark.

In the USA a large cohort study of over 250,000 portable and mobile telephone subscribers was undertaken to investigate all cause mortality for users of the two types of phones. After one year of follow-up, in 1994, no difference in overall mortality among these two groups (RR=0.86 90%C.I: 0.5-1.5 for portable vs. mobile phone users) (Rothman et al. 1996). The cohort was extended to include a second mobile phone operator (resulting cohort size 285,561 subjects) and information was obtained ï for non-corporate users ï concerning start of service date, number of minutes billed and numbers of calls made and received during 2 months in 1993. For legal reasons, the follow-up could not be prolonged and the length of follow-up for this cohort study is restricted to one year, yielding 95 deaths from cancer, including 2 from brain tumours and 4 from leukaemia among mobile phone users. This cohort therefore provides no information on risk of cancers related to RF radiation from mobile telephones.(Dreyer et al. 1999).

A similar study was conducted in Denmark, where a nationwide cohort was set-up including 420,095 persons with a first cellular non-corporate telephone subscription between 1982 and 1995 (Johansen et al. 2001). This cohort was followed-up for cancer morbidity through 2002 (Schuz et al. 2006c). Significant deficits were observed in the incidence of cancer in general (SIR = 0.95; 95% CI 0.93, 0.97, based on a total of 14,249 cancers), of smoking related cancers (SIR 0.88, 95% CI 0.86, 0.91 ï 3,758 cases) and of a number of other cancer types in men, compared to the

general population, suggesting that the population of mobile phone subscribers may have a healthier lifestyle than the general population in Denmark, and hence that the SIRs in this study may be underestimated. For brain tumours, an SIR of 0.97 was observed overall, based on 580 cases; when analyses were restricted to subjects who had subscriptions for 10 years or more, the SIR was significantly reduced (OR 0.66, 95% CI 0.44, 0.95), based on only 28 cases. The SIRs for acoustic neuromas (0.73), salivary gland tumours (0.77) and eye tumours (0.96) were not elevated; they are based on small numbers (32, 26 and 44 cases respectively) and no analyses are presented for long-term subscribers. There was also no increased risk of leukaemia (SIR 1.00, based on 341 cases). The use of information on subscriptions obtained from operators rather than from the study subjects, as is the case in most of the case-control studies described below, has the advantage of not being subject to recall bias. It does, however, carry other problems of its own. In particular, it happens fairly frequently that the subscriber is not the primary user of the phone, in particularly in a family. Further, no information is available on the actual amount of use of the phone and the fact of having had a subscription 10 years in the past does not necessarily mean the subject has used the phone for that long. Also, the cohort does not include persons with corporate subscriptions (who may in fact, particularly in early years, have been heavier users than those with personal subscriptions) or subjects who started their first subscription after 1995. As these subjects are included in the general population (i.e. the comparison population), SIRs in this study are likely underestimated. It is therefore difficult to draw conclusions from this study on the possible association between mobile phone use and the risk of cancer.

Case-control studies

The vast majority of studies of cancer risk in relation to the use of mobile telephones used a case-control rather than a cohort study design, focusing generally on tumours that arise in some of the tissues that absorb most of the RF energy during phone conversations, the CNS (glioma, meningioma and acoustic neurinoma) and the parotid gland.

All of the studies published to date, except the earliest studies (Inskip et al. 2001;Muscat et al. 2000;Muscat et al. 2002;Auvinen et al. 2002), have either been conducted either within the framework of the international collaborative INTERPHONE study (Cardis et al. 2007) or by the group of Hardell and collaborators in Sweden (Hardell et al. 2005b;Hardell et al. 2005a). The study designs are therefore summarised briefly here in order to avoid repetition in the individual subsections below.

Study design

Swedish Hardell studies

The studies by Hardell and collaborators included both men and women aged 20-80 at the time of diagnosis and living (unless otherwise specified in the sections below for specific tumour types) in the medical administrative areas of Stockholm, Uppsala/Örebro, Linköping and Gothenburg in Sweden.

Cases were identified from the regional cancer registries and had to have a histopathology record. An additional eligibility criterion compared to most other studies is that the case had to be still alive at the date of start of the study. One control was extracted from the Swedish Population Registry for each case and was matched for sex, age (in 5-year age groups) and geographical area. Information on mobile and cordless telephone use was collected through a mail questionnaire sent to both cases and controls, at least 6 months after the diagnosis for cases.

Questions were included about the type of phone, years of use and brand name, prefix of phone number (to identify analogue and digital phones) and, for each type of phone, mean number and length of daily calls, use of hands-free devices and side of the head on which the phone was generally used. Calculations of mobile phone variables (number of years of use, cumulative hours of use) did not include phone use in the year preceding the diagnosis for cases (and the same year for matched controls).

INTERPHONE studies

The national INTERPHONE studies were all based on a common core protocol (Cardis et al. 2007). INTERPHONE was set-up as a multinational caseï control study, to investigate whether mobile phone use increases the risk of cancer and, more specifically, whether the RF fields emitted by mobile phones are carcinogenic. The study focused on tumours arising in the tissues most exposed to RF fields from mobile phones: glioma, meningioma, acoustic neurinoma and parotid gland tumours.

Sixteen study centres in thirteen countries (Australia, Canada ï centres: Montreal, Ottawa, Vancouver ï, Denmark, Finland, France, Germany, Israel, Italy, Japan, New Zealand, Norway, Sweden, and the UKï centres: North and South) participated in INTERPHONE.

Study population

In Australia, Canada, France, Germany, Italy, Japan and New Zealand, the source population was restricted to major metropolitan areas where mobile phones were first introduced. Major treatment centres for the diseases of interest are concentrated in these areas and most of the population is unlikely to go out of the region for diagnosis and treatment. In Denmark, Finland, Israel, Norway and Sweden the study was largely nationwide. The UK-South study was restricted to the South East of England, urban and rural, and the UK-North study encompassed both urban areas and sparsely populated rural areas.

All residents in the study regions (men and women), aged 30 to 59 were eligible for the study; additional eligibility criteria, such as citizenship and proficiency in the local language were imposed in some study centres. The choice of age range aimed to maximise the likelihood of exposure. Mobile phone use is a relatively new phenomenon. Until the late 1990ôs, for economic and social reasons, mobile phone use was mainly restricted to people in the age range most likely to use the phones for business purposes (Cardis and Kilkenny 1999). In some instances, however, individual countries chose to widen the age range for the cases.

Case definition and ascertainment

Eligible cases were all residents of the study region diagnosed during the study period with a confirmed first primary glioma, meningioma, or acoustic neurinoma. Eight centres (Australia; Canada-Montreal, -Ottawa and -Vancouver; Denmark; Israel; Italy; Sweden) also included malignant parotid gland tumours. Because benign parotid gland tumours may be treated in a very large number of institutions, most centres found it logistically difficult to ensure complete ascertainment, and only Canada-Ottawa, Israel and Sweden included them. All diagnoses were either histologically confirmed or based on unequivocal diagnostic imaging.

Each centre established procedures for the rapid ascertainment of cases from participating diagnostic and treatment units, which was particularly important for glioma patients, whose health can deteriorate quickly. Close monitoring of case ascertainment was essential and study centres used secondary sources to improve ascertainment levels. Secondary sources included medical archives, hospital discharge and billing files, and hospital or regional cancer registries. Enrolment

of cases through secondary sources often implied longer delays in case ascertainment and consequently lower participation.

Control eligibility and selection

Controls were randomly selected from the source population. The sampling frame depended on the local situation. The study design called for controls to be individual- or frequency-matched to cases, with the number of controls varying according to the tumour type: 1 control per case for brain tumours; 2 for acoustic neurinoma; and 3 for parotid gland tumours. In Germany, two controls were selected for each brain tumour case. In Denmark controls found to have had any previous cancer (excluding non-melanocytic skin cancer) were excluded. Controls were matched at least on year of birth (within 5-year categories), sex and study region. In Israel controls were also matched on country of birth.

Controls were individually matched to cases in seven study centres (Canada-Ottawa, -Vancouver, France, Israel, Japan, New Zealand and UK-North). In the other centres, individual matching was conducted *post hoc*, with cases being assigned one or more controls (depending on the type of tumour), chosen to have been interviewed as close as possible in time to the case, from among those who fit the matching criteria.

Collection of information on individual study subjects

Whenever possible, consenting subjects were interviewed face-to-face by trained interviewers using a computer-assisted personal interview (CAPI) questionnaire. Only Finland used a paper version of the questionnaire. In situations where cases were quite ill or confused, a spouse or partner or other family member could assist in the interview. In exceptional cases, telephone interviews were conducted with difficult-to-reach subjects. When the study subject had died or was too ill to participate, a proxy respondent was interviewed where this was possible and permitted by ethics committees.

The study questionnaire covered demographic factors, mobile phone use (detailed below), use of other wireless communication devices including cordless DECT telephones, occupational exposures to EMF and other potential confounders or risk factors for the diseases of interest (including exposure to ionising radiation, smoking and the subjectôs personal and familial medical history). Specific questions on exposure to loud noise and hearing loss were asked of acoustic neurinoma cases and their controls (and of all controls in centres using frequency matching for all tumour types combined).

The questionnaire contained a detailed section on history of mobile phone use. These questions were asked only of regular mobile phone users (defined as those with an average of at least one call per week for a period of 6 months or more). A compendium of show cards of mobile phones, including pictures of hundreds of models, was compiled and updated during the course of the study to assist study subjects in recognising the phones they had used.

For each phone used, detailed questions were asked about the phone model, the operator, the initial pattern of use of the phone (including network operator and average number and duration of calls) and any subsequent changes in use. Questions were also asked about the proportion of time in which the phones were used in urban, suburban or rural settings, while stationary or moving in a vehicle, how often the antenna was extended, and whether headsets or hands-free kits were used. The side of the head on which the phone was usually held (i.e. the laterality of phone use) and the handedness (left or right-handed) of the subject were recorded.

Attained level of education was used as a proxy for SES. As education systems and attained levels do not have a direct correspondence from one country to another, country-specific options for

responses were used. Marital status and, where appropriate, education level of the spouse were also recorded.

Detailed diagnostic information was obtained from medical records for all cases interviewed and for non-interviewed cases in most study centres. This information included anatomical location and side of the tumour, its histopathology, including whether benign, malignant or of uncertain behaviour.

Since intracranial RF-energy deposition from mobile phones is non-uniform, with most of the energy absorbed in the vicinity of the phone, the probable location of the origin of the brain tumours was identified as precisely as possible so that the RF ñexposureò at that location could be evaluated. Neuro-radiologists in each centre reviewed the radiological images (MRI and CT scans) or records and recorded tumour location on a generic 3-dimensional grid map of the human head, made up of cubes 1 cm^3 in size, which was developed for the purpose. The cuts used in the grid correspond to the most commonly used acquisition planes in MRI and CT scans (sagittal, coronal and axial). The details of this methodology will be published separately.

Methodological studies

A number of methodological papers have been published or are in preparation (Vrijheid, Deltour et al, 2006; Vrijheid, Cardis et al, 2006; Cardis, Richardson et al, 2007; Berg et al, 2005; Hepworth et al, 2006; Parslow et al, 2003; Samkange-Zeeb et al, 2004; Lakhola et al, 2005; Cardis et al, 2008; Vrijheid et al 2008; Tokola et al, 2008; Vrijheid et al, accepted), addressing issues of study design, participation bias, recall error and exposure assessment that are essential in the interpretation of results from the study:

Validation studies were conducted to evaluate potential error in the recall of phone, indicating that of phone use was subject to moderate systematic and substantial random error (Vrijheid et al. 2007;Vrijheid et al. 2008a). Errors appeared to be larger for duration of calls than for number of calls, and phone use was under-estimated by light users and over-estimated by heavy users. Comparison of a sample of cases and controls in three countries showed little evidence for differential recall errors overall or in recent time periods, but apparent overestimation by cases in more distant time (Vrijheid et al. 2008a).

The possible effects of recall errors were evaluated using Monteï Carlo computer simulations. Results suggest that random recall errors can lead to a large underestimation in the risk of brain cancer associated with mobile phone use. The large random errors seen in the validation study were found to have larger impact than plausible systematic errors. Differential errors in recall had very little additional impact in the presence of large random errors (Vrijheid et al, 2006). However, the apparent overestimation by cases in more distant time periods could cause positive bias in estimates of disease risk associated with mobile phone use (Vrijheid et al, 2008).

Participation rates varied by tumour type and between cases and controls (Table 2). The overall participation was 65% for glioma cases, 78% for meningioma, 82% for acoustic neurinoma and 54% among controls and showed large variation across centres,. Among glioma cases, the major reason for non-participation was death or ill health; in controls it was refusal (65% of non-participants) and inability to contact (27%). The potential for selection bias was therefore evaluated, using information from non-response questionnaires completed by a sub-set of non-participants. This study suggests that refusal to participate is related to less prevalent use of mobile phones. This could result in a downward bias of 10 to 20%, depending on the scenario used, in odds ratios for regular mobile phone use (Vrijheid et al. 2008b).

Because exposure to RF from phones is localized, if a risk exists it is likely to be greatest for tumours in regions with greatest energy absorption. The spatial distribution of RF energy in the

brain was characterised, using results of measurements made on over 100 phones used in different countries. Most (97ï 99% depending on frequency) appears to be absorbed in the brain hemisphere on the side where the phone is used, mainly in the temporal lobe. The average relative SAR is highest in the temporal lobe and the cerebellum and decreases very rapidly with increasing depth, particularly at higher frequencies. Analyses of risk by location of tumour are therefore essential for the interpretation of results studies of brain tumours in relation to mobile phone use (Cardis et al. 2008;Varsier et al. 2008)

Assessment of exposure from mobile phones

The study used two main approaches to characterising exposure from use of mobile phones. The first depended only on the mobile phone use history derived from questionnaire responses and the second attempted to evaluate the amount of RF energy absorbed in different areas of the brain.

In both approaches, exposure was calculated up to a given reference date, which was set to one year before the date of the diagnosis of the case in each matched set. Evaluation of RF energy absorption required the localisation of the tumour, which was defined crudely in terms of the side of the head, or lobe of the brain, or more precisely, from the exact location of the tumour ascertained and recorded as described above. Exposure for controls was estimated at the location of the tumour of their matched case.

As described above, the responses to the CAPI questionnaire provided detailed information on historical patterns of mobile phone use for regular users. This information allowed the computation of relevant indices of exposure such as cumulative call time, average call duration and cumulative number of calls, overall and within specific time-windows, with and without use of hands free devices.

The distribution of RF energy absorption in the head varies according to a number of factors, including the type of telephone and network (frequency and type of transmission: digital or analogue, continuous or discontinuous, use of power control), as well as the actual patterns of use of the phone described above. There was no existing algorithm or set of coefficients that could be used to estimate exposure given a specific pattern of mobile phone use. A model was therefore developed and validated for such an algorithm, assessing the relative importance of the different factors and testing the adequacy of the proposed approach. The algorithm combines questionnaire responses with information on tumour location, the distribution of the specific absorption rate (SAR) of RF in the head (Cardis et al. 2008) and factors that modify the amount of RF energy emitted by the phone (Vrijheid et al, submitted).

Tumour risk

Brain and CNS tumours

All brain tumours

Auvinen and collaborators conducted a registry based case-control study of brain tumours and salivary gland cancers among cellular phone users in Finland (Auvinen et al. 2002). The study included all 398 brain tumour cases and 34 salivary gland cancers diagnosed in patients aged 20 to 69 years in Finland in 1996 and registered in the Finnish Cancer Registry. For each case, five age and sex matched controls were selected from the Population Registry. Record linkage allowed the collection of information (type of subscription ï analogue vs. digital ï and start and end date of subscription) from the two network operators that were operating in 1996 for cases and controls who had private mobile phone subscriptions. Use of 450 MHz analogue phones was excluded. The

proportion of mobile phone subscribers was low: 40 (10%) of the 398 brain tumour cases had had an analogue subscription (only 17 for more than 2 years) and 16 (3%) a digital subscription (1 for more than 2 years). The corresponding figures among controls were 134 (7%) and 89 (4%) respectively for analogue and digital subscriptions. The OR for ever having had a mobile phone subscription was 1.3 (95% CI 0.9, 1.8) overall ï 1.6 (95% CI 1.1, 2.3) for analogue only.

A case-control study of brain cancer was conducted in 5 US academic medical centres, in New York, Providence Rhode-Island and Boston, between 1994 and 1998 (Muscat et al. 2000). The study included 469 cases aged 18 to 80 years and 422 matched hospital controls (chosen among inpatients of the same hospital admitted for benign conditions or for cancers excluding leukaemia and lymphoma). An active mechanism was set-up to identify cases rapidly and interview them as soon as possible after their diagnosis. Information was collected using a structure questionnaire that included questions, for each type of mobile phone used (handled, bag, car), about subscriptions, number of years of use, minutes/hours of use per month, year of first use, manufacturer and average monthly bill. Information was also collected about the hand used to hold the telephone. Of 571 eligible cases approached, 469 (82%) were successfully interviewed. Among controls, the response rate was 90%. Use of mobile phones among the study subjects was still at the time of the study a rare phenomenon: 66 cases (14%) and 76 controls (18%) reported using them (OR 0.85, 95% CI 0.6, 1.2). The OR was below one for all histological categories or brain cancer except for neuroepitheliomatous cancers (OR 2.1, 95% CI 0.9, 4.7, based on 35 cases and 14 controls). The mean duration of use was less than 3 years in both cases and controls, and only 17 cases and 22 controls had used phones for 4 years or more.

A case-control study was also conducted in hospitals in Boston, Phoenix (Arizona) and Pittsburgh in the US (Inskip et al. 2001). The study included 782 cases (489 glioma, 197 meningioma and 96 acoustic neurinoma) diagnosed between 1994 and 1998 and 799 matched hospital controls with non-malignant conditions. Participation rate was 92% among cases and 86% among controls. A rapid ascertainment mechanism was set-up to identify the cases rapidly after their diagnosis and most (80%) were enrolled and interviewed within 3 weeks after their diagnosis. Again, in this study, use of mobile phones was a relatively recent phenomenon: 232 cases (29%) reported having used a mobile phone at least 5 times, 139 reported regular use and 22 had used one for 5 years or more. The OR for regular use was 0.8 (95% CI 0.6, 1.1).

Glioma

Within the above mentioned registry based case-control study in Finland (Auvinen et al. 2002), analyses were also conducted for glioma specifically, based on 198 cases and their matched controls. Again, the proportion of subscribers was small: 26 out of 198 among the cases had analogue subscriptions, only 11 for more than 2 years and only 10 had digital subscriptions, none for more than 2 years. The OR for every having had a mobile phone subscription was 1.5 (95% CI 1.0, 2.4) overall; it was 2.1 (95% CI 1.4, 3.4) for analogue only and 1.0 (95% CI 0.5, 2.0) for digital only. A slight increasing trend was seen with increasing duration of analogue subscription in continuous analyses (OR 1.2 per year ï 95% CI 1.1, 1.5).

Within their case-control study described above, Inskip and collaborators considered specifically the risk of glioma (Table 3) (Inskip et al. 2001). The study included 489 cases of glioma, 85 of which reported regular use of mobile phones (OR 0.8, 95% CI 0.6, 1.2). Only 11 cases had used phones for 5 years or more.

Hardell and collaborators have conducted three case-control studies of malignant brain tumours, mainly glioma, in Sweden (Hardell et al. 1999;Hardell et al. 2002;Hardell et al. 2005b). They have conducted pooled analyses of the results from the later two studies (Hardell et al. 2006a), and only these are shown here as they are the most comprehensive. The combined analyses included

malignant tumours diagnosed between 1997 and 2003 in the regions of Sweden mentioned above (see section on study design above).The analyses included 905 cases and 2,162 controls, respectively 90% and 89% of the cases and controls who were considered eligible for the study. As noted above, unlike most other studies, cases who had died were not considered to be eligible in this study. Results are presented separately for analogue and digital phones and for all malignant tumours, high-grade astrocytoma and low-grade astrocytoma (Table 3). Overall, 178 cases were classified as having used analogue phones and 402 digital phones. The respective ORs were 1.5 (95% CI 1.1, 1.9) and 1.3 (1.1, 1.6) for analogue and digital phones respectively. The ORs appeared to increase with increasing latency ï OR 2.4 (95% CI 1.6, 3.4) and 2.8 (95% CI 1.4, 5.7) for use 10 years or more in the past for analogue and digital phones respectively. The ORs appeared to be higher for high-grade than for low-grade astrocytoma (Table 3). The ORs were also higher for ipsilateral than for contralateral phone use, although an elevated OR was also seen for contralateral use for analogue phones in high-grade astrocytoma patients. For digital phones, the OR for regular use related to having started using mobile phones before the age of 20 appeared to be higher (3.7, 95% CI 1.5, 9.1, based on 16 cases) than for start at later ages. It should be noted that comparisons of results across the three studies show a trend of increasing ORs with time, with statistically significant heterogeneity between studies (Feychting, personal communication 2008). This may in part be related to the fact that the most recent study includes a higher proportion of long term and heavy users than the earlier studies; other methodological differences in the conduct or analysis of the studies may also contribute to this and hence results should be interpreted with caution.

Within INTERPHONE; results have been published of national analyses in Denmark, France, Germany, Japan, Norway, Sweden and the UK, as well as joint analyses of data from Nordic countries and UK-South ((Christensen et al. 2005;Hepworth et al. 2006;Hours et al. 2007a;Klaeboe et al. 2007;Lahkola et al. 2007;Lonn et al. 2005;Schuz et al. 2006a;Takebayashi et al. 2008). Study characteristics and results are summarised in Table 3.

In most studies, the OR related to ever having been a regular mobile phone user was below 1 (Table 3), in some instances statistically significantly so, possibly reflecting participation bias or other methodological limitations.

In analyses by level of use, results by duration of use and time since start of use vary across studies (Table 3). Confidence intervals are wide however, due to the small number of long-term users in individual studies and results are therefore compatible. Pooling of data from Nordic countries and part of the UK yielded the largest number of long term users (143) (Lahkola et al. 2007). Among these, based on 77 cases, a significantly increased risk of glioma was found for reported use of mobile phones for 10 years or more on the side of the head where the tumour developed (OR 1.39, 95% CI 1.01, 1.92). This finding could reflect either a causal association (as the vast majority of the RF energy is absorbed on the side of the head where the phone is held ï see Methodological Issues section above) or an artefact, related to differential recall between cases and controls.

Results of analyses by level of use (total number of calls, total duration of calls) are difficult to compare and to summarise in a tabular form, as most studies have used different cut points. The most comprehensive information comes from the pooling of data from the Nordic and South-UK INTERPHONE studies (Lahkola et al. 2007). Although all of the ORs by level of use, by number of calls and duration of calls are below 1 (Table 4), it is of interest that the magnitude of the ORs appears to increase with increasing amount of use. This increase is in fact statistically significant for number of calls in analyses in which light users are used as the reference group instead of non-users (this type of analysis is conducted to evaluate the possible impact of a selection bias that could be related to use of mobile phones in the study).

In the Japanese INTERPHONE study (Takebayashi et al. 2008), efforts were made to evaluate the maximum amount of RF energy absorbed at the location of the tumour; such analyses, gave an OR of 1.55 (95% CI 0.57, 4.19) related to the highest quartile of cumulative phone time weighted by maxSAR, based on 15 exposed cases; the OR was 5.84 (95% CI 0.96, 35.60) for subjects with cumulative maxSAR-hours of 10 or more W kg^{-1} ï hour; this result, based on few subjects (7 cases and 4 controls) needs to be investigated further.

Meningioma

Within the above mentioned registry based case-control study in Finland (Auvinen et al. 2002), analyses were also conducted for meningioma specifically, based on 129 cases and their matched controls. The number of subscribers was very small: 8 out of 129 among the cases had analogue subscriptions, only 2 for more than 2 years and only 3 had digital subscriptions, none for more than 2 years. The OR for every having had a mobile phone subscription was 1.1 (95% CI 0.5, 2.4) overall; it was 1.5 (95% CI 0.6, 3.5) for analogue only and 0.7 (95% CI 0.2, 2.6) for digital only (Table 5).

Within their case-control study described above, Inskip and collaborators considered specifically the risk of meningioma (Table 4) (Inskip et al. 2001). The study included 197 cases of glioma, 32 of which reported regular use of mobile phones (OR 0.8, 95% CI 0.4, 1.3). Only 6 cases had used phones for 5 years or more (Table 5).

As indicated above, Hardell and collaborators have conducted three case-control studies of benign brain tumours in Sweden (Hardell et al. 1999;Hardell et al. 2002;Hardell et al. 2005a). They have conducted pooled analyses of the results from the later two studies (Hardell et al. 2006b), and only these are shown here as they are the most comprehensive. The combined analyses included 916 meningioma diagnosed between 1997 and 2003 in the regions of Sweden mentioned above (see section on study design above) and 2,162 controls. Results are presented separately for analogue and digital phones (Table 5). Overall, 113 cases were classified as having used analogue phones and 295 digital phones. The respective ORs were 1.3 (95% CI 0.99, 1.7) and 1.1 (0.9, 1.3) for analogue and digital phones respectively. The ORs were slightly higher when use 10 years or more in the past was considered ï OR 1.6 (95% CI 1.02, 2.5) and 1.3 (95% CI 0.5, 3.2) respectively for analogue and digital phones. The ORs were also slightly higher for ipsilateral than for contralateral phone use, although an elevated OR was also seen for contralateral use for analogue phones. .

Within INTERPHONE; results have been published of national analyses in Denmark, France, Germany, Japan, Norway and Sweden, as well as joint analyses of data from Nordic countries and UK-South (Christensen et al. 2005;Hours et al. 2007a;Klaeboe et al. 2007;Lonn et al. 2005;Schuz et al. 2006a;Takebayashi et al. 2008;Lahkola et al. 2008). Study characteristics and results are summarised in Table 5.

The OR related to ever having been a regular mobile phone user was below 1 (Table 5), in all studies, in some instances statistically significantly so, possibly reflecting participation bias or other methodological limitations.

In analyses by level of use, results by time since start of use vary across studies but are generally close to 1 (Table 5). Confidence intervals are wide however, and these results are based on very small numbers of long-term users in individual studies, reflecting the fact that meningioma is more prevalent in women than men and that, in the early years of mobile telephony, most users were ñbusinessmenò. Pooling of data from Nordic countries and part of the UK yielded the largest number of long term users (73) (Lahkola et al. 2008) and an OR of 0.91 (95% CI 0.57, 1.26) related to start of use 10 years or more in the past. As for the glioma results, all of the ORs by number of calls and duration of calls are below 1.

Acoustic neurinoma

As part of the large case-control study in New York, Providence Rhode-Island and Boston mentioned above, Muscat and collaborators also studied the risk of acoustic neurinoma (Muscat et al. 2002). The study included 90 cases (18 years or older and diagnosed between 1997 and 1999) and 86 hospital controls (chosen among inpatients of the same hospital admitted for benign conditions or for cancers excluding leukaemia and lymphoma). Again, use of mobile phones among the study subjects was infrequent 18 cases and 23 controls reported using them (OR 0.9, CI not given) (Table 6). A non-significant increase was seen in subjects who reported using the phone for 3 years or more (OR 1.7, 95% CI 0.5, 5.1), based on 11 cases.

Within their case-control study described above, Inskip and collaborators considered specifically the risk of glioma (Table 6) (Inskip et al. 2001). The study included 96 cases of glioma, 22 of which reported regular use of mobile phones (OR 1.0, 95% CI 0.5, 1.9). Only 5 cases had used phones for 5 years or more and a non-significantly increased risk was seen among them (OR 1.9, 95% CU 0.6, 5.9),

The combined analyses of the two case-control studies of brain tumours conducted by Hardell and collaborators included 243 acoustic neurinoma diagnosed between 1997 and 2003 in the regions of Sweden mentioned above (see section on study design above) and 2,162 controls (Hardell et al. 2006b). Results are presented separately for analogue and digital phones (Table 6). Overall, 68 cases were classified as having used analogue phones and 105 digital phones. The respective ORs were 2.9 (95% CI 2.0, 4.3) and 1.5 (1.1, 2.1) for analogue and digital phones respectively. The ORs was similar higher for analogue phones when use 10 years or more in the past was considered ï OR 3.1 (95% CI 1.02, 2.5), based on 19 cases ï but lower for digital phones 0.6 (95% CI 0.1, 5.0) based on 1 case only. The ORs were also slightly higher for ipsilateral than for contralateral phone use, although elevated ORs was also seen for contralateral use. .

Within INTERPHONE; results have been published of national analyses in Denmark, France, Germany, Japan, Norway and Sweden, as well as joint analyses of data from Nordic countries and UK-South (Christensen et al. 2004;Lonn et al. 2004a;Takebayashi et al. 2006;Klaeboe et al. 2007;Schlehofer et al. 2007;Hours et al. 2007a;Schoemaker et al. 2005). Study characteristics and results are summarised in Table 3.

Again, in most studies, the OR related to ever having been a regular mobile phone user was below 1 (Table 6), possibly reflecting participation bias or other methodological limitations.

In analyses by level of use, results by time since start of use vary across studies (Table 6). Confidence intervals are wide however, due to the very small number of long-term users in individual studies and results are therefore compatible. Pooling of data from Nordic countries and part of the UK yielded the largest number of long term users (47) (Schoemaker et al. 2005). Among these, based on 31 cases, an increased risk of neurinoma was found for reported use of mobile phones for 10 years or more on the side of the head where the tumour developed (OR 1.30, 95% CI 0.8, 2.0) and a significantly increased risk in relation to duration of use of 10 years or more (OR 1.8, 95% CI 1.1, 3.1, based on 23 cases). As for glioma, this finding could reflect either a causal association (as the vast majority of the RF energy is absorbed on the side of the head where the phone is held ï see Methodological Issues section above) or an artefact, related to differential recall between cases and controls.

Other adult tumours

Salivary gland tumours

Within the above mentioned registry based case-control study in Finland (Auvinen et al. 2002), analyses were also conducted for salivary gland tumours specifically, based on 34 cases and their matched controls. The number of subscribers was very small: only 3 cases had analogue subscriptions (1 for more than 2 years) and only 1 had a digital subscription (Table 7)

A case-control study of salivary gland tumours was conducted in Sweden by the group of Hardell and collaborators (Hardell et al. 2004). The study included all cases diagnosed in the whole of Sweden between 1994 and 1999 or 2000, depending on the region. A total of 267 (out of 415 identified) cases and 1,053 (out of 1,152) controls participated in the study. Information about mobile phone use was collected through the same mail questionnaire as used by this group in their brain tumour study described above. The ORs were 0.92 (95% 0.58, 1.44) for use of analogue phones and 1.01 (95% CI 0.68, 1.50) for digital phones, based on 31 and 45 exposed cases respectively. The study included few long term users; only 6 cases had used analogue phones 10 years or more in the past and none had used digital phones for that long. Results for parotid gland tumours specifically were similar (OR for analogue phones 0.73, 95% CI 0.41, 1.29 and for digital phones 0.98, 95% CI 0.62, 1.55, based on 18 and 33 cases respectively) (Table 7).

Within INTERPHONE, results were published of analyses of the parotid gland case-control study in Sweden and Denmark (Lonn et al. 2006) and in Israel (Sadetzki et al. 2007) (Table 7). The analysis of data from Sweden and Denmark (Lonn et al. 2006), included 60 cases of malignant parotid gland tumours, 112 benign (pleomorphic adenoma) and 681 controls. 25 of the malignant cases and 77 of the benign were classified as regular users (ORs 0.7, 95% CI 0.4, 1.3 and 0.9, 95% CI 0.5, 1.5 respectively for malignant and benign tumours). The numbers of long term (2 and 7 respectively among malignant and benign tumour cases) and heavy users was small in this study. For benign tumours, a non-significantly increased OR was observed for reported use of 10 years or more on the side of the head where the phone was held (2.6, 95% CI 0.9, 7.9, based on 6 cases) although a decreased risk was observed when the phone was reported to be held on the other side of the head (OR 0.3, 95% 0, 2.3, based on 1 case). These results are difficult to interpret however as contralateral use is included in the reference group for the ipsilateral analyses and ipsilateral use in the reference group for contralateral analyses, thereby exaggerating any difference between the results of the two analyses.

The Israeli INTERPHONE study (Sadetzki et al. 2007) included 402 benign and 58 malignant cases and 1,266 individually matched controls. For the entire group, the OR related to regular mobile phone use was OR 0.87 (95% CI 0.68, 1.13) (Table 7); this OR, and all of the ORs in relation to level and duration of use were below 1, possibly reflecting selection bias or other methodological limitations. For ipsilateral use, the odds ratios in the highest category of cumulative number of calls and cumulative call time were 1.58 (95% CI 1.11, 2.24) and 1.49 (95% CI 1.05, 2.13), respectively. The risk for contralateral use was reduced, but not significantly so for either of these variables. Analyses restricted to regular users (in which light or recent users were used as the referent category instead of non-users in order to compensate for a possible selection bias related to mobile phone use) and to conditions that may yield higher levels of exposure (e.g., heavy use in rural areas) showed consistently elevated risks, suggesting a possible relation between heavy mobile phone use and risk of parotid gland tumours. Although this study included few long term users (13 cases had used mobile phones for 10 years or more), the Israeli mobile phone users are exceptionally heavy users compared to users in the other INTERPHONE countries. Additional investigations of this association, with longer latency periods and large numbers of heavy users, are needed to confirm these findings.

Intratemporal facial nerve tumours

A case-control study of tumours of the intratemporal facial nerve (IFN) was conducted in the US (Warren et al. 2003) at an academic, tertiary-care referral centre, using a structured telephone survey. METHODS: Patients with IFN tumours (n = 18) were case-matched with patients treated for acoustic neurinoma (n = 51), rhinosinusitis (n = 72), and dysphonia or gastroesophageal reflux disease (n = 69). The OR for IFN tumour was 0.4 (95% CI, 0.1-2.1) with regular cellular telephone use. Results from this study are difficult to interpret given the small number of cases, the inclusion in the control group of acoustic neurinoma (a tumour possibly related to mobile phone use) and the absence of long term heavy users in the study.

Uveal melanoma

Two case-control studies of uveal melanoma were conducted in Germany in the mid to late 1990s to assess the effects of occupational exposures on this type of tumour (Stang et al. 2001). Questions were asked about occupational use mobile phones and of radio sets. Together, the studies included 118 cases and 475 controls; 9 cases and 21 controls reported having used radiosets and 6 cases and 15 controls mobile phones at work. Increased ORs were found both for radioset exposures (OR 3. 95% CI 1.4, 6.3) and for probable and certain exposure to mobile phones (OR 4.2, 95% CI 1.2, 14.5). Information about mobile phone use in this study is very limited, and subjectôs answers were uncertain (with some reporting ñpossibleò exposure to mobile phones at work).

A descriptive epidemiological study in Denmark compared trends in the incidence of ocular malignant melanoma and in mobile phone subscriptions (Johansen et al. 2002). There was little evidence of an increase in incidence of this tumour in the period 1943 to 1996 or of a relation with trends in phone subscriptions in the latter part of the period (1982-1996). The number of subscriptions was relatively low, however, until 1992, and this study therefore provides little information about risk of this tumour.

Lymphoma

A case-control study was conducted in 4 areas of Sweden to evaluate the possible association between mobile phones and risk of non-Hodgkin's lymphoma (NHL) (Hardell et al. 2005c). The study included cases aged 18-74 and diagnosed between 1 December 1999 to 30 April 2002. Controls were frequency matched and selected from the national population registry. Information about mobile telephone use was obtained by questionnaire. A total of 910 (out of 1,129 eligible) cases and 1016 (92%) controls accepted to participate in the study. The vast majority of cases (819) were B-cell lymphomas; there were 53 T-cell lymphoma cases. No association was seen between use of mobile telephones (whether analogue or digital, ever or 10 years or more in the past) and the risk of B-cell lymphoma. Regarding T-cell lymphoma, a non-significantly increased risk was seen for ever use of analogue or digital phones (OR 1.56, 95% CI 0.64, 3.81 and 1.41, 95% CI 0.68, 2.92, based on 14 and 31 exposed cases, respectively). There was no apparent trend with time for analogue phones; for digital phones, the risk appeared to increase with increasing latency but this was based on very small numbers of cases.

Testicular cancer

A case-control study of testicular cancer was also conducted by the same group in Sweden (Hardell et al. 2007). The study included all cases diagnosed in men aged 20-75 in the whole of Sweden between 1993 and 1997. Overall 981 (out of 1,021 eligible) cases participated (542 seminoma and 346 non-seminoma cases) and 870 (89%) controls participated in the study. The

ORs for seminoma were 1.2 (95% 0.9, 1.6) for use of analogue phones and 1.3 (95% CI 0.9, 1.8) for digital phones, based on 125 and 98 exposed cases respectively. The study included few long term users; only 13 cases had used analogue phones 10 years or more in the past (OR 2.1, 95% CI 0.8, 5.1) and none at that time had used digital phones for that long. For non-seminoma, the ORs were 0.7 (95% CI 0.5, 1.1) and 0.9, CI (95% CI 0.6, 1.4), respectively for analogue and digital phones, based on 50 and 66 exposed cases. There was no evidence of an exposure response relationship and no association was found with place where the mobile phone was kept, such as trousers pocket.

Reproductive outcomes

The association between prenatal and postnatal exposure to cell phones and behavioural problems in young children was investigated within the framework of national birth cohort study in Denmark (Divan et al. 2008). Mothers of 13,159 children completed a follow-up questionnaire when their children reached 7 years of age in 2005 and 2006. The questionnaire included questions concerning the current health and behavioural status of their children, as well as past exposure to cell phone use, specifically use of mobile phone during pregnancy (including numbers of times per day and proportion of time the phone was on, use of hands-free equipment and location of the phone when not in use) and for children, current use of cellular and other wireless phones. After adjustment for potential confounders, the odds ratio for a higher overall behavioural problems score was 1.80 (95% CI 1.45, 2.23) in children with both prenatal and postnatal exposure to cell phones. Similar ORs were seen for different types of behavioural problems and ORs tended to be higher for prenatal than for postnatal exposures. Results of this study are difficult to interpret at present. The fact that the questionnaire was administered post-hoc, at age 7, may have led to differential recall bias. Only 65% of eligible mothers returned the questionnaire and this may represent a selected sample of the cohort. Further, confounding by some factors, including behavioural factors that may correlate with maternal phone use, could affect the results. It will be important to examine this association in other similar cohorts and to collect information about mobile phone use in pregnancy rather than at age 7 when the behavioural problems that are being investigated are already manifest.

Summary and conclusions - status of knowledge today

This report reviews and evaluates published epidemiological studies on RF and health. Included in the assessment are scientific studies that have been published primarily in peer reviewed scientific journals.

As outlined in the previous sections, many of the epidemiological studies reviewed here suffer from inadequate assessment of radio frequency exposure and, in particular in the case-control studies, from possible recall errors and selection bias. In addition, many studies had inadequate sample size, incomplete follow-up of subjects, lack of information on potential confounding variables and, in some cases, inadequate comparison groups and methods of analyses.

On the basis of the epidemiological studies reviewed, because of the inconsistencies of results and the limitations of these studies, it is not possible to evaluate at this time whether there exists a health risk from exposure to RF radiation, particularly at the levels of concern for mobile communication. A number of recent large studies of glioma, acoustic neurinoma and possibly parotid gland tumours appear to suggest a possible increased risk related to long term or heavy use of phones. It is unclear, however, whether the observed associations are real, reflecting a causal association, or artefactual, reflecting differential reporting between cases and controls.

In the short term, more information on a possible carcinogenic risk will be provided by the results of the international INTERPHONE analyses, based on larger numbers of long-term and heavy users than the individual studies, taking into account the results of the various methodological sub-studies and detailed localisation of tumours. The results of more detailed analyses, also underway, focusing on more precise localization of tumours using 3-dimensional radiological images, and on the analysis of the effect of RF exposure at the location of the tumour, using a gradient of RF emitted by mobile phones, will also be of great importance.

Research recommendations

INTERPHONE will mainly provide information on effects of exposure to RF in adulthood and only on the risk of brain and CNS tumours and of tumours of the parotid gland.

Studies of other outcomes and of exposures in childhood and adolescence are therefore sorely needed, as are surveillance studies of cohorts of mobile phone users in order to assess possible effects on a variety of cancer and non-cancer endpoints ï see for example research recommendations by a number of international bodies (WHO 2006;SCENIHR 2007;EMF-Net 2006). A number of studies are underway or starting that will address these issues (COSMOS, CEFALO, Mobi-Kids) in the medium and longer term future.

Further studies of occupationally exposed populations will also be important.

For these studies to be informative, however, it will be essential that the above described limitations are overcome and, in particular, that reliable and accurate individual estimates of RF exposure be available for all study subjects.

Evaluation of the Effect of Radiofrequency Radiation Emitted From Wi-Fi Router and Mobile Phone Simulator on the Antibacterial Susceptibility of Pathogenic Bacteria *Listeria monocytogenes* and *Escherichia coli*

M. Taheri[1], S. M. J. Mortazavi[2,3], M. Moradi[1], S. Mansouri[1], G. R. Hatam[4], and F. Nouri[5]

Abstract

Mobile phones and Wi-Fi radiofrequency radiation are among the main sources of the exposure of the general population to radiofrequency electromagnetic fields (RF-EMF). Previous studies have shown that exposure of microorganisms to RF-EMFs can be associated with a wide spectrum of changes ranged from the modified bacterial growth to the alterations of the pattern of antibiotic resistance. Our laboratory at the nonionizing department of the Ionizing and Non-ionizing Radiation Protection Research Center has performed experiments on the health effects of exposure to animal models and humans to different sources of electromagnetic fields such as cellular phones, mobile base stations, mobile phone jammers, laptop computers, radars, dentistry cavitrons, magnetic resonance imaging, and Helmholtz coils. On the other hand, we have previously studied different aspects of the challenging issue of the ionizing or nonionizing radiation-induced alterations in the susceptibility of microorganisms to antibiotics. In this study, we assessed if the exposure to 900 MHz GSM mobile phone radiation and 2.4 GHz radiofrequency radiation emitted from common Wi-Fi routers alters the susceptibility of microorganisms to different antibiotics. The pure cultures of *Listeria monocytogenes* and *Escherichia coli* were exposed to RF-EMFs generated either by a GSM 900 MHz mobile phone simulator and a common 2.4 GHz Wi-Fi router. It is also shown that exposure to RF-EMFs within a narrow level of irradiation (an exposure window) makes microorganisms resistant to antibiotics. This adaptive phenomenon and its potential threats to human health should be further investigated in future experiments. Altogether, the findings of this study showed that exposure to Wi-Fi and RF simulator radiation can significantly alter the inhibition zone diameters and growth rate for *L monocytogenes* and *E coli.* These findings may have implications for the management of serious infectious diseases.

Introduction

Antibiotic resistance is one of the most important threats to global health.[1] According to World Health Organization, this problem is rising dangerously to high levels worldwide, which leads to longer hospitalization, higher medical costs, and raised mortality.[2]

Bacteria are becoming resistant to almost all commonly available antibiotics and this is a worldwide problem.[1] Today, greater use of telecommunication technologies like Global System for Mobile communication (GSM), cordless phones, mobile base stations, wireless personal, and local area networks, such as bluetooth, has led to ever increasing exposure to radiofrequency electromagnetic fields (RF-EMF).[3] Therefore, living organisms are now being exposed to microwaves and radiofrequency radiation signals from various sources.[4] The effects of these radiations on the biological functions of living cells shows an emerging area of interest in human health with respect to environmental effects.[5] Several studies were conducted to confirm the effects of electromagnetic radiation on cell functions[6-8]; however, the findings obtained in these studies were controversial. In particular, it was proven that EMF can affect functional parameters (cell growth and antimicrobial susceptibility).[9-12]

Listeria monocytogenes is a gram-positive, facultative anaerobe, nonspore-forming, motile, and rod-shaped bacterium.[13] In 1952, it was recognized as the main cause of neonatal infection, meningitis, and sepsis.[14] Listeria infection in adult patients is related to immunocompromised systems like HIV infection,[15] organ transplants, individuals who have received corticosteroids, and immunosuppressant drugs for their malignancies. *Escherichia coli* known as *E coli*, a gram-negative, rod-shaped, facultatively anaerobic bacterium,[16] is a common cause of life-threatening infections such as bloodstream and urinary tract infections, otitis media, and other complications.[17]

Our laboratory at the nonionizing department of the Ionizing and Non-ionizing Radiation Protection Research Center has performed experiments on the health effects of exposure to animal models and humans to different sources of electromagnetic fields such as cellular phones,[18-20] mobile base stations,[21] mobile phone jammers,[22,23] laptop computers,[24] radars,[25] dentistry cavitrons,[26] magnetic resonance imaging,[27,28] and Helmholtz coils.[29,30] In this study, we assessed whether the exposure to 900 MHz and 2.4 GHz RF-EMF emitted from GSM and a common Wi-Fi router could change the susceptibility of microorganisms to different antibiotics.

Materials and Methods

Antibiotic Susceptibility Test

In the current study, *L monocytogenes* ATCC 19115 was used and *E coli* strain was isolated from patients in Faghihi hospital, Shiraz, Iran. *Escherichia coli* strain was characterized by conventional methods including morphological and biochemical tests and confirmed using API 20 E method. The pure cultures of *L monocytogenes* and *E coli* were diluted in Mueller-Hinton Broth to reach 0.5 McFarland turbidity standards to get 1.5×10^8 CFU/mL as the total count.[31] Bacterial suspensions were spread on plates and cultured with a set of 6 antimicrobial substances; they were tested by disk diffusion method (Kirby-Bauer method) on Mueller-Hinton agar (MHA-Biolife, Italy) plates and *E coli* ATCC 25922 was used as the quality control for antibiotic susceptibility tests, according to the Clinical and Laboratory Standards Institute guidelines (CLSI, 2013). The incubation period was 18 to 24 hours at 35°C, and then inhibition zones for each disk were measured.

Antimicrobial Agents

Antibiotics used for *E coli* tests were imipenem (10 μg), levofloxacin (LEVO 5 μg), aztreonam (30 μg), ciprofloxacin (CIPR 5 μg), cefotaxime (CTX 30 μg), and piperacillin (100 μg). *Listeria monocytogenes* tests were conducted using doxycycline (DOX 30 μg), sulfamethoxazole–trimethoprim (SXT 25 μg), LEVO 5μg, CTX 30 μg, CIPR 5 μg, and ceftriaxone (CTR 30 μg) antibiotics.

All antibiotic disks were purchased from ROSCO Diagnostica (DK-2630 Taastrup, Denmark). Results of antibiotic susceptibility tests before and after exposure to either Wi-Fi or GSM mobile phone radiation were measured and analyzed. The inhibition zone of each plate was recorded as the average of at least 2 different measurements (in millimeters). Three replicate agar plates were used for each regime, according to CLSI guidelines (2013).

Wi-Fi Router

A D-Link Wi-Fi router (D-Link, D-Link Corporation, Taiwan) was used in this study as the exposure source. During the exposure period, data were exchanged between the modem and a laptop computer that was placed in another room (5 m away from the Wi-Fi router).

The Wi-Fi router operated with a power level of 1 W and the specific absorption rate at the distance 14 cm between the bacterial suspension (broth medium) and Wi-Fi router was 0.13 W/kg. During the exposure, bacterial samples were collected in different times 3, 6, 9, and 12 hours after being exposed using sterile swabs.

Radiofrequency Simulator

In this study, all exposures were performed using a GSM 900 MHz mobile simulator operating in the "Talk mode." This mobile phone simulator was developed at the Department of Medical Physics and Biomedical Engineering, School of Medicine, Shiraz University of Medical Sciences, Shiraz, Iran, by the collaboration of the private sector.

Outgrowth Curve

For the evaluation of radiofrequency exposure effect on the growth rate of bacteria, optical density (OD) was measured.

Abbreviations: AZT, aztreonam; CIPR, ciprofloxacin; CTX, cefotaxime; IMI, imipenem; LEVO, levofloxacin; PIPRA, piperacillin; RF, radiofrequency.
[a]Statistically significant diffidence.

For each bacterium, a precisely specified concentration of bacterial suspension inoculated in the broth medium and then divided into 2 series as a control and RF simulator exposure groups. For estimating the number of bacterial cells in a broth medium, the turbidity of each group was recorded in 625 nm absorption at different times using a spectrophotometer (UNICO UV-2100 Spectrophotometer, UNICO, USA).

Statistical Analysis

All experiments were replicated 3 times for exposed and nonexposed groups. The means were compared using the nonparametric Mann-Whitney *U* test, and statistical significance of any difference observed among the mean values was determined using SPSS version 15. $P < .05$ was considered significant.

Results and Discussions

In our study, we have evaluated *E coli* and *L monocytogenes* for their in vitro susceptibility to various antibiotics in the presence of radiofrequency radiation. For each antibiotic, inhibition zone was measured and the test was repeated 3 times. Data obtained for exposed and nonexposed (control) bacteria are summarized in Table 1.

According to Table 1, for *E coli*, exposure to Wi-Fi and RF simulator decreased the inhibition zone diameters that show an antibacterial resistance pattern. At first, there was no change in sensitivity, but after increasing the exposure time, a specific range of antibacterial resistance was observed.

After 24 hours of exposure, as it can be seen in Table 1 and Figures 1 and 2, the bacteria that were exposed to radiation showed less resistance compared to early-time exposure. However, they didn't return to time 0 exposure condition.

According to Figures 3 and 4, for *L monocytogenes*, comparison of data obtained from exposed and nonexposed groups did not show any significant changes in their antibacterial activity except for DOX. However, for *E coli*, there was a significant change in antimicrobial activities that suggest exposure condition to radiation could influence the degree of antibiotic susceptibility of *E coli* more than Listeria. In a similar pattern, for *L monocytogenes*, a specific window of response was observed (Figures 3 and 4). *Listeria monocytogenes* response to each antibiotic was different, for DOX, and the window response occurred after 6 hours of exposure to Wi-Fi and RF simulator radiation. However, for other antibiotics, these changes were only observed at the ninth hour of exposure to Wi-Fi while this response could not be observed for RF simulator radiation. After 9 hours of exposure to Wi-Fi for CIPR and SXT antibiotics, bacteria had a tendency to become more resistant. This was in contrast to the pattern observed for LEVO, CTX, and CTR antibiotics, which an increased sensitivity

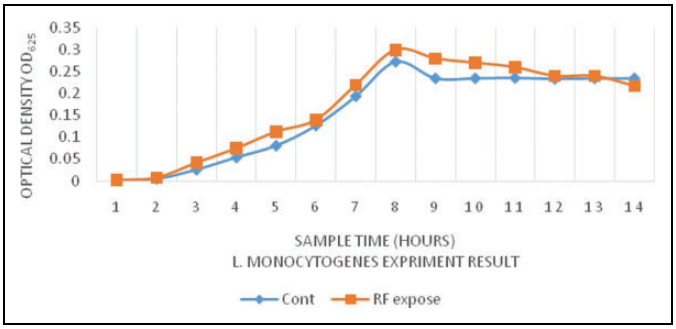

Figure 6. Growth curves *Listeria monocytogenes* in broth medium preexposure and postexposure.

was observed. As mentioned above, for Listeria, limited antibacterial changes were observed for DOX after exposure to Wi-Fi and RF simulator radiation. On the other hand, we have previously addressed the bioeffects of the exposure of bacteria to electromagnetic radiations and investigated different aspects of the challenging issue of the ionizing or nonionizing radiation-induced alterations in the susceptibility of microorganisms to antibiotics.[19,32-34]

In the current study, the pattern of the response of *E coli* to Wi-Fi and RF simulator radiation was identical. The maximum differences in the diameters of inhibition zones were observed between 6 and 9 hours of the bacterial exposure to radiation (Figures 1 and 2). After 12 hours of exposure, the bacterial responses to radiation as a stressor led to returning to the preexposure status. This observation is in line with the previous reports of Mortazavi et al,[18,19,34-36] who showed that the radiation-induced stimulatory/beneficial effects in bacteria can be observed only within a narrow window of radiation dose. Based on this theory, when the radiation level is within the window (between the lower and upper levels of the window), stimulatory effects of ionizing or nonionizing radiation can be detected. Therefore, the response of the bacteria and other microorganisms to any environmental stressors can be determined by some key factors such as the magnitude of the dose and dose rate. This type of response was previously confirmed in *Klebsiella pneumoniae*.[34]

We have also evaluated the effect of radiofrequency radiation on the growth rate of bacteria. As shown in Figures 5 and 6, during each investigated time period, remarkable differences

were observed in the rate of bacterial growth in exposed and nonexposed groups (Table 2). In particular, gram-negative (*E coli*) and gram-positive bacteria (*L monocytogenes*) showed a significant growth after exposure. Moreover, the time to reach the logarithmic phase in the growth curve of the bacteria was faster in exposed groups. However, after 8 hours, based on OD_{625} absorbance, the total count of *E coli* bacteria in the exposed group was less than that of the control group. These observations are in line with the finding of Akbal et al.[37] However, the total counts of *L monocytogenes* after 24 hours of exposure was higher than that of the control group. At a broader view, our data confirm previous studies that showed that radiofrequency radiation could induce changes in cell growth and antibiotic sensitivity in *E coli.*

Some researchers have indicated that organisms acquire resistance through several known factors such as patient noncompliance or in vitro exposure to radiofrequency radiation.[38-40] Nowadays, our world is surrounded by enormous radiofrequency sources such as Wi-Fi routers and laptop computers that can lead to serious health problems. When someone is infected with a microorganism that obtained its resistance from the host environment, it causes a serious problem for health-care systems and treatment failure or receiving a higher dosage of antibiotics will be possible. Therefore, this may lead to more side effects and finally prolonged hospitalization.

In several studies,[10,41] it was shown that antimicrobial sensitivity alterations were affected by the intensity of electromagnetic fields. Antibacterial sensitivity also depends on the physical properties of the electromagnetic fields such as frequency and magnetic flux density, exposure duration, and type of bacteria. Based on this point, evaluation of the effect of radiofrequency radiation on bacteria is not only essential to investigate their environmental effects, but it is also vital for detecting the antibiotic resistance pattern in the clinical laboratories and environment.[42-45]

Since the frequency of Wi-Fi router is 2.4 GHz while it is 900 MHz for the mobile simulator, we can conclude that the difference in response to Wi-Fi and the mobile simulator is possibly due to the frequency of radiation.[46] In several studies on bacteria,[34,47,48] one of the factors that influenced antibacterial sensitivity was the cell wall structure of bacteria and peptidoglycan (PG) nature in gram-positive and gram-negative bacteria. In gram-positive ones like Listeria, cell wall thickness is greater than that of gram negatives. The thicker the PG,[49] the permeability of the cell wall to permit the entrance of molecules to the cells will be decreased. According to these findings, the frequency of radiation can make some changes in PG of cell wall and enhance the permeability of the membrane to antibiotics.[8,50] Torgomyan showed that alteration in the oxidoreduction state of proteins in the bacterial cell membrane can be the major membranous mechanism after exposure to low-intensity electromagnetic field.[51]

Also, the effect of electromagnetic radiation on *E coli* cultures was studied by Justo et al,[52] which found that cell growth could be changed (stimulation or inhibition) under magnetic field. Furthermore, the exposure of *E coli* ATCC 25992 to the magnetic field of 2 mT at the frequency of 50 Hz caused significant alterations in the morphology, growth curves, structural parameters, and the sensitivity to certain antibiotics such as nalidixic acid, amoxicillin, and erythromycin.[9,53] These results were confirmed by the study of Stansell et al,[54] who found that static magnetic fields at moderate intensities are able to decrease the antibiotic sensitivity and make *E coli* WHMC 4202 more resistant.

In our study, we used several antibiotics that act through various mechanisms including protein and DNA synthesis

Table 3. Antibiotics Classification.

Antibiotic Classification	Mechanism	Antimicrobial Agents	Abbreviation
Sulfonamide	DHFRI	Trimethoprim/ sulfametho-xazole	SXT
Penicillin	Inhibits cell wall synthesis	Ceftriaxone	CTR
		Cefotaxime	CTX
		Piperacillin	PIPRA
		Imipenem	IMI
		Aztreonam	AZT
Tetracycline	Protein synthesis inhibition (30 s)	Doxycycline	DOX
Fluoroquinolones	Nucleic acid synthesis inhibition	Ciprofloxacin	CIPR
		Levofloxacin	LEVO
Aminoglycoside	Protein synthesis inhibition (30 s)	Amikacin	AMI

Abbreviation: DHFRI, dihydrofolate reductase inhibitors.

inhibition, cell wall inhibition, and dihydrofolate reductase inhibition (it is summarized in Table 3). Each antibiotic enters the cell via a specific pathway. Some of them enter via efflux pumps in the cell membrane,[34,55,56] and others enter via ion channels through the cell wall.[57] All of these antibiotics may enter the cell via a nonspecific mechanism such as endocytosis. In this mechanism, molecules pass the membrane based on the permeability of the cell wall.[58-60] Considering our results, we believe that Wi-Fi and mobile exposure can serve as physical methods to alter the antibacterial susceptibility of microorganisms. In this light, the permeability of the membrane can be changed by radiofrequency radiation. It seems that the radiation can alter the sensitivity of the efflux pumps or ion channels by permitting the entrance of the molecules through the cell wall. In order to verify these theories, it would be better if this study is replicated with other pathogenic bacteria both gram-positive and gram-negative ones with various forms of antibiotics.

Conclusion

Based on our results, it can be concluded that the bacterial strains used in this study respond differently to EMFs. These bacteria were capable of responding to environmental stresses that act by activating some specific systems such as ion channels, change via the membrane, DNA repair system, and probably ion efflux pumps in the membrane as well as interactions of molecules and antibacterial agents.[61] There are some ambiguities that need further investigations regarding answering questions such as which cellular mechanism is responsible for adaptation? Which factors are involved in alterations of antibacterial sensitivity? And subsequently, what are the differences in the response to radiation in gram-negative and gram-positive bacteria? Moreover, experiments on different bacterial strains with various electromagnetic fields should be performed in the future to better clarify these uncertainties.

EMF/EMR Science, reports and Studies

Contents

Preview

Through the years several governments, committees and international bodies issues warning regarding RF and ELF EMF/EMR. As more science and proof is becoming clear and wide spreed, more and more warning have been issues and more reports have concluded that exposure to RF and ELF fields is not healthy, and can have health effects that are not related to the heat effect.
This is while other governments, committees and international bodies consider EMF radiation is "not dangerous" and while the industry continue to push for more and more wireless technologies world wide.
I think that even today, the ever growing body of science should be enough to except the potential danger of EMF and call for drastic measures to reduce EMF exposure and usage of Radio Frequency emitting devices, both on the government level and specially on the personal level.

Can non ionizing radiation photon cause damage?

The industry, and scientist which follow it, argue that RF and ELF photon does not have enough energy to damage DNA and therefor it is 100% safe. Well that is obviously a simplification of the reality in which other less direct mechanisms effects and damage biological systems when radiated by RF and ELF EMF. SALFORD showed in 2003 that the brain-blade-barrier is damaged when a brain is being radiated with RF radiation. This BBB damage cause other neurological damage to the brain. FRIDMAN showed in 2007 the mechanism in which free radicals are created when a tissue is radiated with RF radiation. Free radicals can lead to DNA breaks. Hanry Lai showed in his research from 1998 that DNA breaks do occur when DNA is being radiated with "safe" levels of RF radiation.

Reports

- 05/2015 - **The "International EMF Appeal -**
  About 190 scientist call on to the UN, WHO and states in order to adopt more protective guidelines that will be based also on biological changes and damages caused by EMF.
  Press here to Read more about it...
- **WHO/IARC** - "IARC CLASSIFIES RADIOFREQUENCY ELECTROMAGNETIC FIELDS AS POSSIBLY CARCINOGENIC TO HUMAN" (06/2011)- http://www.iarc.fr/en/media-centre/pr/2011/pdfs/pr208_E.pdf .
  It is important to note that this decision was accepted after a conflict of interest was exposed in the committee:
  - http://www.microwavenews.com/Ahlbom.html
  - http://www.monanilsson.se/document/AhlbomConflictsIARCMay23.pdf
- **European Parliament 2009 -**

  Health concerns associated with electromagnetic fields

- COUNCIL OF EUROPE - "The potential dangers of electromagnetic fields and their effect on the environment " by the "COUNCIL OF EUROPE - Parliamentary Assembly" (6/05/2011) - http://www.assembly.coe.int/Mainf.asp?link=/Documents/AdoptedText/ta11/ERES1815.htm
- **Russia** - "The Russian National Committee on Non-Ionizing Radiation Protection (RNCNIRP) has published a new resolution entitled: "Electromagnetic Fields from Mobile Phones: Health Effect on Children and Teenagers" - http://www.scribd.com/doc/55420788/Electromagnetic-Fields-from-Mobile-

Phones-Health-Effect-on-Children-and-Teenagers.

- **INDIA** - "REPORT OF THE INTERNAL MINISTERIAL COMMITTEE ON EMF RADIATION " - "Government of India, Ministry of Communications & Information Technology, Department of Telecommunications" - http://www.dot.gov.in/miscellaneous/IMC%20Report/IMC%20Report.pdf.
- **ISRAEL** - The environmental and health committee in the KNESSET (Israel parliament) called the government to adopt the recommendations of a technical committee to reduce and to prevent exposure to electromagnetic radiation of students in schools to, due to the possible health effect of electromagnetic radiation might have on their health - http://norad4u.blogspot.com/2010/11/article-about-reduction-and-prevention.html.
- The **Bioinitiative** (www.bioinitiative.org) report, which was published in 2007, quotes 2000 studies that show many and diverse health effects of EMR. In 2012 an update of this report was published with additional 1800 studies that show none thermal effect of both Radio Frequency and Extreme Low Frequency Electromagnetic Radiation. The authors of the report warn while the scientific data showing none thermal biological effect of non-ionizing radiation accumulate, and while the damage to public health seems to get bigger and wider, the industry does it's best to continue the deployment of radiation emitting technologies and devices while trying to hold back the information of the possible risk from the public.
  On the Bioinitiative website there is a color table of studies, named "RF Color Charts" , that show a the studies along side the RF levels that biological effects and changes are caused in. The RF Color Charts makes it very easy to understand how very law levels or RF radiation effect Biologic systems. To view the chart, go to the main page and search for the "RF Color Chats".
- **The REFLEX study** - Carried out in 12 institutes, in 7 different countries, found that exposure to ELF (Extreme Low Frequency) EMF, and RF EMF (Radio Frequency emitted from cellphones) caused changes in genes and in their expressions (genotoxic effects) in living cells in-vitro. The team concluded that in-vitro damage is read and that in vivo damage should be studied in humans.
  The REFLEX study
  About the REFLEX study
  About the REFLEX study on BBC
- **ICEMS** (www.icems.eu) - the **International Commission for Electromagnetic Safety** published several resolutions that reviews many health effects of EMR other than heat related effect.
- **WHO/IARC** - "IARC CLASSIFIES EXTREAM LOW FREQUENCY MAGNETIC FIELDS AS POSSIBLY CARCINOGENIC TO HUMAN" (2002)- https://apps.who.int/inf-fs/en/fact263.html
- **Carl Blackman - 2009** - **Cell phone radiation**: Evidence from ELF and RF studies supportingmore inclusive risk identification and assessment
  A review of about 131 studies showing NTE (None Thermal Effect) of EMF radiation.

  "This paper will review some of the salient evidence that demonstrates the existence of NTE and the exposure complexities that must be considered and understood to provide appropriate, more thorough evaluation and guidance for future studies and for assessment of potential health consequences"

Sites with lists of studies

Since I am not a scientist I am not going to bring a list of studies and then explain them. If you need a list of studies, so you can read and decide for yourself, I can recommend the following site that has a list of most studies about health effect of Electromagnetic Radiation that were published: http://www.powerwatch.org.uk/science/studies.asp

In addition you can find more studies on the following pages:

- The studies page on the "EM Watch" site.
- The latest research page on the "EM Radiation Research Trust" site.
- The news and media page on the "Electromagnetic Health" site.
- Dr. Zuri Glazer Review and Summary of ~2000 studies that show effects of Radio frequency radiation. The first addition of this review was printed in 1971 as part of a US Navy Research. The review is now available on Prof. Magda Haves web site.

RF (High frequency) EMR Influence, damage & health effect studies

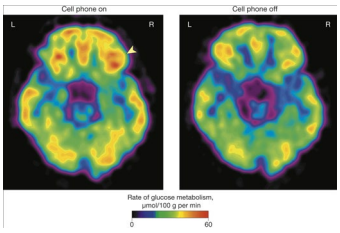
More and more studies show biological damage and health effects of RF EMR, even at very low levels which don't cause any heat effect and were considered to be safe.

Studies about influence of RF EMR in so called "safe" levels (partial list)

Effects of Cell Phone Radiofrequency Signal Exposure on Brain Glucose Metabolism - Nora D. Volkow, MD 2011

"In healthy participants and compared with no exposure, 50-minute cell phone exposure was associated with increased brain glucose metabolism in the region closest to the antenna. This finding is of unknown clinical significance."

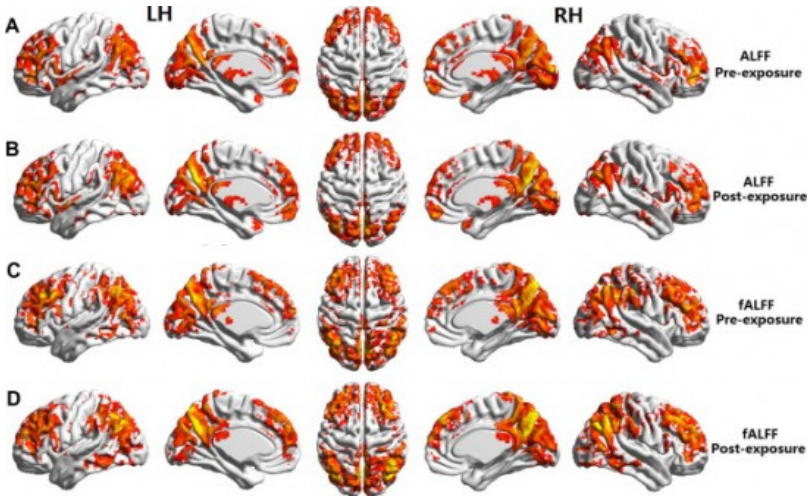
The study - http://jama.jamanetwork.com/article.aspx?articleid=645813



The alteration of spontaneous low frequency oscillations caused by acute electromagnetic fields exposure - 2013

"The study provided the evidences that 30min LTE RF-EMF exposure modulated the spontaneous low frequency fluctuations in some brain regions."

Link - http://www.ncbi.nlm.nih.gov/pubmed/24012322
About the study - http://www.prlog.org/12215083-lte-cell-phone-radiation-affects-brain-activity-in-cell-phone-users.html



picture - brain activity after exposure to LTE RF radiation

Studies about biological damage in so called "safe" levels (partial list)

This is a partial list of the most important studies that show Biological damage and mechanisms of damage caused by RF EMF exposure.

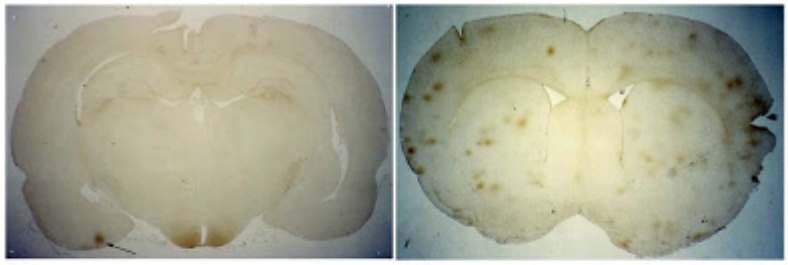
Brain damage after RF-MW exposure - Salford -2003

The picture below is taken from the "**Nerve Cell Damage in Mammalian Brain after Exposure to Microwaves from GSM Mobile Phones**" study by **Leif G. Salford, Arne E. Brun, Jacob L. Eberhardt, Lars Malmgren, Bertil R.R. Persson.** (please see the source link below for full study).
Please notice the red spots on the radiated brain (Right picture), these are "protein leakage from blood vessels" marking the damage to the brain's blood vessels which can cause headaches and other symptoms.

Source: http://www.ncbi.nlm.nih.gov/pubmed/12782486

Full study : http://www.ncbi.nlm.nih.gov/pmc/articles/PMC1241519/pdf/ehp0111-000881.pdf

Video of a lecture with Dr Leif Salford: http://youtu.be/E_WJ_aJPWIA



(a) (b)

Figure 1

Fig. 1 . (a) Slightly enlarged cross section of central parts of the brain of an unexposed control rat, stained for albumin which appears brownish in the central inferior parts of the brain, the hypothalamus, a normal feature. In the left lower corner (arrow) a brown spot representing an occasional focal leakage.
(b) As (a) for an RF exposed rat , stained for albumin , which appears brownish in multiple small foci representing leakage from many vessels.

DNA brakes - Henry Lai and Dr Narendra -1996

The comet trail "dust like" particles in the pictures are DNA breaks. The picture below clearly shows that DNA breaks accusers after exposure to X-ray and Cell phone radiation. The source of the picture is from **Dr Henry Lai and Dr Narendra** research about "**Single- and double-strand DNA breaks in rat brain cells after acute exposure to radio-frequency electromagnetic radiation"**

Source: http://www.ncbi.nlm.nih.gov/pubmed/8627134

Dr. Neil Cherry about Motorola attempt to contradict this study:

Dr. Neil Cherry wrote number of papers regarding the danger of RF radiation. One was specifice about the studies that Motorola founded in order to allegedly contradict Henry Lai studies. The parper used to be availible on this link, but it seems to be removed. The info also appear on other papers of Neil Cherry. click on the links bellow and search for "Motorola":

1. Evidence of Health Effects of Electromagnetic Radiation, To the Australian Senate Inquiry into Electromagnetic Radiation - **Dr. Neil Cherry**
2. Evidence that Electromagnetic Radiation is Genotoxic: The implications for the epidemiology of cancer and cardiac, neurological and reproductive effects - **Dr. Neil Cherry**

Video of a lecture given by Dr Henry Lai about DNA breaks as an outcome of RF exposure: http://youtu.be/JrBjQJhHfzk

Fig.1 Unexposed control. Bundle of DNA (No-Tail)

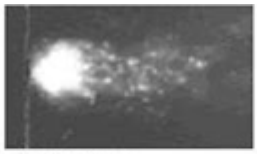


Fig.2 X-ray calibration 25.6 rads. DNA breaks are very obvious

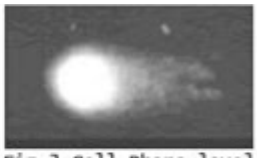

Fig.3 Cell Phone level microwave exposure 2hrs 2.45GHz reaching so called Safe SAR levels

Comet Tail = DNA Damage

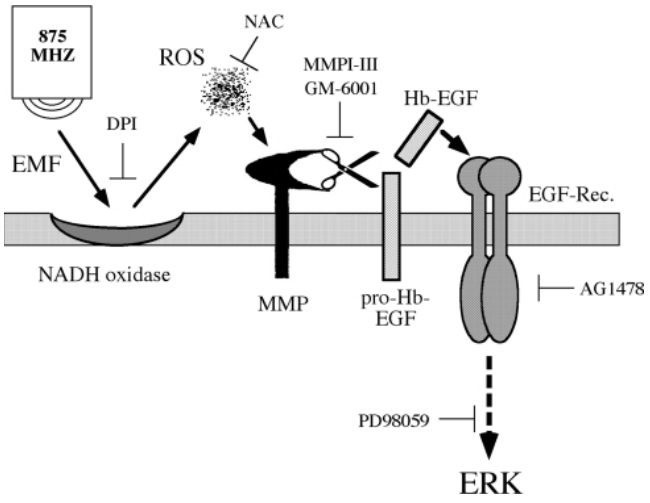
Lymphoma cancer in mice - Repacholi MH -1997

Mike Repacholi exposed mice to RF radiation, similar to that emitted from cellphones, and found that the risk for Lymphoma was found to be significantly higher in the mice that were exposed. Several years after the research was done, Repacholi took back his finding and was appointed to several roles in the WHO and was lately hired as a consultant to the industry.

The research: http://www.ncbi.nlm.nih.gov/pubmed/9146709

Creation of Free radicals as a result of RF radiation exposure - Friedman J- 2007

On their research Mechanism of short-term ERK activation by electromagnetic fields at mobile phone frequencies from 2007, Dr. Joseph Friedman and Prof. Roni Seger, from the Department of Biological Regulation, The Weizmann Institute of Science, found that exposure to RF electromagnetic radiation caused oxygenate stress and for the first time showed a detailed molecular mechanism by which electromagnetic irradiation from mobile phones interacts and changes cell communication and activities.



RF EMF Health effect and epidemiological studies

Cell phone usage by pregnant women and of children causes behavioral difficulties - Divan HA, Kheifets L, Obel C, Olsen J - 2008

"Exposure to cell phones prenatally-and, to a lesser degree, postnatal-was associated with behavioral difficulties such as emotional and hyperactivity problems around the age of school entry"
Link to the study: http://www.ncbi.nlm.nih.gov/pubmed/18467962

27 minutes of cellphone use per day incress brain cancer risk - The interphone study - 2010

The interphone study final result ware published on 17/05/2010, after 5 years of delay. a first look suggests that using a mobile phone actually protect you from brain cancer, how could that be? a second look shows that people who use their mobile phone for more then 27 minutes per day (1640 hours in 10 years) have 40% higher risk of getting a brain tumor. In the study itself there were many issues and problems that cause the results to be moderated. Appendix 2 of the study try to mathematically fix some of the problems in the study resulting with higher risk (please see picture bellow).

Polish army RF-MW exposure study - Szmigielski S - 1996

"Cancer morbidity in subjects occupationally exposed to high frequency (radiofrequency and microwave) electromagnetic radiation". this study tracked the RF-MW exposure levels and health records of army personal of the polish army for 15 years (both soldiers that were exposed and those who were not). The study shows that personal that was exposed to RF-WM radiation had added risk of 2.07 of cancer, and that their morbidity rate was higher.

About the study: http://www.microwavenews.com/news/backissues/m-j95issue.pdf

Additional scientific information and tests

However I would like to show you the following video, 2 pictures and a single chart that can maybe tell the all story.

http://www.ncbi.nlm.nih.gov/pubmed/20551697

What happens to your blood when radiated:

Few years ago I came across pictures and articles about live blood cell analysis of human exposed to RF radiation. For years I search for a good, simple, easy to understand video clip that explains the test and shows parts of it.

This video, made by Dr. Magda Havas from the Environmental & Resource Studies, Trent University, Peterborough, ON, Canada, is the best I have ever seen until today. It is short, self explanatory and easy to understand. Dr. Magda Havas explains the test and the outcome while showing pictures and videos from the test itself.

The video show what happens to a human blood when exposed to electromagnetic radiation from a computer and also from a cordless phone. The test outcomes are clearly seen and can explain some of the symptoms of Radiation exposure and of Electromagnetic Hyper sensitive (EHS).

Dr Magda Havas about "Live Blood Analysis"

Does exposure to EMR from DECT phone effect the hart bit?

The answer is yes, exposure to electromagnetic radiation from DECT phone does change the hart bit of some people (electro hypersensitive included). The below video summeriest the experiment done by DR. Magda Havas and DR. Jeff Marrongelle that was done in March 2010 and will be published later on in 2010. The experiment tested if exposure to EMR from DECT phones effect people hart rate. The outcomes show that it does, watch the following video for more info.

More about Dr. Magda Havas at http://www.magdahavas.com/ and http://www.magdahavas.org/.

Industry funded resource vs. independent resource

The cart below was done by Lloyd Morgan and it original (fully functional links to all the studies that appear in the chart as dots) can be found on www.powerwatch.org (see link below).
The chart below clearly shows that **industry funded research (in red color)** show none or small increased risk while **independent resource (in blue)** shows that the risk increases a great deal more. In addition some of the industry funded research show improvement or less risk than the control group. This can be cause by faults in the study or it can really represent a change in the functional of the body (that can have good measured aspects but also some hidden bad aspects).

ELF (Extreme Low frequency) magnetic field health effect studies

Extreme low frequency electromagnetic fields have been calcified by the WHO/IARC as "possibly carcinogenic to humans" in 2002. The classification came after several studies and pool analysis showed that people, and specially children, that lived or studies next or under to high voltage power line had a much larger risk of getting different types of cancer. Some studies did not show a link because of a wrong working premise that the exposure from the power line extends up to 200 meters from the power lines, while in reality the magnetic field reaches only 50 meters from each side of the power line. A pool analysis of the data was done using the 50 meters as the exposure limit and showed the risk and the link to cancer.

The level that is considered to be the risk threshold is 2-3 mG. The ICNIRP, very high, standard of 1000 mG deals with only short term exposure, yet it is being considered by many governance and electrical companies as the only standard that covers also long term exposure. The ICNIRP's standard takes into consideration only one health effect which is muscle tension.

Leading studies about the likes between ELF from power lines to cancer

Obesity epidemic caused by EMF exposures in the home according to startling new research

Thursday, July 11, 2013 by: Lloyd Burrell
Tags: *obesity epidemic*, *dirty energy*, *electropollution*

(NaturalNews) Two-thirds of the U.S. population is overweight, and about one-quarter to one-third of adults are obese. Fact. Poor diet and a lack of exercise are at fault, the experts say. But what if the cause of this epidemic was something even more insidious? What if that which is considered the lifeblood of our modern day lives, electricity or more precisely dirty electricity, was really to blame?

The answer to these questions is an unequivocal yes. At least according to Samuel Milham, MD, MPH, author of an alarming new study on the link between obesity and exposure to dirty electricity (a form of electromagnetic field pollution).

According to Dr. Milham's study just published in *Electromagnetic Biology and Medicine*, EMFs (in the form of dirty electricity), are contributing not only to obesity, but to a myriad of other health concerns which plague Americans in today's disease-ridden society.

Dr. Milham found evidence of the link between dirty electricity exposures and obesity and diabetes through analyzing worldwide health metric data. He noticed that many small islands known for having the highest BMIs (marker for obesity), worldwide in addition to the highest incidence of diabetes did not draw their energy supply from an electrical grid. An alternative source of energy was commonly used, a diesel generator set, known to be a major source of dirty electricity.

What is dirty electricity?

Dirty electricity, defined as electrical pollution contaminating the electrical grid, stems from the use of many commonplace items found in or around the home but also from the poor design of our electrical distribution system. As Dr. Milham says "the high obesity levels in the US is not surprising, because the U.S. uses the earth as the major conduit for neutral return currents."

Studies show the human body suffers adverse affects at a cellular level from this constant exposure to dirty electricity. Combine this with the fact that there are actually more overweight and obese people living in the United States than people who are living within a healthy weight range and Dr. Milham's conclusions start to make sense.

Electricity and the diseases of civilization

In his book *Dirty Electricity: Electrification and the Diseases of Civilization*, Dr. Milham reveals that as electricity spread throughout the United States in the 20th century, so did other diseases of civilization including:

• ADHD

• Suicide
• Cancer
• Obesity
• Asthma
• Diabetes
• Cardiovascular disease

Affected populations

Is it a coincidence that locations utilizing less electricity have the lowest levels of these exact same diseases? Unlikely.

When comparing the levels of exposure to dirty electricity between the Amish and non-Amish populations the findings cannot be ignored. The Amish people are well-known for their lack of dependency on electrical power. The upshot is a population with half the rate of diabetes and cancer and virtually no obesity or ADHD.

Other recent findings stemming from a reduction of or less exposure to dirty electricity found:

• The number of children requiring albuterol (asthma inhalers) decreased from 37 to only three in one U.S. schoolhouse.
• A lower risk of cancer for California middle-school teachers.

How to reduce exposure

Utility companies should be made to face up to their responsibilities. Supplying consumers with a highly polluted electricity supply which puts populations at considerable risk of harm is not acceptable.

Householders need to act to protect their home and work environment as much as possible. By eliminating certain devices in the home which contribute to this problem, and introducing capacitive filters, many home and work environments can be effectively cleaned up.

Exposure to Electric and Magnetic Fields (EMF) Linked to Neuro-Endocrine Stress Syndrome: Increased Cardiovascular Disease, Diabetes, & Cancer

By Donald Hillman, Ph.D., Professor Emeritus, Michigan State University

Published by Shocking News,[1] No. 8 **Email: donag1@aol.com** **November 2005**

SUMMARY – My heart rate increased 29%, systolic blood pressure increased 10%, diastolic blood pressure increased 48%, and body temperature increased while I was sitting on the sofa with my feet in the 20 to 50 milliGauss (mG) magnetic field corona from the ground wire below the floor. I recorded 228 millivolts and 2.44 amperes (A) of electrical current passing through my body during the 35-minute exposure. Lansing Board of Water and Light utility engineers recorded voltage, 1.5 average to 8.8 A maximum current, 200% Total Harmonic Distortion, and 100-320 mG (10-32 microTesla) magnetic fields for 24-hours at the ground wire in my home. These exceeded IEEE (Institute of Electrical and Electronic Engineers) 519-1992, standards for harmonic distortion (5%), OHSA Directives for hazardous current (1.0 milliampere) and published values related to cancer.

Discovery of EMF in My Home.

A cellular telephone company's request to place additional signal generators-transmitters and antennae on the East Lansing-Okemos Water Tower led to concerns about health risks to citizens in the community and a decision to measure the electrical output from the cellular phone installation. The water tower is located in Patriarche Park across the street from St. Thomas Aquinas School and within 87 to 400 feet of twenty neighborhood homes. Oscilloscope measurements of voltage, frequency, and current on the ground wire from the cell station revealed up to 10 volts (peak-peak), a broad spectrum of harmonic frequencies ranging from 180 hertz to megaHertz radio frequencies (rf) including 1.25 gigaHertz microwaves, with 1.8 amperes (A) of current and 100 or more milliGauss (mG) magnetic fields at the ground wire. Similar readings were on the ground wires and water pipes of at least six homes and the school.The utility mitigated the EMF from the ground wire in my home by installing a dielectric coupling in the water pipe to which the ground wire was attached. These findings were reported to the utility and neighbors in *Shocking News* #7, May, 2005.

EMF - Link to Stress: The present report addresses the physiological connection between the observed increased heart rate and blood pressure, my and neighbors' medical history of cardiovascular disease, diabetes, abdominal aortal aneurysm, diverticulosis, gastro-esophageal acid reflux, and nonHodgkin's lymphoma as evident in an extensive review of literature. The maladies are associated with a broad spectrum of physiological changes involving stimulation of the hypothalamus, pituitary, and adrenal gland secretions mediated through the central nervous system (CNS) which include the brain and spinal cord. Neuro-endocrine reactions comprise the autonomic nervous system which monitors internal and external environmental stimulation through the sympathetic and parasympathetic neuro-endocrine system to achieve homeostasis.

My cardiovascular problems began with irregular heart beat (skipping every 4th beat) and corresponding high blood pressure some years earlier for which I was administered daily diltiazem, a calcium ion channel blocker. I have had two quadruple coronary by-pass surgeries ten years apart, abdominal aortal aneurysm repair, prostate reduction surgery, intestinal diverticulosis, gastro-esophageal acid reflux syndrome, and Type II diabetes diagnosed 4 years ago for which I was prescribed daily endogenous insulin-stimulator drugs. I experienced body temperature rise and perspiration (sweats) which subsided without treatment during the night, and joint-muscle pain. My wife has had difficulty sleeping in the house, has had tumors in the uterus requiring hysterectomy, a gall-bladder ablation, a shrunken kidney, borderline erythrocytic anemia.

A neighbor located 87 feet from the cell tower was suffering from a fibrillating heart, had a heart-valve replaced about five years ago and a pacemaker installed. The pacemaker was replaced after about five years, and a defibrillator was installed to maintain a functional heart rhythm. His wife suffers from multiple sclerosis, a disease associated with scattered demyelination of nerve axons in the central nervous system affecting motor control. Myelin is the insulation coating of nerves that protects them from electrical interference.

The lady next door was currently in the local hospital under chemotherapy and radiation treatment for recurring lymphoma cancer. Her duplex-neighbor lady had surgery for replacement of a knee within the last year and her son, age circa 30 years, is Type-I diabetic using an insulin pump.

Effects of EMF exposure on heart rate and blood pressure were reported by other investigators. Resting blood pressure of ten volunteers increased during exposure to a GSM

[1]***Shocking News*** (dba) is a registered publisher of science-based information dedicated to public awareness of electric and magnetic fields (EMF) in the living environment and their effects on the health and welfare of humans and animals. Editor is Don Hillman, Ph.D.,Professor Emeritus, Department of Animal Science, with help from wife Mary, MS, Michigan State University, East Lansing, MI. Don is a member of the American Society of Agricultural Engineers and The American Dairy Science/Animal Science Association. Telephone: (517) 351-9561.

900 MHz radio-frequency (rf) electromagnetic field for 35 minutes (Braune, S., et al., 1998), and rf fields influenced cardiovascular and hormonal parameters of the autonomic nervous system (Braune et al., 2002). Alteration of diurnal rhythms of blood pressure and heart rate occurred in workers exposed to radio frequency electromagnetic fields in the range 0.738 - 1.503 MHz and 200 - 550 volt/meter (V/m) electric fields, but the changes did not occur in a comparison group at lower exposure levels (Szmigielski et al., 1998). Similar changes in heart rate and heart rate variability occurred in subjects exposed to occupational levels of 50 Hz circular polarized magnetic fields (Sait et al., 1999).

Heart rate and sleep were affected when healthy young men were exposed to 900 MHz spatial peak specific absorption rate (SAR) 1 W/kg simulating exposure to a cellular telephone signal pulsed at a rate of 9 to 14 Hz. While EMF exposure was to the head, workers estimated that exposure of the hypothalamus was 0.1 W/kg, sufficient to affect heart rate and sleep (Huber et al., 2003).

Cardiovascular disease associated with hypertension and ischemia of the heart was 4 to 5 times greater with maximum Odds Ratio 19.1 times higher among men 30 to 39 years of age who were radar trackers in a civil airport compared to co-workers not exposed to EMF (Tikhonova, G. I., 2003). Spectral analysis of heart rate and arterial pressure short-term variability, consists of two major components: low- (LF, 0.04 - 0.15 Hz) and high- (HF, synchronous with respiratory rate). Both heart rate and respiratory rate were modified with sympathetic spinal nerve stimulation (Montano et al., 2001). Modulation of microwave, pulse signals, and continuous wave (CW) magnetic fields affected frog isolated heart pacemaker function and heart rate due to microwave heating of tissues which occurred over a wide range of microwave frequencies (Pakhomov et al., 1995, 2000). Nocturnal 60 Hz exposure affected heart rhythm (Sastre et al., 1998) and brain frequency magnetic fields altered cardiac autonomic control mechanisms (Sastre et al., 1994). Graham et al. (1994) found a dose response slowing of heart rate and alterations in the latency and amplitude of event-related brain measures derived from electroencephalograms (EEG) when human subjects were subjected to 9 kV/m electric fields and 20 microTesla (µT–Tesla is a measure of the flux density or intensity of a magnetic field) exposure compared to 6 kV, 10 µT, and 12 kV, 30 µT dose combinations in blind studies. This study confirmed earlier reports that a combined 9 kV, 20 µT dose resulted in slowing of heart rate, changes in brain wave potentials, and changes in reaction time during challenge testing of humans (Cook et al., 1992). We measured 8 kV/m at head height below a 46 kV transmission line passing through a barnyard where the owner developed high blood pressure and irregular heart beat near Leslie, MI.

Cardiac sympathetic nerve fibers originate in the intermediolateral columns of the upper five or six thoracic and lower one or two cervical segments of the spinal cord. Changes in heart rate usually involve a reciprocal action of the sympathetic and parasympathetic divisions of the autonomic nervous system. Thus, heart rate increases with a decrease in parasympathetic activity (vagus nerves) and an increase in sympathetic activity; and decreases with the opposite effect as described by Berne et al. (1998). The parasympathetic nervous system does not enervate the body wall but only structures in the head and the thoracic, abdominal, and pelvic cavities. Thus, location of exposure to specific frequencies may be important in the heart response to electrical stimulation. However, stimulation of peripheral efferent nerves affects the heart through the neuro-endocrine system and exogenous signals need not penetrate the heart directly. Similarly the heating effect produced by stimulation of the thyroids (TSH) can account for the specific absorption rate (SAR) temperature increase upon electrical stimulation of intact man or animals.

The EMF Cortisol Connection – Cortisol in blood, heart rate, and blood pressure increased; and release of oxytocin was delayed when dairy cows were exposed to 4.0 and 8.0 mA contact current compared to no exposure in controlled experiments (Gorewit et al., 1984). Cortisol is released from the adrenal gland when ACTH (adrenocorticotropic hormone) is released from the pituitary by electrical stimulation of peripheral nerves. Similarly, oxytocin release from the pituitary stimulates excretion of milk (milk release) from the mammary gland upon stimulation of the udder by suckling or massaging of the udder in preparation for machine-milking. Impaired milk let-down, i.e., incomplete milking, was a common complaint of dairy farmers raising the stray voltage issue. Milk retained in the udder can increase incubation of low-level infections in the udder resulting in increased somatic cell count (SCC) according to Mein (1998) which may result in exclusion of milk from the market. Therefore, “uncontrolled electricity” can cause severe economic consequences for dairy farmers, in addition to affecting the health and milk production of the herd and the family. Epinephrine administration significantly reduced milk yield in heifers and cows but did not inhibit oxytocin release in response to milking. Investigators found that as little as 50 µg epinephrine inhibited mammary blood flow to the udder by as much as 90% (Gorewit and Aromando, 1984). ACTH, cortisol, oxytocin, and epinephrine are all involved in the chronic electrical-stress syndrome. These responses are activated by chronic stimulation of the autonomic nervous system as described by Berne et al. (1998).

Cortisol Effects on Connective Tissue – Inhibition of collagen synthesis by cortisol produces thinning of the skin and the walls of capillaries. The resultant fragility of the capillaries leads to intracutaneous hemorrhage (Berne et al., 1998). In this regard, a medical officer for an aircraft manufacturer reported finding between 75 and 100 cases of unexplained bleeding tendency, as well as a significant excess of leukemia and brain tumors among workers exposed to low-strength microwaves (Becker, 1990). Collagen in smooth muscle is an important component of blood vessels, the intestinal tract, bone-joint cushions, cartilage and skeletal muscle connectors to bone. Its integrity is impaired by excessive cortisol and cortisol is increased by EMF exposure. A small step of logic allows the conclusion that EMF affects integrity and elasticity of the aorta and other vessels permitting aneurysm, development of weak smooth muscle, gastrointestinal diverticulosis, ulcers, and gastro-esophageal acid-reflex syndrome. Joint-muscle pain is a common complaint associated with EMF exposure and diabetes, as experienced by the author. Type I personalities are often

associated with a stress syndrome and cardiovascular disease, etc. EMF exposure is clearly another source of neuro-endocrine stress. Which part will give out first under chronic electro-stress environmental conditions is the diagnostic puzzle.

The increased cortisol in blood of cows during short-term electrical stimulation concurs with results obtained when rats were exposed to 0.5 mW/cm^2 for periods of up to 25 months. The exposure was 20 times below the ANSI (American National Standards Institute) and military acceptable standard at the time (A. W. Guy, in Becker, 1990). Blood cortisol of all rats was equal at the beginning, but cortisol of exposed rats increased above controls shortly after the experiment began. By the end of the experimental period, cortisol was lower in exposed rats compared to controls. The cortisol pattern was a typical adrenal response to stress finally resulting in adrenocortical fatigue, as in Addison's disease of humans. While the rats used in the Guy experiments were gnotobiotic (germ and virus free), 18% of the exposed rats had cancers of the pituitary, adrenal, and thyroid glands, and only 5% of the controls had cancer (Becker, 1990; Chou, Guy, et al., 1992). In earlier experiments, serum corticosterone was depressed 31.7 %, while albumen levels increased 28.2%, and body weight was 6.6% lower in rats exposed to150 V/m for 30 days compared to unexposed controls (Marino et al., 1975). Similarly, Imaida et al. (1998) found that mean levels of corticosterone, ACTH, and melatonin were higher for rats exposed to near field TDMA modulated 929.2 MHz RF EMF at 50 pulses/sec, 0.33 duty cycle, than for unexposed controls. The experiment was repeated with rats exposed to TDMA modulated 1.439 GHz RFEMF whole body SARs 0.680-0.453 W/kg for 90 minutes per day, 5 days/wk for 6 weeks. Significant increases were found in the serum levels of corticosterone, ACTH and melatonin in the RFEMF group compared to the sham group. However, no difference was found in the incidence of liver cancer. Cancer of pituitaries and adrenals was not reported (Imaida et al., 1998b, in Heynick et al., 2003).

Note that the level of exposure in each of the above cases was less than the 1.6 W/kg SAR allowed by the FCC and Congressional Telecommunications Act of 1996. The ANSI standard was lowered from 10 mW/cm^2 to the present permissible 1.6 W/kg specific absorption rate (SAR) in 1982 on the basis of "new" information. Apparently, it should be lowered again on the same basis, and technology for controlling exposure needs improvement.

Experimental chronic exposures with intact live animals support the hypothesis that pituitary, adrenal, and pineal glands are affected by modulated, pulsed signals as produced by cell phone signal generators, electronic devices using switch mode power supplies, and by power line 60 Hz, 4 to 8 mA contact current. Current and EMF on the ground wire, water pipes, and kitchen sink 1.68 ± 1.0 A, average of 26 measurements in East Lansing homes was comparable to EMF in the living area and current on the ground wire and bathtub in studies conducted by EPRI, the Electric Power Research Institute (Kavet et al., 2005, 2000, 1999).

The pituitary gland produces hormones and neurotransmitters that affect essentially all functions of the body. In addition to ACTH stimulating the adrenal glands (glucose energy supply) and oxytocin stimulating mammary muscle [and uterine contractions at parturition], the pituitary produces thyroid stimulating hormone (TSH) which controls the release of thyroid hormones and determines metabolic rate and heat production, somatotrophic hormone (growth hormone) which influences body mass, protein and energy utilization (i.e., conversion to milk production, and growth), gonadotrophins: follicle stimulating hormone (FSH) causes growth of the ovarian follicles and stimulates spermatogenesis in the testes; luteinizing hormone (LH) transforms ovarian tissue into corpus luteum which produces progesterone and inhibits the estrus cycle following ovulation. Retained CLs are common in dairy cattle and impair reproduction. Prolactin (PRL) initiates milk synthesis of mammary cells. Antidiuretic hormone (ADH) regulates electrolyte concentrations in the blood and water excretion by the kidneys. The neurotransmitters involved in afferent impulses to the hypothalamus are largely, norepinephrine, acetylcholine, as well as serotonin the most important neurotransmitter in the brain.

Serotonin is also secreted by the pineal gland in the hypothalamus, and serotonin receptors are responsive to EMF exposure (Johnson et al., 2003; Sieren et al., 2004). Dopamine, acetylcholine, γ-aminobutyric acid, and the opioid peptide β-endorphin act as neurotransmitters for efferent impulses to the median eminence of the neurohypophysis. These impulses regulate the discharge of releasing hormones or inhibiting hormones into the adjacent capillaries. Virtually all of the tropic hormones from the adenohypophysis cause changes in the concentrations of either peripheral target gland hormones (thyroid, adrenal, gonadal) or of substrates, such as glucose or free fatty acids.

The enormous influences of chronic cortisol stimulation on body functions are well known in medical circles but the influence of environmental EMF on the neuro-endocrine stress syndrome and human health has been overlooked, perhaps because the pieces to the complex puzzle have not been assembled recently.

Chronic excessive stimulation of either sympathetic or parasympathetic control mechanism causes a stress reaction involving the central nervous system, through stimulation of peripheral nerves and activation of the autonomic nervous system response in the brain and the hypothalamus which contain the pituitary and pineal glands. The pituitary issues hormonal responses in the blood, neurotransmitters, which influence the adrenal glands and the function of virtually all organs in the body (Berne et al., 1998, *Physiology*).

The Diabetes Connection – Cortisol maintains glucose production from protein, *"Although the major impact of cortisol is on liver glycogen, an excess of the hormone eventually increases blood glucose levels. This increase occurs because cortisol powerfully antagonizes the actions of insulin on glucose metabolism. Hence, cortisol inhibits insulin-stimulated glucose uptake in muscle and adipose tissue, and it reverses the insulin suppression of hepatic glucose production.* ***In short, cortisol is an important diabetaogenic, antinsulin hormone. Its primary hyperglycemic and lipolytic and secondary ketonic actions are usually exhibited only when its secretion is greatly stimulated by stress"*** (Berne et al., *Physiology*, 1998).

Insulin secretion of pancreatic islet beta-cells was attenuated by exposure of cells to EMF in three of four laboratory experiments, *in vitro,* (Sakurai, et al., 2004). Exposure of insulin to 0.7 V/m electric field of 50 Hz pulsed frequency EMF produced significant time-dependent differences in the conformation of the insulin molecule, reduced the binding capacity to its receptor, reduced the intracellular tyrosine phosphorlation level, and modified gene expression of insulin-signaling pathways and hepatic cell proliferation (Li et al., 2005). Primary deficiency of insulin as a consequence of selective β-cell destruction is known as Type I or insulin-dependent diabetes mellitus. The disease usually results from a genetically conferred vulnerability to an environmental insult that initiates a destructive autoimmune process. Electricity in the environment may be that insult.

An estimated 18 million people in the United States have Type II diabetes. Because a major cause of this form of diabetes is resistance to insulin, the EMF observations by Li et al. (above) offer promising suggestions for mitigating diabetes by following a specific electron diet or reducing electron exposure to specific frequencies and time periods.

The above factors help explain how EMF, millivolts of high frequency Graham/Stetzer Units (Graham, M., 2003) during environmental exposure in the home was related to increased blood glucose of diabetics ($R^2 = 0.83$) and decreased blood glucose and insulin requirements of diabetics when frequency filters were installed in wall outlets to reduce EMF exposure (Havas and Stetzer, 2004). Similarly, the incidence of Type II diabetes was higher among persons living near high power transmission lines and was positively related to an EMF index (mG x time) daily exposure in Australia (Beale et al., 2001). Milk and milk-fat of cows decreased when exposed to 10 kV/m electrical field and 30 μT magnetic fields (Burchard et al., 2004). Similarly, milk fat was lower from cows exposed to 1-5 and 8-12 mA contact current during milking (Aneshansley et al., 1992). Because insulin is necessary for absorption of glucose into mammary cells, and glucose is essential for milk-fat synthesis, cows exposed to EMF and contact current may have been diabetic.

Cortisol facilitates fat metabolism, supports responsiveness of the vascular tree, modulates central nervous system function, and profoundly affects the immune system. In addition to its effect on glucose and fat metabolism, Berne et al. highlighted the following specific effects of cortisol: **Effects on muscle.** Cortisol maintains the contractility and work performance of skeletal and cardiac muscle. [Remember that short-term stress increases cortisol and long-term EMF stress results in adrenocortical fatigue]. **Effects on bone**. Cortisol inhibits bone formation by several mechanisms: reduces Type I collagen formation; decreases the rate of differentiation of osteoprogenitor cells to active osteoblasts; decreases the absorption of calcium from the intestinal tract by antagonizing vitamin D_3. The result of these actions is a reduction in the availability of calcium for bone mineralization. Thus, one major consequence of excess cortisol production is an overall reduction in bone mass (osteoporosis). **Effects on the vascular system.** *Cortisol is required for the maintenance of normal blood pressure.* [However electrical stress increased cortisol, blood pressure and heart rate of cows and humans as noted above.] **Effects on the kidney.** *Cortisol influences the rate of glomerular filtration. The hormone is also essential for rapid excretion of a water load.* In the absence of cortisol, the synthesis and secretion of antidiuretic hormone (ADH) are increased and its action on renal tubules is enhanced; free-water clearance is diminished and dilution of the urine is limited. Diabetes insipidus, the inability to produce concentrated urine and frequent urination (Gotta-Go syndrome) is the hallmark of ADH deficiency. **Effects on the central nervous system**. Cortisol modulates excitability, behavior, and mood of individuals; the electrical activity of neurons is influenced. Both Type I and Type II glucocorticoid receptors (GRs) are present in various areas of the brain, particularly in the limbic system and the hippocampus. Cortisol decreases rapid eye movement (REM) sleep but increases both slow-wave sleep and time spent awake. In excess, cortisol can cause insomnia, strikingly elevate or depress moods, decrease memory and hippocampal volume and memory function. EMF affected sleep in experimental trials (Akerstedt et al., 1999; Huber et al., 2003, 2004) and student behavior in the classroom (Havas & Stetzer, 2004) and electro-hypersensitive persons had higher heart rate and heart rate variability (Lyskov, 2001). Cortisol also specifically decreases the ability to detect a salty taste and dampens acuity to gustatory, olfactory, auditory, and visual stimuli. On the other hand, cortisol improves the ability to integrate those sensations that are perceived and to organize appropriate responses. **Effects on the fetus.** *Cortisol facilitates in utero maturation of the central nervous system, retina, skin, gastrointestinal tract, and lungs.* (See Berne et al. for details). However, in a study of 1583 pregnant women, those using computers more than 20 hours per week had 40% more miscarriages compared with female workers who did not use computers (Goldhaber et al., 1988). Prenatal development of the central nervous system is a particularly sensitive marker of heat-induced developmental abnormalities and can be correlated with heat-induced behavioral deficits (Saunders and McCaig, 2005). Body heat increased during EMF electrical exposure. Extensive reviews of EMF effects on reproduction, embryonic and fetal development were published by Brent 1999; Heynick et al., 2003; and Levin 2003). **Effects on inflammatory and immune response.** *Cortisol has a profound influence on the complex set of reactions evoked by tissue trauma, chemical irritants, infection, or foreign proteins.*

The EMF Cancer Link – Cortisol inhibits recruitment of circulating leukocytes to trauma or infection sites, decreases phagocytic and antibacterial activity of circulating neutrophils, i.e., increases neutrophils release from bone marrow but decreases their effectiveness for controlling disease, and (EMF decreases AMP to ATP energy transfer in neutrophils), decreases number of circulating eosinophils, decreases number of thymus derived T-lymphocytes, and depresses the immune system response to invading organisms or substances such as viruses.

Melatonin a hormone secreted from the pineal gland is associated with the function of the circadian clock which regulates sleeping, and many related functions of the body.

Leukemia and lymphomas (tumors) are characterized by the abnormal proliferation and reduced differentiation of developing lymphocytes and other blood cells in peripheral blood, bone marrow, and tumor tissues. The diagnostic report for the lymphoma patient revealed: “cytogenetics tests of bone marrow

cells were abnormal in culture cells stimulated by lymphoid mitogens. Two of the metaphases were abnormal due to multiple structural and numerical aberrations characterized by additional material on the short arm of one chromosome 2, trisomy 3 with one being abnormal, rearrangements of 6q, 8p and trisomy for chromosomes 7 and 18 and 2 markers. The spectrum of abnormalities are most consistent with the presence of a lymphoma or other lymphoid disorder. Skin biopsies of both lower left leg lateral and medial section morphological features were consistent with diffuse large B cell lymphoma. Otherwise, the patient was a chromosomally normal female, Karyotype 46,XX ."

Cytotoxicity of a T-lymphocyte line against lymphoma target cells was inhibited by exposure of the lymphocytes to 450 MHz field sinusoidally amplitude-modulated at frequencies between 3 and 100 Hz (Lyle et al., 1983). Exposure of the effector cells to the field prior to adding them to the target cells in the cytolytic assay resulted in a similar inhibition, suggesting a direct interaction of the field with the cytolytic T lymphocytes (Lyle et al., 1993). This corresponds to changes in immunological response of B- and T-lymphocytes to mitogens after long term chronic exposures reported by Guy et al. (1985) and was similar to the failed lymphoblast response to staphyloccus *aureus* antigens in cows exposed to low-level intermittent electricity for two-weeks in a report to Advisors to the Minnesota Public Utilities Commission (Reinemann et al., 1999).

Secondly, changes in the absolute numbers and ratios of CD4+/CD8+ lymphocytes in favor of CD8+ cells of cows at Farm A housed under a 380 kV transmission line exposed to 1.98 to 3.28 μT magnetic fields compared to cows at a distant Farm B considered zero exposed, except in brief periods (3 min × 4 times/day) during which 0.2 to 0.7 μT were present while a feed distributor was running. Investigators found that the mean values of CD8+ and CD6+ leucocyte sub-populations were significantly higher in cows from the exposed farm. Two typologies of CD8+, called Dim and Bright in function of the cytofluorescence analysis, are evident in the exposed farm whereas the population remained single in the not-exposed farm.

Melatonin concentrations are higher during darkness and decrease during daylight. Melatonin is believed to produce strong oncostatic, immunological, and antioxidant functions in the blood. EMF exposure has decreased melatonin concentrations in blood, or urinary excretion of its metabolite, in humans sleeping under an electric blanket (Wilson et al., 1990), electrical workers exposed to 60 Hz magnetic fields while working in substations or on 3-phase conductors (Burch et al., 2003), women exposed to visual display units (computer monitors) during office work (Arnetz and Berg, 1996), in dairy cattle exposed to overhead EMF (Burchard, 2003), and in laboratory animals (Reiter, 1994).

A study conducted in Denmark (Olson et al., 1993) investigated 1707 cases of leukemia, brain tumors, and malignant lymphomas recorded in the Danish cancer registry and were restricted to children of less than 15 years at diagnosis. Controls were selected at random from the central population registry. The study revealed that exposure to magnetic fields (in the order of 0.4 μT, (4 mG) increased cancer. The risk for lymphoma was already increased for fields above 0.1 μT (1 mG). In a study by Robinette et al., (1980) on naval personnel and radio operators it was shown that workers in this occupation had a higher than normal risk for brain cancer. Mortality from cancer was increased close to air force bases compared with other places. It was concluded that this was due to the proximity of radar installations. Similarly, the rate of brain tumors was higher among navy radar operators than among other appropriate controls following the Korean War (Lin, 1985, in Becker, 1990).

EMF-Cancer (Direct Evidence) – Electrical currents had been traced from utility down-ground wires to water pipes where 180 Hertz current combined with 3rd, 5th, and 7th harmonics in the living areas of homes were positively associated with cases of leukemia, lymphoma, and brain tumors where victims had died in Denver, Colorado (Kuane et al., 2002). Positive associations between power line EMF and leukemia, lymphoma, brain tumors, spontaneous miscarriages, alzheimer, and suicide of electrical workers, etc. were reported by California Department of Health Services. For access to some 400 references see (Neutra et al., 2002) at the website listed below or address in the references at the end of this article. Many articles have appeared since 2001 when the California reference list was compiled. Childhood and adult leukemia, lymphoma, and brain tumors have been associated with odds ratios 2 to 4 times greater risk among persons exposed to 4 mG or higher EMF (Kaune et al., 2002; Neutra et al., 2001; Ahlbom et al., 2000; Villeneuve et al., 2000; Robinson et al., 1999; Coghill, 1996; Verschaeve, 1995; Fechting and Ahlbom, 1993; London et al., 1991; Loomis et al., 1990; Thomas et al., 1987; Savitz et al., 1988; and Wertheimer and Leeper, 1979, 1982, 1995). Furthermore, efforts were made to identify possible confounders, that could bias the results of these studies (e.g., air pollution, socio-economic conditions, water quality, traffic patterns, static magnetic fields and resonance models, but no evidence of such confounders has been identified.

Horst et al. (2004) found that persons living within 400 meters of a cellular phone tower had 3 times more cancer than those living more than 400 meters from the tower. Our evidence showing the high frequency EMF typical of the rf and microwaves produced by the cell phone signal generator transmitter measured from the ground wire, and measured on the ground wires and water pipes of a neighbor lady with nonHodgkin's lymphoma, concurs with the results of Ontario, Canada Hydro Electric employees. Incidence of nonHodgkin's lymphoma was 3 to 4 times higher in the top thirty percent exposure-time index of electrical employees based on measured electric fields (thresholds 10 and 40 V/m) compared to administrative and office employees with low exposure (Villeneuve et al., 2001).

Electro-Sensitivity of people is now recognized as a physical impairment by government health authorities in the United Kingdom and Sweden. The UK Health Protection Agency (HPA) recognized that people can suffer nausea, headaches, and muscle pains when exposed to electromagnetic fields from mobile phones, electricity pylons and computer screens. They recognize that general practitioners (GPs) are not generally aware of the electro-sensitivity syndrome and HPA will provide guidelines for GPs to follow in diagnosing the disease.

Doctors may need to examine EMF in the home, and perhaps in their own office to identify the sources and will need to add EMF meters to their instrument bag to confirm a diagnosis.

Development of cardiovascular disease, diabetes, and nonHodgkin's lymphoma of the immediate occupants in this study is consistent with recognition of health authorities that chronic disease "Cancer, Cardiovascular, and Diabetes" account for two-thirds of the $1.55 billion spent on health care in this country and are increasing, according to the Center for Disease Control (Lansing State Journal, 10/02/05). Secondly, our finding supports the likelihood of increased risk of other major diseases caused by excessive exposure to EMF.

National Institutes of Environmental Health mentioned possible EMF associations with sudden cardiac death, dementia, suicide (NIEHS, Portier and Wolf, 1998), and spontaneous abortion (Li et al., 2002, and Lee et al., 2002) as reported by California Department of Health Services (Neutra et al., 2002, p. 10) on website:
http://www.dhs.ca.gov/ehib/emf/RiskEvaluation/riskeval.html

Some of the California EMF findings and Michigan's 51,000 new cancer cases per year were in Shocking News #2, May, 2004, and are on the website www.electricalpollution.com

Sources of EMF – The Ground Wire in Homes, Schools and Workplaces – Our electrical data concur with studies by EPRI (Electric Power Research Institute), the research arm of the power industry. Kavet el al. (2000) found strong correlations with the average magnetic field in the living area and the 24-hour average net current on the service drop (the ground wire) and the number of service drops on the same transformer. Similarly, Kavet (2005) found that EMF in living areas was correlated with volts on water pipes, and volts on the bath tub. Excessive voltage and current was on water pipes, the kitchen sink, bathtub, sheet metal air ducts, chair springs, and bed springs in our home (Shocking News #7).

Modern Household Appliances and Office Equipment with electronic controls, i.e., heating and air conditioning units, television, VDUs (computer monitors), printers, copy machines, MRI, digital clocks, microwave ovens, TV, radio, refrigerators, stoves, etc., produce harmonics and emit large amounts of EMF to distances of 1 to 6 feet from the appliance in our home.

- G/S meter readings from wall outlets in Kellogg Center, MSU were 700 to 1760 G/S Units, while in my home they now read 15 to 20 G/S Units, down from 120-200 (units of high frequency current) in wall outlets.

Mitigation of EMF has been achieved by:

1. Installing a dielectric union (rubber insulated connector) in the water pipe to which the ground wire is connected. Some homes may already have this isolation. You need to know if yours does. If it was built before 1975, it may not have a dielectric connection and magnetic fields on the ground wire and water pipes could be very high.
2. Installation of high frequency filters in the wall outlets of homes can dramatically reduce the EMF from the outlets and the EMF environment in living areas. Contact dave@stetzerelectric.com
3. Installation of a shielded neutral isolation transformer between the utility (source) and the customer (end-user) service connection will prevent the high frequency signals from passing from the utility wires to your home or business circuits. This should be required of all businesses that produce a large amount of high frequency residue (dirty electricity) on the ground wire.
4. Improved maintenance of utility (primary) and/or customer (secondary) wiring to reduce resistance on circuits by installing adequately sized transformers, and neutral to the substation wire conductors serving customers. Most utility engineers know what to do, but executive $ objectives often take precedence over risks to human health and life.

CONCLUSIONS

Excessive electrical current and high frequency rf and microwave magnetic fields were tracked via oscilloscope measurements from the cellular telephone station at the water tower in Patriarche Park. Signals were on the utility ground wire and radiating into the living areas of homes and a school in East Lansing. Heart rate, heart rhythm, and blood pressure were affected during exposure to electromagnetic fields (EMF) in a home. Similarly, occupational exposure and controlled laboratory studies confirm these findings. Diabetes, NonHodgkin's lymphoma, and other health impairments that occurred to residents near the park, plus leukemia, and brain tumors have been associated with EMF in other studies. Cardiovascular disease, diabetes mellitus and impaired immunity are typical physiological responses to neuroendocrine stress. Pituitary and adrenal gland responses to both contact current and electromagnetic current have been demonstrated in humans and animals. Excessive current and mG of magnetic fields were observed at ten homes in the area. Recorded measurements were outside of IEEE stands for power quality and OSHA standards for electrical hazards. Methods for mitigation of environmental contamination are known and should be encouraged by utilities and government agencies responsible for electrical safety and human health.

Michigan Public Service Commission promulgated Rules R460.2701 to RR460.2708, etc. would not require utilities to identify any electrical problem other than 60 Hertz, steady state voltage or current, and would not require using appropriate instruments to detect the problems in the East Lansing community or elsewhere in the state. Further, the MPSC proposed rules will have the effect of using the power of the state to allow utilities to avoid their responsibility to protect citizens and residents from unhealthy and unwanted electrical damage.

Abstract

Electromagnetic fields (EMF) have been implicated to influence a range of bodily functions. Given their ubiquitous nature, widespread applications, and capability to produce deleterious effects, conclusive investigations of the health risks are critical. Accordingly, this paper has been constructed to weigh the bioeffects, possible biointeraction mechanisms, and research areas in bioelectromagnetics seeking immediate attention. The several gaps in the existing knowledge do not permit one to reach a concrete conclusion but possibility for harmful effects cannot be underestimated in absence of consistent findings and causal mechanisms. Several studies with appropriate methodologies reflect the capacity of electromagnetic radiations to cause adverse health effects and there are several credible mechanisms that can account for the observed effects. Hence, need of the hour is to activate comprehensive well-coordinated blind scientific investigations, overcoming all limitations and demerits of previous investigations especially replication studies to concretize the earlier findings. Furthermore, appropriate exposure assessment is crucial for identification of dose-response relation if any, and the elucidation of biological interaction mechanism. For the time being, the public should follow the precautionary principle and limit their exposure as much as possible.

1. Introduction

The terrestrial electromagnetic environment has been and is being rapidly altered by humans as a result of technological advancements. This was well recognised very early in the seventies by Dr. Robert O. Becker (twice nominated for Nobel Prize) who said “I have no doubt in my mind that, at the present time, the greatest polluting element in the earth’s environment is the proliferation of electromagnetic fields (EMFs).” On one hand, these electromagnetic waves (EMW) provide immeasurable benefits; on the other hand, they may also create potential hazards through uncontrolled and excessive radiation emissions. There are various types of electromagnetic radiations (EMRs) and

depending upon their frequency and wavelength they are categorized into different types. Broadly the EMFs are categorized into two groups, namely, extremely low frequency (ELF) EMF (>3 Hz–3 kHz) and radiofrequency radiation (RFR) EMF (3 kHz–300 GHz). Scientific investigations concerning the interaction of EMF with living systems, especially its health effects, are increasing in number. There are arguments for both positive [1–3] and negative bioeffects [4–8]. However, the lack of sufficient knowledge on biological effects of the vast majority of frequencies even below the safety limit leads to several apprehensions [9–11]. The discussion is still ongoing especially regarding the contentious nonthermal effects. It is considered that the energy absorbed calculated in terms of specific absorption rate (SAR) [12] is too low to produce biological effects [13]. At the same time, several studies have demonstrated the influence of EMF by energies that are much lower than those capable of producing temperature changes in living tissues [10, 14]. The cell physiology either in vitro [14] or in vivo [15] can be affected by these temperature-insensitive reactions. Whether this could result in pathological alterations in higher life forms is a matter of debate [16]. Despite the documentation of temperature-insensitive biological effects, they have not been considered in the existing EMF safety standard; rather it is principally based on heating effect of EMF [17]. The current SAR values for general and occupational groups are presented in Table 1. As a result, current recommendations are established on the lowest exposure known to induce acute observable effects due to heating [7].

tab1

Table 1: Showing the SAR values for general public and occupational groups laid by ICNIRP [18], International Commission on Nonionising Radiation Protection; SAR stands for specific absorption rate expressed in Watts per kilogram (W/kg).

In the past, when much of the attention was centered on certain EMW called ionizing radiation, the others called nonionizing radiation (NIR) were generally assumed to be harmless. However, after World War II, this assumption has been reconsidered. The overwhelming scientific investigations concerning health effects of NIR have highlighted their potential to affect the well-being of biological organism. Several researchers have raised questions regarding adequacy of current safety limits [17] and asserted for their revival so that the new biologically based exposure limits will be capable of eliminating the possibility of bioeffects [19].

Some of the documented bioeffects include changes in melatonin levels [20–25], induction of heat shock protein (hsp) [26], effects on spatial memory [27, 28], alteration of intracellular calcium concentration [29], changes in blood-brain-barrier permeability (BBB) [30], enzyme activity [31], genotoxicity [32, 33], nonspecific disabilities, and subjective symptoms [34–37] to name a few. Also, radiation exposure from mobile phones (MPs) has been linked with tinnitus, brain tumours, and acoustic neuroma [38–41]. Additionally, studies at cellular/molecular level are important in illuminating the actual primary injury produced by EMFs [17, 27].

The field of bioelectromagnetics is surrounded with controversies because some studies are contradictory [11, 42] and not always corroborated by independent researchers [35]. The lack of any accepted causal mechanism further adds to the controversy. As a result, important details are simply not comprehended and generate confusion in the general public. As uses expand, the new situations are likely to further increase the environmental EMF levels. To cope with these situations and to promote life of biological organisms more comfortably and efficiently achieving a scientific understanding of the biointeractions of these fields and evaluation of health risks is highly desirable. This paper, therefore, has been constructed to weigh carefully the bioeffects, biointeraction mechanisms and lacunae in EMF research areas seeking immediate attention so that the public is not excessively exposed nor the technological advancements suffer a setback by unjust fears that may or may not exist. In this review, we shall restrict our discussion to the health relevant effects of ELF-EMF and RFR-EMF.

ELF and RFR-EMF related studies were identified by peer-reviewed literature and data searched in electronic database (PubMed) using a number of key words and their combinations (electromagnetic field, health effects, electric, magnetic, reproductive outcome, and biointeraction mechanisms as examples) in order to find English-language reports related to electromagnetic field health effects and their probable modes of action. A number of papers were retrieved by hand searching several journals and few were obtained through direct correspondence with the authors. Unlike other review papers, no strict inclusion criteria were set. However, a rational explanation of the experimental design, use of control/sham population, exposure conditions, blinding of the research, statistical assessment of the data, and role of artifacts could be reached for most, but not all investigations.

2. Health Effects of Electromagnetic Fields

2.1. Electromagnetic Hypersensitivity (EHS)

EHS is a recent phenomenon of occurrence of subjective signs and symptoms in some sensitive individuals with EMF experience from varied electronic sources. Despite lower levels of exposures, symptoms of ill health have been observed among the subjects [34]. According to WHO [43], about 1–3% of the world's population are affected by this EHS syndrome. The exposure to EMFs especially at lower levels and for long duration was originally reported among the East European radar workers and linked with a number of subjective and objective (skin and mucosa-related) symptoms. Sufferers often label EHS as loner's disease because of the consequent social isolation [9]. Epidemiological investigations have been conducted on people complaining about unpleasant symptoms (Table 2). Complainants have related their symptoms most frequently to exposure to MP base stations (74%) followed by MPs (36%), cordless phones (29%), and power lines (27%) [36]. Objective skin symptoms of EHS have been related to increase in mast cell counts and their degranulation, thereby causing the release of inflammatory substances such as histamine responsible for allergic hypersensitivity, sensation of itch and pain, edema, local erythema, and many kinds of dermatoses [19]. With reference to effects of ELF-EMF, Barsam et al. [44] studied the effect of occupational exposure on sleep quality in high voltage substation workers. In their case-control study, they found poor sleep quality among 90.5% of cases and 85.3% of controls. Despite, the increased prevalence of poor sleep quality in exposed group, no statistically significant difference was reached. Similar occupational studies conducted in substation units of a petroleum complex also revealed higher percentage of poor sleep quality in addition to poor health condition in exposed population when compared to control population [45]. However, the researchers in this group also could not reach any statistically significant correlation between the ELF-EMF exposure level and poor quality of sleep and health status. Another case-control study undertaken on the occupational group of electric utility workers highlighted the increased rate of suicide attempts in exposed group as compared to controls [46]. The authors also suggested that the occurrence of depression in the exposed workers might be the plausible reason. A study by Beale et al. [47] demonstrated the occurrence of psychological symptoms like suicide, depression, and unmanageable emotional condition amongst the residents exposed to chronic 50 Hz MF exposure as a result of their residence in the vicinity of high-voltage substations and power transmission lines. Case studies and anecdotal reports in this regard indicate that people's health problems like diabetes, multiple sclerosis, asthma, and so forth could have some association with biologically active dirty electricity which has been found to improve when levels are reduced [48]. Dirty electricity present in the surroundings has been shown to affect the well-being of teachers and pupils. Use of filters ameliorated the effects, thereby protecting sensitive individuals [49].

tab2

Table 2: Subjective signs and symptoms of electromagnetic hypersensitivity (EHS) [34, 36].

As regards RFR-EMF, Navarro et al. [37] carried out a health survey in the vicinity of a cellular phone base station, working in DCS-1800 MHz frequency range with exposition time greater than 6

hours/day, 7 days/week, in 95% of the subjects. Exposure assessment was done by measuring microwave power densities at residence of respondents. Statistical analysis revealed a significant correlation between the declared severity of symptoms and measured power density. The study also showed an increase in the declared severity in groups with higher exposures. Comparable studies have also been performed reporting significant relation of some symptoms to the measured exposures [34]. Epidemiological studies suggest that frequency and severity of symptoms tend to increase with duration of exposure and are reversible if exposure is discontinued temporarily or permanently with symptomatic and general supportive treatment and also severity weakens for those residing far away from exposure source. For instance, in one of the health surveys among self-declared EHS individuals, 90% of subjects reported occurrence of health symptoms when present in the exposure area and disappearance of the same after leaving the exposure area [36]. Studies have also highlighted the significant link between longer duration of daily MP use and health effects [31, 50, 51]. The MP use by children in this regard can be deleterious as their nervous system is under development and greater amount of energy is absorbed because of their thinner skull bones as compared to adults; additionally longer exposure duration increases their vulnerability to a greater extent [52]. However, to date, quality double-blind studies have not shown any correlation between subjective health complaints and RF exposure [43]. At the same time, epidemiological studies of EMF well-being are difficult to conduct because of imprecision in exposure assessment [53–56] and lack of objectivity in measuring health effects or complaints [35]. In addition, the symptoms are nonspecific and subjective, based on self-reporting, and hence difficult to prove clinically in absence of clear diagnostic criteria for the condition [57]. The subjective complaints of well-being also vary from individual to individual and are a function of several variables like age, sex, social status, anxiety, current health status and accompanying disease, and personality traits [35] as well as the fear generated due to awareness of adverse effects from EMF exposures [34]. Psychological stress may be one of the consequences of EHS in patients and incomplete understanding of pathophysiology of these complex symptoms in absence of any single biomarker so far recognized unique to EHS makes the diagnosis and medical treatment a complicate endeavour [9, 35]. It has also been suggested that subjective symptoms could be the consequence of already prevailing psychiatric condition or stress response resulting from EMF health concerns instead of the exposure itself [43]. In today's modern world, when we cannot part away from electronic gadgets, the EMF experiences are real and practically unavoidable, resulting in disturbances, which could be devastating for a few afflicted individuals. In dearth of any visible causal mechanism and pathophysiological biomarker, its etiology is quite incomprehensible. The pain of EHS patients aggravates further, when the majority of population do not experience any symptom with EMF exposures. The increasing number of reports on EHS however warns us to take this research promptly and locate the biomarkers that could give some clue in ameliorating the problems of such individuals. More investigations are hence needed to completely delineate the pathophysiology of EHS along with the generation of clear diagnostic criteria to identify the problem and develop strategies to limit the suffering of afflicted individuals. Besides, investigations dissecting the relation between EHS manifestation in elderly, children, and diseased persons (like neurodegenerative diseases, mentally and genetically unstable conditions) with EMF experiences are crucial. The lacunae in human studies, with regard to exposure assessment, inclusion of suitable controls, and data collection, and so forth, need to be eliminated to reach fruitful insights. For the time being, individuals with EHS need to be supported by the family, society, and the government to lead a normal and respectable life.

2.2. Cytotoxic and Genotoxic Effects

DNA alteration is considered to instigate carcinogenesis [8, 58] and change in DNA or micronuclei (MN) generation is an accepted indication for genotoxicity [59]. Different cell types and organisms have been reported to react differently to differing exposure characteristics [26, 32, 60]. Concerning this, Ivancsits and coworkers [61] have identified three responders (fibroblast and melanocytes from human, granulosa cells from rat) and three nonresponder cell types (lymphocytes, monocytes, and

skeletal muscle cells from human) when exposed to intermittent ELF-EMF using alkaline and neutral comet assays. Delimaris et al. [62] examined the effect of pulsed 50 Hz EF on human lymphocytes and showed significant DNA damage in exposed group in comparison to controls. However, Scarfì et al. [58] could not detect any statistically significant genotoxic difference in human fibroblasts exposed to intermittent 50 Hz EMFs. A number of studies have demonstrated the potential of ELF-EMF to cause DNA damage [33, 63–66].

As regards RFR-EMF, d'Ambrosio and coworkers [67] have documented significant micronuclei occurrence with phase modulated RFR as against no effect by continuous wave (CW). Phillips et al. [68] observed reduced and increased SSB, at least in some experiments at low and high SARs, respectively, with RF-EMF exposures as opposed to sham controls. Increased DNA damage was reported in human lens epithelial cells exposed to 1.8 GHz at 3 W/kg [69]. Similar findings were reached by Sun et al. [70] on the same cell types after two-hour exposure to 1.8 GHz at SARs of 3 and 4 W/kg. DNA damage at 4 W/kg was found to be irreversible. Studies on marine radar operators also registered significant increase in MN frequency and comet parameters of % of DNA in tail and tail moment after EMF exposures [1]. A detailed summary of various studies have been tabulated (Table 3). The occurrence of aneuploidy is well acknowledged to enhance the risk of tumour. In this context, linear and SAR dependent aneuploidy rise for chromosome 17 detected by fluorescence in situ hybridization post RFR exposure further substantiates their carcinogenic potential [67]. Significant DNA damage occurred after EMF exposure [71], which decreased with free radical scavenger treatment suggesting free radical involvement in inducing damage [3, 33]. Ferreira et al. [72] found a significant increase in erythrocyte MN frequency in newborn pups from irradiated pregnant rats suggesting the genotoxic potential of EMF exposure. Some investigations have shown the genotoxic potential of EMFs only when coupled with some mutagen or carcinogenic or physical agents indicating their synergistic effect [13, 64]. Cell-culture studies by Luukkonen and coworkers [73] conducted on human SH-SY5Y neuroblastoma cells to study the combined effect of CW-RF (872 MHz) and global system for mobile communication (GSM) with menadione suggested that 872 MHz CW-RF radiations at 5 W/kg might enhance chemically induced reactive oxygen species (ROS) production and thus cause secondary DNA damage. At the same time, enhancement of chemically induced DNA damage observed in this study was associated only with the CW-RF; no effects were seen with GSM signal. Amid these positive effects, Lagroye and coworkers [8] did not find any alkali-labile DNA damage, DNA-DNA cross-links, and DNA-protein cross-links in mouse fibroblast cells exposed to continuous 2450 MHz at 1.9 W/kg for two hours implying their inability to produce genotoxic effects directly by damaging the DNA. Proteomic study on endothelial cell-lines showed the manifestation and phosphorylation of various, chiefly unidentified proteins with RF-EMF exposure [14]. Amid these proteins is Hsp 27, a biomarker for cellular stress. Variation in the expression of cellular stress marker Hsp 90 postirradiation suggests the complex cell defense mechanism and cell response to EMF [26]. EMF interaction with biological system is a very complex process and is a function of several biological, physical, and environmental factors. The exquisite sensitivity of biological systems to EMF experiences leads to intriguing results and regardless of scientific evidences accumulated so far, it is difficult to conclude about EMF toxic effects as the contradictory findings tangle the results confounding the true findings. The differences in experimental protocols in terms of frequency applied, modulation, intensity, investigated endpoints, cell type used, sample size, and so forth have also added to the controversy [5, 10, 60]. Evaluation of present data also becomes difficult due to relatively small number of replication studies because of want for funding. However, possibility of genetic hazard cannot be eliminated in view of conflicting scientific outcomes and lack of accepted causal mechanisms, as the confusion has been generated by some commercial groups in their own interest. Therefore, the need of the hour is to critically analyse the differences and similarities in study variables with greater emphasis with regard to biological systems used, exposure characteristics, study protocol used, findings, data interpretation, and conclusions

drawn along with recognising the source of funding, rather than giving weight to the number of studies either observing or not observing an effect. Addition of statistically sound scientific investigations dissecting EMF biointeraction with respect to field direction, orientation, polarization, duration and time of exposure, and so forth needs to be elucidated to gain fruitful insights into cellular behaviours and their responses. However, this province seems of least interest in bioelectromagnetics research. Further investigations investigating the link between EMF exposures and the blue print, that is, the DNA of children, aged, and sick (neurodegenerative, genetic, or mental disease), are needed and will further substantiate the earlier findings. Given the inconspicuous nature of EMF health effects, even slight deviations in experimental protocols can head towards intriguing outcomes. Therefore, sound experimental designs with appropriate methodologies are critical in order to reach firm grounds. In light of the researches done so far, we conclude that the bulk of literature on EMF and cytogenetic endpoints reflect both positive as well as negative effects. Hence, for now, precautions should be taken to limit the exposures as much as possible.

tab3

Table 3: Studies on the cytotoxic and genotoxic effects of electromagnetic fields.

2.3. EMF and Cancer

Epidemiological investigations have focused attention towards association between ELF-EMF exposures and incidence of tumours [6, 40, 41, 77]. Investigations concerning military personnel also indicate the development of tumours [17]. Amongst all cancer endpoints weighed in epidemiological investigations, childhood leukemia in connection to postnatal exposure exceeding 0.4 μT gets the maximum support for an association [54]. Recently, a formal assessment for suggestion of carcinogenesis from exposure to static and ELF fields by the International Agency for Research on Cancer [78] concluded that ELF-MFs are possibly carcinogenic to humans and grouped them in 2B category.

With regard to RFR-EMF, Hardell et al. [38] in their study suggested that occurrence of vestibular schwannoma has increased in the decades after introduction of cell phones in Sweden, the country with the highest use of mobile technology [17]. Hardell et al. [38] conducted a cross-sectional study in order to find the association between cell phone usage and vestibular schwannoma. Self-administered questionnaire was used for exposure and symptom assessment. Cases were identified from the Swedish cancer registries with age, sex, and geographical area matched control. Histopathological and anatomical tumour localization was done by CT and MRI scans. The authors reported risks for vestibular schwannoma among cell phone users. Significant rise in risk was reached for analogue phone users. Elevated risks were also calculated for cordless and digital phones but these results could not reach statistical significance. The researchers also reported cases of unilateral tinnitus in some persons using cell phone on ipsilateral side; however, a causal relation could not be established on the basis of case report. With regard to association between vestibular schwannoma and cordless and cellular phones, another interesting finding was observed. The highest rising incidence was obtained for men and the age group of 50–59 years. MP use has also been associated with ipsilateral cerebral brain tumours [77, 79], astrocytoma and acoustic neuroma [40, 41], and contralateral temporal tumours [79]. Muscat et al. [79] evaluated the risk of brain tumour in relation to handheld cellular phone use. They included the malignant brain tumour patients as cases (469) and hospital patients as controls (422) after matching for gender, age, race, hospital, and month of admission. Structured interview was employed to gain information related to MP use. The mean duration of MP usage for cases and controls was found to be 2.8 years and 2.7 years, respectively. Out of the 41 measurable tumours, 26 appeared on the ipsilateral side while 15 appeared on the contralateral side. The authors did not find any association between short-term handheld cellular phone use and cerebral brain tumour risk. Another study by the same group [80] based on hospital derived acoustic neuroma patients as cases (90) and patients with nonmalignant diseases as controls (86) reported an average cell phone use

of 4.1 and 2.2 years, respectively. Odds ratio was found to increase from 0.5 for 1-2 years cell phone use to 1.7 for 3–6 years group; however, the relative risk did not differ significantly with regard to the frequency, duration, and lifetime hours of use. The study by Muscat group was surrounded with limitations like lack of data on long-term users especially with regard to under-estimation of risks for slow growing tumours. Hepworth et al. [81] found no association between increased glioma risk and MP use along with absence of any relation with time since first use, years of use, total hours of use, or number of phone calls. The positive association observed between glioma risk and ipsilateral MP use in conjunction with the negative association as regards contralateral MP use was attributed to recall bias as the glioma patients tend to overreport the use on the same side of the tumour while under mentioning the same on the opposed side. This large case-control study was carried out with cases identified from hospital records and cancer registries whereas controls were selected randomly from the general practitioner's list after matching and personal contact. The details regarding the tumour site and laterality and tumour grade were judged from the pathology reports and scans. Computer assisted personal interviews were used to extract the details pertaining to MP use, number of calls made and received, start and stop year, side of use, model and make of MP used, network operator, use of handsfree, usage in rural/urban area, and so forth. On the basis of two case-control studies on brain tumours with regard to MP and cordless phone use, the Hardell group found an elevated risk for ipsilateral exposure with >10 years latency period and subjects started using MP and cordless phone below 20 years of age as regards both astrocytoma and acoustic neuroma [41]. Questionnaire method was employed to evaluate the exposures and cases were identified from the cancer registries. The tumour was assessed with regard to the anatomical region in the brain and was associated with the head side used during phone calls with ipsilateral use defined as greater than 50% and contralateral as less than 50% of the calling time. A review was undertaken with an aim to assess the brain tumour risk in relation to long-term use of mobile phones greater than 10 years and ipsilateral exposure [40]. The reviewers based their findings on the basis of 18 studies (2 cohort and 16 case-control) and found an increased risk for acoustic neuroma and glioma. In addition, the chance of tumour was found to be the highest for ipsilateral exposure in all the studies as reflected by the increased odds ratio. Another review by Levis et al. [82] concluded that the risk for head tumours doubles with long-term MP use. They also observed that methodological flaws with regard to nonblinding of experiments produce negative results and underestimate the risk for tumour development, whereas those studies, which are free from errors, biases, and financial interests, therefore, employing blind protocols, yield positive results indicating a cause-effect link between log-term use of MPs and statistically significant rise in head tumour risk. With increasing number of dynamic MP users worldwide, scientists consider this as the "largest biophysical human experimentation" ever conducted in the past history [17]. An interesting finding was reached in which incidence of brain tumour was found to be higher in populations of cell phone users in rural areas as compared to urban [39]. Also, average exposures have been observed to be slightly higher in rural areas compared to urban areas from MP base stations [34]. In this regard, the connection between exposures and geographic area, ethnicity, nutritional status, economic status, and so forth may provide some remarkable insights and further enhance our understanding. However, association between brain cancer incidence and MP use remains unclear due to inconsistent findings. Short-term and long-term cellular telephone use also did not reflect any connection with cancer risk [6]. As far as cancer risk in animals is concerned, lymphoma risk was found to be significantly higher in experimental groups of mice exposed to pulsed RFR 900 MHz coming from cellular phone than in controls [83].

Study by Cho and Chung [59] suggested the role of low density ELF-EMF as an enhancer in initiation process of Benzopyrene rather than as an initiator of mutagenic effects in human lymphocytes. Most reviews, however, do not support EMF exposures to be carcinogenic. Lack of supportive animal data for carcinogenic potential of EMF also makes the understanding of epidemiological outcomes a difficult enterprise along with faults in human experiments especially with respect to exposure

assessment. Majority of the reviews have indicated lack of evidence for cancer initiation by magnetic field (MF) alone; however, accumulating evidence suggests that they could act as cocarcinogens if given in combination with known genotoxic or nongenotoxic carcinogens showing their synergistic effect. Additionally, the DNA damaging potential of EMFs by free radical generation and also by increasing their lifespan coupled with alterations in DNA repair mechanisms is of concern. However, considering the information in hand on carcinogenesis, cocarcinogenesis with tangling results in the absence of established mechanisms, strict limitations to exposures are suggested till the time any firm conclusion is reached.

2.4. Effects on Endocrine System

Among the several hormones secreted by the body, melatonin gained the focus of most of the EMF investigations. Melatonin, essentially a tryptophan derivative produced chiefly from the pineal gland has been documented to be affected by EMF in animals [25, 84, 85] as well as in humans [21, 22, 24]. In addition, the enzyme machinery involved in melatonin biosynthesis has also been reported to be affected by EMF action [86, 87]. Recently, Bellieni et al. [88] investigated the effect of ELF-EMFs from incubators on melatonin production in newborns who had been kept in the incubators for at least 48 hours. In their study, they found a transitory rise in melatonin secretion almost immediately after the babies were taken out from the incubators, highlighting the EMF potential to influence newborn melatonin production. Significant melatonin depression was registered in an occupational cluster of electronic equipment repairers exposed to ELF-EMFs due to their work in comparison to controls [89]. Epidemiological studies performed on Swiss railway workers exposed to 16.7 Hz MFs exhibited statistically significant reductions in mean evening 6-OHMS (6-hydroxymelatonin sulphate) concentrations after first and fifth days of exposure [24]. The result of yet another occupational study conducted among male electric utility workers exposed to 60 Hz yielded a decrease in postwork shift 6-OHMS/creatinine excretion with temporally stable MF exposures [21]. However, the reduction was found on second and third days of exposure whereas no change was observed on the very first day as opposed to that by Pfluger and Minder [24] indicating the role of exposure duration and that exposure effect may be delayed by several days. Anyway, the experiment of Wood et al. [22] suggested that exposure of humans to 50 Hz circularly polarized 20 μT MF result in a delay in the onset of rise of plasma melatonin concentrations. As regards animal studies, Kumlin et al. [20] found an interesting augmenting effect on the circadian rhythm of melatonin synthesis in female mice strain (CD2F1) exposed to 50 Hz MF having no or very low natural melatonin rhythm in contrast to previous researches using rodents showing chiefly diminishing effects. The findings do not corroborate the registered melatonin diminution in MF-exposed animals but do imply MF effects on pineal gland. Another experiment showed striking reduction in night-time melatonin concentrations as a result of exposure to rapid on/off mode MFs during the day for several days [25]. The authors pointed that rapidly changing exposure conditions create difficulties in acclimatization as opposed to stable exposure characteristics. The inadequacy in exposure characterization and the conduct of investigation at different times, for different exposure durations and at different locations, render the comparison among studies complicated [87]. Melatonin is highly accepted for its antioxidant and tumour inhibiting properties; hence, if oxidative stress (OS) is accompanied by suppression of melatonin levels, it may produce deleterious effects [87]. Given the importance of melatonin for organisms, further studies with better EMF characterization and standardization are crucial. Hormone serotonin, a tryptophan derivative produced chiefly from the pineal gland, has also been documented to be affected by EMF [85, 90]. However, there are very few studies investigating serotonin and EMF connection. Serum cortisol and ACTH concentrations were found to rise significantly in male guinea pigs exposed to 50 Hz EMF reflecting the capacity to cause stress regardless of being a low frequency [91]. Noticeable depression in melatonin and corticosterone levels were reached in a study investigating the effect of continuous EMF emission from video display units in exposed embryos and young chickens [92]. In addition, significant rise in fetal loss was also registered indicating the adverse effects of these EMF

emissions. Occupational studies focused on the effect of EMFs released from magnetostrictive cavitrons used by dentists showed serum cortisol diminution [93]. In the midst of all these studies reporting either an increase or decrease in cortisol concentration, another group of researchers reported no significant change [94] reflecting the inconsistency in this field. With regard to adrenaline and noradrenaline level, significant suppression was registered in electric utility workers exposed occupationally to 50/60 Hz EMFs [95].

As regards RFR, 900 MHz with 217 Hz pulse frequency from digital wireless communication was reported to have no significant effect on salivary melatonin in healthy male students [96]. Cortisol which is a steroid hormone and one of the key stress biomarkers released from adrenal glands has been shown to be affected by RFR-EMF experience [96–99]. It is assumed that RFR-EMF may act as a stressor evident from the increased cortisol concentration documented in previous investigations with animals [100, 101] and humans [102–104]. However, the reports of cortisol increase are contradicted by the results of cortisol diminution [97, 98] and investigations reflecting no effect on adrenal cortisol secretion [96, 105] highlighting the disagreement in this field of investigation. Given the relevance of cortisol, any imbalance can lead to health impairments in due course [103]. More studies therefore in this connection are required to assess the course of action of the biological system in response to EMF stress. ACTH levels were reported to decrease [98] as well as not being affected [97] by RFR exposure. Significantly, higher levels of the stress biomarkers adrenaline and noradrenaline have been reported in physiotherapists [103]. Buchner and Eger [106] also assessed the catecholamines in subjects exposed to cell phone base station. They examined the acute as well as chronic effects of EMF exposure and found a significant increase in adrenaline and noradrenaline levels after EMF exposure, following a drop, but the normal levels were not restored even at the end of the study (about one and a half year). They also observed significant diminution in dopamine levels. Given the role of these catecholamines in controlling B.P., heart rate (HR), and other biological functions, the shift from baseline values due to stress has immense significance for health and well-being and, hence, their continual alteration may prove harmful in due course. Decreases in testosterone concentration with EMF exposure have been stated by some research groups [98, 105, 107] with no effect as well in some reports [97]. FSH levels have also been found to reduce with EMF exposure at MP frequency [105]. So far as, effect on female reproductive hormones is concerned, there is limited number of studies. The few investigations on RFR from MPs and base stations have shown to mutate prolactin but not progesterone levels indicating the consequent effects on menstruation and pregnancy [98]. Significant rise in serum progesterone concentration has also been reported in pregnant rats after microwave exposure [108]. In addition, parallel studies investigating prolactin levels have documented normal levels even after exposure to radio-cellular phones [97, 109]. As far as thyroid hormones are concerned, decrease in T3 [98, 100] and T4 [98, 110] and increase in T4 [100] in parallel to no effect or retention of normal T3 levels [110] have all been documented with EMF contact. These findings when taken together reflect the variation in EMF research and puzzle the understanding about EMF biointeraction and therefore urge for more studies. In light of the above evidences, it seems that EMF acts as a stressor and has the potential to affect the various endocrine secretions posing a significant health threat.

2.5. Effects on Cardiovascular System

An experiment on human head exposure to 37 Hz EMF at a flux density of 80 μT suggested that EMF could alter nociception and may be associated with cardiovascular abnormalities [111]. Håkansson et al. [112] indicated a low level rise in AMI risk in the highest exposure group and observed by means of the synergy index of 2.7 in monozygotic twins that the genetically predisposed subjects have an increased EMF influence for AMI, possibly induced by reduced heart rate variability (HRV). A cohort study on electric utility workers pointed towards an association between occupational 50 Hz ELF-EMF exposure and arrhythmia related heart disorders [113]. On the contrary, a cohort study of railway

workers exposed to 16.7 Hz intermittent MF indicated no association with fatality from arrhythmia related heart diseases or acute myocardial infarction (AMI) [4]. Because of the electric character, the circulatory and the nervous system particularly the autonomic nervous system is vulnerable to EMF effects [114]. More explicit damage of neurovegetative regulation, especially a decreased parasympathetic function, may result with high-intensity EMFs leading to cardiovascular malfunctioning [115]. ELF-EMFs have been also implicated to affect the HRV in newborns [116] and interfere with electronic medical equipment like implanted pace makers, but only when kept close to chest [117]. The detailed summary of various investigations concerning cardiovascular system effects have been listed (Table 4). Ali et al. [118] has attributed the alterations in rat heart functions as a result of decreased RBC membrane elasticity, permeability, and changes in molecular structure of haemoglobin exposed to 50 Hz, 0.2 mT MFs. Yet another study on rats linked the observed histopathological alterations like unclear cytoplasm, polymorphic nucleus, disrupted fibrous tissue, necrosis, and bleeding in heart epithelial tissue with 50 Hz EMF exposure [119].
tab4
Table 4: Studies concerning the effects of electromagnetic fields on the cardiovascular system.

As regards RFR-EMF, Bortkiewicz et al. [115] found more impairment in 24-hour and resting ECG in AM (amplitude modulation) broadcast station workers when compared to radio-link station workers who are supposed to have less exposure. A significantly higher frequency of irregularity identified as conduction, rhythm, or repolarization disturbances in resting and 24-hour ECG (electrocardiography) was noticed among subjects exposed to medium frequency when compared to control [120]. Stress is considered to increase B.P. (blood pressure) and exposure to EMFs has been implicated to cause stress [103, 111]. Vangelova and colleagues [121] found significantly higher systolic and diastolic B.P., total cholesterol, and low-density lipoprotein cholesterol levels in radio operators exposed to RFR and confirmed stronger association between RFR-EMF exposure and the likelihood of becoming hypertensive and dyslipidemic. The researchers, however, noted that the results could be influenced by the extended shifts and monotonous work as well. The study also revealed that majority of the hypertensives who were under medication reached their normal B.P. only when stayed away from the station. Earlier findings have also reported increased hypertension with RFR exposures [115]. Significantly higher levels of stress biomarkers like adrenaline, noradrenaline, and cortisol have been documented in medical staffs with RFR-EMF exposures, which could also influence B.P., heart rate (HR), and so forth, [103]. Recent findings have highlighted the possibility of small short-term and medium-term effects on HR and cerebral blood flow to intermittent universal mobile telecommunication system (UMTS) exposures [122]. Andrzejak and coworkers [123] reported an increased parasympathetic tone and decreased sympathetic tone during MP use measured by HRV analysis and indicated the potential of MPs in affecting the autonomic balance in healthy individuals. However, the confounding effect of talking during measurement of the parameters cannot be neglected. Similar results of sympathetic domination and parasympathetic suppression were reached by Kodavanji et al. [124] pointing towards the link between long-term MP use and adverse effects on HRV, thereby affecting the autonomic balance in healthy individuals. However, since the study was undertaken on a small population without randomization, the results need further confirmation. To add, a recent investigation with the intent to find the effect of RFR-EMF from MP on the electrocardiographic parameters in ischemic heart disease patients taking into account the gender aspect reached some interesting results. They observed prolongation of QT interval in male subjects with or without ischemic heart disease in addition to interference with voltage property of ECG records in myocardial ischemia patients excluding the female counterparts from these effects [125]. In the midst of studies reporting positive findings, parallel studies reporting absence of effects [126–128] create confusion and hampers our understanding. Further long-term studies with better exposure characterization and health assessment are essential to depict the true picture in light of the prevailing

controversy with the employment of the latest techniques. In this connection, EMF effect on newborns and patients with electronic implants or on life supporting systems needs immediate attention.

2.6. Effects on Nervous System

The inability of neuronal cells to divide and repair once damaged makes the organism susceptible to develop several neurodegenerative diseases. The occurrence of Parkinson's disease, and so forth, has been linked to cumulative DNA damage in brain tissues [60]. The increased prevalence of Alzheimer's disease reported among workers of textile factories exposed to ELF-MFs [129] could be one such instance. Ahlbom and coworkers [54] in their review also indicated towards a possible relation between amyotrophic lateral sclerosis (ALS) and occupational ELF-EMF exposure. However, effect of confounders cannot be ruled out. Cognitive performances like attention, perception, and memory have been reported to diminish instantly by 50 Hz, 1 mT ELF-EMF exposure in human subjects [130]. In concert, authors have found significant alterations in learning and information acquisition in passive avoidance learning task in both male and female mice exposed to 8 mT, 50 Hz ELF-EMF [131]. Authors have also found association between occupational ELF-EMF exposures and problems like dementia and depression [132, 133]. Results from animal studies in mice have also established the induction of depression at ELF-EMF exposures due to increased nitric oxide levels in cortex, hippocampus, and hypothalamus [134]. Studies have indicated that short-term ELF-EMF exposure may cause small alterations in neurotransmitter metabolism and in circulating amino acids [90] as well as influencing monoamine metabolism when exposure is in the same direction as the mouse position [42]. In connection, Rajeswari et al. [135] highlighted the importance of orientation of the field exposure with respect to the subject in human experiments. They found the subjects to be restless and aggressive when exposed to pulsations in north orientation, and cholinesterase levels in serum were significantly increased. In east, west, and south orientations, the subjects appeared to be calm and serum cholinesterase levels were normal, which suggested the increase of cholinesterase due to MF stress. Prato and colleagues [136] have reported significant inhibitory effects of a variety of ELF-MFs on endogenous opioid and exogenous opiate induced analgesia in snail Cepacea. Zecca et al. [137] found that higher field strength exposure may raise norepinephrine levels in pineal gland of rats accompanied with key changes in brain involving opioid system in frontal cortex, parietal cortex, and hippocampus. Pertaining to this, the documented calcium ion efflux from brain tissue at RFR exposure can be an important neurochemical effect as their significance in routine nervous system operation is well known, for example, neurotransmitter release for cellular interaction [138].

With reference to RFR-EMF, authors have reported that RFR-EMFs interact with cognitive functions like shortening of reaction times, particularly during tasks that require attention or manipulation of information in the working memory [27, 143]. In yet another study, shorter latency in passive avoidance task was registered in MP RF-EMF exposed rats reflecting significant impairments in memory retention and retrieval [144]. The authors suggested that the RFR-EMF exposure induced damage might lead to alterations in neuronal functioning of both hippocampus and amygdala resulting in changed behaviour during task performance. A cross-sectional study meant to detect neurobehavioural deficits among residents living close to base stations found the prevalence of neuropsychiatric complaints such as memory changes, headache, sleep disturbance, depressive symptoms, dizziness, and tremors to be significantly higher among exposed inhabitants than controls [145]. The study outcomes were based on a questionnaire survey, clinical examination, neurobehavioural test battery (NBTB), and environmental measures with age, sex, education level, smoking habit, occupation, and MP use matching. The NBTB indicated that the exposed inhabitants exhibited a significantly lower performance than controls in one of the tests of attention and short-term auditory memory. The inhabitants opposite the station showed a major reduction in performance in problem-solving test than those under the station. However, in the tests of visuomotor speed and one test of attention the exposed individuals performed significantly well as compared to controls. A cross-

sectional community based study conducted among hand-held cellular telephone users in Singapore found headache to be the most prevalent central nervous system symptom as compared to nonusers and the prevalence increased significantly with increased duration of usage per day [146]. The findings were further substantiated by reduced prevalence by more than 20% among those who used handsfree equipment as opposed to those who never used them. The reduced exposure as a result of using handsfree equipment could be possible because the antenna is kept farther away from the head. Studies have proved the sensitivity of brain cells towards RFR-EMF exposures [139, 140]. Significant increases in brain glucose metabolism in regions closest to MP antenna have been observed with acute exposures [147]. GSM-MP radiations have been demonstrated to induce seizures in rats made seizure prone by subconvulsive picrotoxin doses and to alter the cerebral activity reflected by significantly higher c-Fos levels in some brain regions, which raises question for persons with epileptic disorders [15]. MP-EMFs have been suggested to affect the normal neurophysiology through alterations in cortical excitability as a result of demodulation or direct interference with membrane ionic changes, which results in depolarisation and excitation of nerve cells [53]. However, no histopathological changes have been observed with long-term MP exposures [148]. Increased BBB permeability has also been documented not only immediately but also after seven days of exposure to MPs [30]. So far, the most reliable findings have been reached regarding the brain electrical activity [10]. Impairment in spatial learning and memory functions has been demonstrated in animal studies [27, 143]. Details of investigations with exposure characteristics have been tabulated (Table 5). Lai et al. [28] pointed towards 2450 MHz MW induced short-term memory deficits in rats by the stimulation of endogenous opioids in brain resulting in depressed cholinergic activity responsible for memory functions. The results of Xu et al. [149] pointed towards the connection between extended low intensity GSM 1800 MHz (2.4 W/kg) exposure and synaptic activity evident by decreased excitatory synaptic activity and excitatory synapse number in cultured rat hippocampal neurons. A study investigated the effect of GSM modulated 900 MHz RF-EMF at 1 W/kg on neuron development in two different cell systems by the assessment of morphological parameters and mRNA expression for β-thymosin and stress-related proteins [150]. The authors found a diminution in neurite generation from the soma without any effect on branching and neurite length in both the cellular systems, which was also found to be associated with β-thymosin mRNA overexpression. Yuasa et al. [151] conducted an investigation in order to study the acute effects of pulsed high frequency MP-EMF emissions used for 30 min on somatosensory evoked potentials (SEPs) in healthy individuals. They demonstrated negative effects on SEPs as well as their recovery function indicating the absence of immediate effects on the sensory cortex. EMRs from MP base stations may expose residents to risk of developing neuropsychiatric difficulties and alterations in performance of neurobehavioural functions either by inhibition or facilitation [145]. The comparative analysis of studies relating cognitive and nervous system performance with EMF experience gets complicated due to different assessment tools employed and exposure situations and despite the bulk of scientific evidence, the results turn into conflicting and unconvincing outcomes. At present, the precise mechanism of EMF ill effects on neurons lacks sound understanding; however, some investigations have indicated the role of lipid peroxidation and free radical generation [2, 152]. To add, the nervous system is chiefly helpless to ROS insults because of its high metabolic rate, inadequate oxidant protection, and reduced cellular turnover [152].

tab5

Table 5: Studies concerning the health effects of electromagnetic fields on the nervous system.

2.7. Effects on Reproductive Functions

Rising male infertility cases in recent times have led to scientific investigations, which indicate the involvement of EMRs as one of the possible environmental factors [153]. Understanding of EMF effect on reproductive functioning is also clouded by contradictory findings [154] despite several decades of research. MPs rather than being a status symbol nowadays have become a part and parcel of everyone’s life since the past decade and a half [155]. As it is often carried in pockets in very close

proximity to body and the reproductive system, effect of the same on male infertility is an important issue, which seeks immediate attention. Various studies have been undertaken to investigate the potential of ELF field characteristics in inducing damage to the reproductive system [156–160]. In this regard, intermittent 50 Hz low frequency horizontal EF exposure has been reported to cause significant histopathological alterations like focal tubular atrophy, necrosis, and seminiferous epithelial erosion in rat testis [156]. The serum testosterone levels, however, did not differ significantly between exposed and control groups. Toxic effects of 60 Hz, 1 mT ELF-EMF were also reported in male rat offspring exposed from gestation day 13 to postnatal day 21 [159]. The study found a reduction in the count, diameter, area, and volume of seminiferous tubules and height of seminiferous epithelium along with leydig cell count indicative of the harmful effects on testis development. On the contrary, 60 Hz, 500 μT exposure for 21 hours/day from gestation day 6 to postnatal day 21 in pregnant rats did not elicit any significant difference between the exposed and the controls with regard to spermatogenesis and fertility in male offspring [160]. With reference to investigations in mice, 60 Hz EMF was found to raise significantly the germ cell death and defects in seminiferous tubules without any effect on the body or testes weights. At the same time, the same frequency of EMF at 0.5 mT was shown to induce DNA breakage though cell survival was not significantly impaired [157]. Another study at 60 Hz, 14 μT, and 200 μT reported the induction of apoptosis in mice testicular germ cells [158].

As regards RF-EMF exposure, animal studies undertaken so far document higher levels of sperm head abnormalities, positively correlated to RF-EMF exposures suggesting a dose-response effect [165]. Aitken et al. [166] reported alterations in genome of epididymal spermatozoa in mice exposed to 900 MHz RF-EMW, 12 h/day for 7 days. Parallel studies in rats have documented lower spermatocyte counts along with leydig cell hyperplasia and elevated testosterone levels at 2.45 GHz frequency [154]. Significant decline in protein kinase C and total sperm count together with increased apoptosis was reported in male rats exposed to RF-EMF (2 hours/days, 35 days, 0.9 W/kg) from MPs [167]. The investigators indicated the possible role of ROS behind these findings. Previous study on rats found major impairments in OS equilibrium in reproductive tissues along with modified semen parameters reflecting the fundamental connection between RF-EMR exposures and mutations in semen quality [168]. In contradiction, no difference in testicular function was found at GSM-RF exposure from cellular phone in rats [169]. An in vitro study assessing the effect of 900 MHz MP radiation at a SAR of 2.0 W/kg on human sperm's fertilizing potential found no harmful effects on acrosome reaction [170]. However, the researchers did reach significant findings with regard to sperm morphometry and a measurable decline in sperm binding to hemizona was found thus indicating a significant effect of RF-EMF on male fertilizing potential. Interesting findings were reached in a study evaluating the effects of RFR released from GSM multiband MP (900/1900 MHz at a SAR of 1.4 W/kg) in Drosophila melanogaster exposed during the 10-day developmental period from egg laying through pupation [171]. The authors reported elevation in offspring count, stress protein hsp70 concentration, and binding activity of serum response element (SRE) in conjunction with phosphorylation of nuclear transcription factor, ELK-1 indicative of cellular stress, which could further lead to critical alterations in the organism. Observational studies conducted in connection to RFR-EMF exposure reported diminution in semen quality by reduced sperm count, motility, viability, and normal morphology which were also found to be a function of duration of MP use [163]. Wdowiak et al. [172] also demonstrated an increase in the proportion of sperm cells with abnormal morphology and a decrease in the proportion of rapid progressive sperms with the frequency of exposure from GSM-MPs. Davoudi et al. [161] also reported a decrease in rapid progressive motile sperm due to GSM-MPs. The details of investigations have been summarised in Table 6. Extended MP uses have been reported to elicit harmful effects on sperm motility in previous researches as well [162, 173]. Studies show a possible relationship between occupational exposure to radiofrequency equipment including radar and reduced fertility and sperm quality [164, 174]. Epidemiological investigations have indicated a link between male infertility and MP use, but the mechanism of action is unclear. The role of hyperthermia in

causing infertility is apparent but the nonthermal effects are debatable [154]. However, it has been speculated that the effect could be specific to EMR effect, a thermal effect, or due to the combination of both [168]. So far, motility or sperm movement is the only factor observed to be affected significantly [155]. Reproductive functions like meiosis, fertilization, and so forth are particularly vulnerable to toxic insults [154]. De Iuliis et al. [153] have highlighted the occurrence of ROS and DNA fragmentation after RF-EMR exposure putting a question mark on the safety of MP use especially in the context of fertility and children's health. Until now, the malfunctioning porous cell membrane and disrupted calcium homeostasis along with OS can be accounted for the damaging effects on testicular cells [12]. Conclusive outcomes have not yet been reached despite extensive researches. So far, long-term studies concerning EMF effects on male reproductive functions are lacking to substantiate the findings and give any clue regarding the biointeraction mechanisms. As far as effect on female reproductive system is concerned, there is limited number of studies. RFR from MPs and base stations have been shown to mutate prolactin but not progesterone levels indicating the consequent effects on menstruation and pregnancy [98]. Miscarriage risks have been shown to be higher in pregnant physiotherapists due to their occupation [175]. Han et al. [176] found significant rise in risk of embryo growth cessation in the first pregnancy trimester of pregnant women especially with the medical history of embryo growth termination with regard to increased exposures from television and MPs. Animal investigations also support the toxic effects of RFR. In this connection, Gul et al. [177] registered a fall in follicles count in rat ovaries submitted to intrauterine RF exposures whereas Xu et al. [178] demonstrated toxic alterations in the reproductive organs. Further studies in females are wanted with special relevance for pregnant women, who are also carrying the future generation. Children form yet another group of prime importance since their reproductive systems are immature and exposures are prolonged; hence, they can be the worst sufferers.
tab6
Table 6: Studies concerning the health effects of electromagnetic fields on the reproductive system.

2.8. Auditory and Ocular Effects

A recent study [179] concluded that higher ELF-EMF exposure at 50 Hz, 10.182 kV/m coupled to 4.45 pT MF may give rise to adverse auditory effects especially to the organ of Corti and outer hair cells as a result of decreased distortion product auto acoustic emission amplitudes in higher frequency region localized in basal turn of cochlea in rabbits which have also resemblance with human's frequency spectra. As regards RFR-EMF, MP use has been associated with tinnitus and acoustic neuroma [38, 41]. Ear is the first biological structure to be hit by EMFs from MP. In addition, relatively greater vulnerability of cochlear outer hair cells to injuries from a diversity of exogenous and endogenous agents makes the system a victim of radiation emissions [179, 180]. These days, about 50% of world's population possesses a MP [30] and even greater than that are experiencing EMF emissions through "passive mobile phoning" [181]. Hearing problems reported in few observational studies [50] have also been investigated to occur in animals [179] with parallel contradictions [180, 182]. Studies with ten minutes acute MP radiation exposures have resulted in no immediate effect on hearing threshold level of pure tone audiometry, transient evoked otoacoustic emissions [183], auditory brain stem response [184], and any depreciation in hearing in young human volunteers. However, regular long-term MP use has been linked to increased relative risk of acoustic schwannoma [39]. Despite the interests in EMF effects due to MP, there is lack of solid evidence regarding the ill effects on auditory system and, hence, we are far from any conclusion and not able to develop safe and sound communication devices necessary for safeguarding one of the senses [11].

Heat-related skin injury and lens defects reported in eyes of man are the only undisputed harmful effects of MW exposure [56]. Carpenter [185] in late seventies reported that microwaves have the capability to induce cataracts and affect the eyes by reducing the ascorbic acid content of the lens coupled with the inhibition of DNA synthesis and mitosis in lens epithelium thereby slowing down the

recovery process. In addition, the lens becomes more vulnerable to EMF threats because of decreased water content and absence of vasculature [12, 56, 186]. Spector [187] suggested the role of OS in cataract development due to extensive oxidation of lens protein and lipid at older age. Nevertheless, the database is yet deficient to decide regarding ocular defects including cataracts in human subjects exposed for extended durations.

2.9. Effects on Sleep Parameters

Sleep insufficiency was observed to be more common in the occupational group of electronic equipment repairers exposed to ELF-EMF though not statistically significant when compared to controls [89]. Earlier studies have also documented diminished sleep and sleep efficiency with 60 Hz MF experience [188]. So far, studies evaluating sleep quality in the context of ELF-EMF exposure in humans have not reached any statistical significance [44, 45, 89].

In connection to RFR-EMF, Abelin et al. [189] reported the prevalence of difficulties of falling asleep and, in particular, maintaining sleep, which increased with increasing RF-EMF exposure in the vicinity of short-wave broadcast transmitter. In addition, sleep quality was found to improve after interruption of the exposure. A similar study found an association of EMF exposure with sleep quality and melatonin excretion but only in poor sleepers suggesting the sensitivity of a group of people [190]. The authors highlighted that the absence of blinding in their investigation could lead to such results. Another study by Wiholm et al. [191] indicated the negative influence on sleep component during laboratory exposure to 884 MHz wireless signals. Besides, volunteers with no self-reported symptoms related to MP use appear to have more headaches during actual RF exposure as compared to sham exposure. Several studies evaluating RF exposure effects on sleep parameters and sleep EEG are surrounded with contradictory outcomes owing to methodological limitations like small sample sizes and lack of replications of the previous findings. According to a clinical review [192], sleep disturbances do not seem to be a predominant complaint under exposure to high frequency EMF and with the present level of knowledge no final conclusion can be drawn concerning any potential health hazard. Hutter et al. [34] also reported no significant effect on sleep quality and pointed that it could be dominated by the fear of negative health effects of EMF radiations as well as age. Sleep is an important component of the biological species to overcome the daily wear and tear. Studies relating EMF exposures to sleep do suggest some biological effects; however, these do not provide evidence for any adverse health consequences. Further research with well-designed protocols is required with lessons from past experiments so that valuable information is updated in bioelectromagnetics field.

3. Mechanisms of Action

3.1. Thermal and Nonthermal Interactions

Due to lack of sufficient energy required to break the molecular bonds in cells by EMFs, the elicited effects are assumed to be indirect and secondary to other induced biochemical modifications [60, 76]. Ruediger [32] suggested the indirect role of microthermal processes, OS and altered DNA repair mechanisms behind the observed effects. However, studies have also pointed towards the involvement of resonance-like sensing mechanisms working only at specific combinations of frequency and amplitude suggestive of a direct EMF effect [136]. It is proposed that low frequency time varying electric fields (EFs) interact with the body by the induction of electric currents, formation of electric dipoles, and reorientation of existing dipoles whereas interaction of time-varying MFs leads to induced EFs and circulating electric currents. Higher current densities and EFs have been shown to be induced when the direction of external EF is parallel to the longer vertical axis of body (from head to feet) and the MFs are from front to back, respectively, due to better coupling with human body compared to other configurations [193]. Additionally, EMF effects are dependent on a number of physical (frequency, modulation, polarization, wave characteristics, near or far field configuration, duration and orientation of EF and MF exposure, dielectric properties, conductivity and water content of tissues,

and environmental factors like humidity, temperature, etc.) and biological variables (species, shape and size of the body, weight, geometry of the body, and nutritional and health status).

The possible effect of EMF irradiation is either thermal or nonthermal depending on frequency and strength. The elicited effects are assumed to be noticeable when not shrouded by thermal noise also termed as Brownian motion which is a virtue of all objects/materials above absolute zero temperature. The thermal effects are induced as a consequence of heat gained by water contained in body tissues. Hence, body tissues or organs like lens of eye and testes with less vasculature or deficient in water content are the most vulnerable to even small rise in temperature. Usually, body parts with the smallest cross-section like hand, feet, fingers, and toes gain the maximum values of current densities and EFs [193].

3.2. Oxidative Stress

OS resulting from imbalance of reactive oxygen species (ROS) and antioxidants, leading to disruption of cell functions, has been proposed as one of the probable modes of EMF action [2, 5, 60, 71, 196]. EMFs have also been implicated to lengthen life of free radicals particularly by Fenton reaction [33], affect enzyme activity [31], and change protein levels indicative of induction of cellular stress response pathways [14]. Fenton reaction is a process in which hydroxy free radicals are generated from hydrogen peroxide produced during mitochondrial oxidative respiration in presence of transition metals like iron [60, 64]. EMF interaction with free radicals and transitional metals has also been linked to the observed genotoxic effects [33, 64]. In this regard, cells, which are metabolically active, or have higher cellular concentrations of free iron and superparamagnetic iron particles (magnetites) in body tissues like brain cells, are more vulnerable to EMFs [60]. Several studies have demonstrated OS inducing ability of EMF including MP-RFR in different animal models [31, 152, 196–198] or in cell cultures [64, 73] paralleled with negative findings as well [5, 7]. Studies demonstrating EMF's ability to cause OS are summarised in Table 7. Given the credence of free radicals in signal transduction and EMF in boosting the free radical lifetime, there are chances of EMF influencing signalling [194].

tab7

Table 7: Studies showing the oxidative stress inducing ability of electromagnetic fields.

3.3. Melatonin Diminution

Several human and animal studies conducted thus far have suggested decrease in melatonin after EMF exposure [21, 23, 24, 87]. Like all other EMF effects, melatonin diminution is also surrounded with conflicting results [87]; however, the effects have been suggested to be somewhat constant, at least in rodents [199]. Some studies have also supported the protective effect of melatonin against oxidative damage induced by EMFs [2, 3, 64, 152, 195] pointing towards the OS mechanism involved in generating negative health outcomes and melatonin's beneficial properties. The hypothesised mechanism of EMF action on melatonin concentration is through the imitation of light rays to the retina [22]. To add, Yaga et al. [86] found significant suppression of N-acetyltransferase (NAT) activity, a rate-limiting enzyme in melatonin synthesis due to MF exposure. The melatonin forming enzyme hydroxyindole O-methyl transferase has also been documented to be affected [87]. Melatonin's shielding actions counter to EMF ill effects are supposed to shoot from its direct free radical foraging and indirect antioxidant property of inhibiting free radical production at the power house of the cell and, hence, diminution of pineal melatonin secretion could be proposed as a possible mechanism of EMF interaction with living organisms.

3.4. Calcium Flux

Calcium ion efflux/influx has also been proposed as the biological mechanism [200] and is dependent on ambient temperature, geomagnetic field intensity, direction, and signal strength [201–203].

Calcium ions are crucial for cAMP pathway as well as serotonin/melatonin conversion and their efflux from pinealocytes is supposed to cause melatonin suppression. Besides, calcium dependent signal transduction systems also have been implicated in the mediation of immune cell effects by low frequency EMF [29]. However, authors have indicated the occurrence of calcium efflux/influx at some specific exposure combinations but not at other relatively closer exposure characteristics mainly due to the "window" effect or nonlinear nature of modulation frequency and intensity effect.

3.5. Molecular Mechanisms

Similar to physiological stress response at the organ system level, there are also cellular stress responses at the cell level to impart protection to the cell from external and internal stressors. The cellular stress response is characterized by an elevation in stress protein concentration [204] in response to a stress causing damage to biomolecules like DNA and proteins [205]. EMFs at ELF, RF, and amplitude modulated RF have been demonstrated to stimulate the same stress response [204, 206, 207]. Unlike the past assumption of absence of DNA-EMF interaction plausibility, recent investigations indicate the potential of EMF both ELF and RF to stimulate DNA and induce protein expression [14, 171, 208, 209]. Various studies have highlighted the genotoxic ability of EMF at both ELF and RF range as evidenced from DNA strand break reports post-EMF experience [33, 63–65, 68]. Recent investigations have further revealed the presence of an EMF reactive sequence in DNA [210] which acts particularly in response to EMF stimulus. These EMF reactive DNA sequences code for the production of the chief stress protein hsp70, in response to the binding of transcription factor, heat shock factor 1 (HSE-1) to heat shock element (HSE) in the promoter region [210–213]. Friedman et al. [209] delineated the molecular mechanism behind the stimulation of the ERKs in response to RFR exposure at MP frequencies. The RF-EMF through its interaction with NADH oxidase in the plasma membrane causes the formation of ROS, which further activate the MMPs (matrix metalloproteinases). Because of activation, the MMPs break into Hb-EGF [heparin-binding EGF (epidermal growth factor)] and stimulate the EGF receptor, which sequentially triggers the ERK cascade. The ERK cascade is one of the four mitogen-activated protein kinase (MAPK) signaling cascades that controls transcription and associated cellular processes like replication, cell-cycle progression, apoptosis, differentiation, metabolism, and so forth, in reaction to extracellular stimuli. The MP radiation induced overexpressed protein transcription factors have been found to regulate the cellular processes such as apoptosis [214] and replication and cell cycle progression [14, 215]. The reported findings with regard to cellular stress response post-EMF experience give critical insights into connection to harmful health-relevant potential of ELFs and RFRs in addition to their role as cellular biomarkers.

In light of several credible biointeraction processes, the OS mechanism appears to gain the maximum support. The hypothesised EMF biointeraction path may involve ROS generation, leading to diminished antioxidant capacity, affecting the antioxidant/prooxidant equilibrium and causing OS, thereby instigating adverse health effects. This sequence may be paralleled by calcium efflux, which alters serotonin conversion into melatonin thus triggering melatonin diminution, which further substantiates OS. At the same time, ROS may lead to the activation of signal transduction pathway trigging the ERK cascade. The cellular stress response mediated by hsp70 overexpression can also be considered but this effect is limited to certain group of cells while other cell types are being nonresponsive [216]. The exact mode of biointeraction mechanism still needs to be elucidated.

4. Research Needs

The limited quality of research works in bioelectromagnetics and methodological problems is an important concern [57, 155]. Until now, epidemiological investigations have failed to get the SAR value which is the most direct dosimetric measure of an individual's exposure at the tissue or organ level under study [217]. Moreover, lack of an appropriate exposure assessment method [55] and

reliable equipment for calculation of energy absorbed in the body and the intricate relation with species, frequency, power, EMF source, and modulation dosimetry has inhibited the utilization of laboratory results to human conditions [53] and the conduct of epidemiological studies [56]. Hutter et al. [34] suggested the usage of personal "exposimeter" or long-term exposure monitoring as the best way for exposure assessment. So far, errors in exposure assessment due to lack of long-term exposure monitoring by EMF dosimeters, exposure has been assessed by crude methods in most studies, such as wiring codes, occupation or residence in relation to proximity to a source, spot measurements, time-weighted average and self-reports, and hence results in underestimation of actual risk and clouds the true relationship. Absence of suitable control population for comparison as all of us are exposed to EMFs every day coming from varied sources with different degrees further complicates the understanding of literature on human EMF exposure [52, 55].

Furthermore, clear understanding is hampered by the multipart interactions of different EMF exposure factors [12, 53] and shape, size, mass, orientation, and electrical characteristics of body and individual characteristics like age, gender, activity level, incapacitation, or illness [218]. Environmental parameters like ambient temperature, wind velocity, humidity, and body insulation also affect the communication between body and the EMF vector. Anatomical differences among humans and animal models as regards size, shape, reproductive tract variations, and so forth further complicate the understanding of observed results [12].

As far as studies investigating exposure of humans to MP radiations are concerned, they have followed the standard method of EMF exposure assessment by retrospective interviews or obtaining information or self-reports of subjects on total duration of use or number of calls, number of years of use, side of use ipsilateral, or contralateral along with exposure duration estimates and billing records from service providers [52, 79]. However, these parameters have been questioned for recall bias [52]. Animal experimentation especially using primates or species closely related to humans would eliminate the chances of recall bias regarding MP use and give meaningful directions. Besides, the duration based exposure assessment is built on the postulation of equivalent power emissions per minute from all phones which may not be correct with expanding use of GSM based phones with variable power outputs ending in miscalculation of true exposure in spite of recall accuracy [217]. Besides, geographic area, physical environment, user location rural or urban, distance between user and base station antenna, handsfree use, individual characteristics of phone handset, and its use as well as technical features of provider network all have some effect on EMF emissions and consequent exposure to the individuals [12, 34, 52, 219].

A research carried out by Erdreich et al. [217] to increase the accuracy of exposure estimation in epidemiological studies of GSM-MPs found that the average power output rate in GSM phones varies with several characteristics of phone use, the largest being the site of investigation, followed by user movement and location (indoor or outdoor), use of handsfree device, and urbanicity. The understanding is complicated further by factors like distance to the phone, holding position, position of antenna, pinna size, elasticity of ear, thickness of skull bone, type of tissue, tissue type distribution, and so forth, governing the actual amount of power absorbed [220]. In addition, lack of long-term studies also restricts our understanding. Apart from this, role of media finds significance in focusing the attention on the potential adverse health effects caused by MP radiations. This may give rise to fear or awareness forcing MP users to report more symptoms than nonusers even if the prevalence of symptoms were equal [146].

Animal and cell culture studies are surrounded with conflicting results as a consequence of the heterogeneous exposure conditions (type of EMF-RF, MW, CW, Pulsed, and so forth, SAR value, exposure duration) [5, 7] and differing assay protocols [53]. At the same time, vested interests of

sponsors also influence the study outcome with quality studies having mixed funding and, hence, sponsorship should be taken into consideration while interpreting the findings [221]. We strongly advocate that with mere swelling number of studies no fruitful conclusions can be reached. If we do not address the limitations of past investigations, we may not be able to truly contribute to the domain of bioelectromagnetics. Therefore, need of the hour is to do innovative research with sound designs and appropriate methodologies rising above the demerits of past researches.

5. Conclusion

Given the ubiquitous nature of EMFs, their widespread applications, and their capability to produce deleterious effects, conclusive investigations of the health risks are critical. With the published literature on EMF, it is still not sufficient enough to reach a concrete conclusion. But the possibility of negative consequences cannot be excluded. Several studies with appropriate methodologies reflect the capacity of EMFs to cause adverse health effects. However, the absence of any established biointeraction mechanism does not diminish the reliability of these studies as there are several credible mechanisms like OS that can account for the observed effects.

Therefore, need of the hour is to restrict the swelling numbers of scientific investigations and in place activate comprehensive well-coordinated blind scientific investigations especially long-term studies overcoming all limitations and demerits of previous findings with suitable replication studies and follow-up. There is a need for standardized research methodology along with the inclusion of appropriate exposure assessment technique which is crucial for identification of dose response relation if any and the elucidation of mechanism for biological interaction. If we do not work upon the demerits of previous findings, we may remain far from any concrete conclusion. At the same time, it is critical to analyse the EMF investigations giving more weight to the similarities and dissimilarities rather than giving more importance to the endpoints reached.

For the time being, since it is difficult to protect oneself from EMFs, the only practical way to check exposures is to distance oneself from the source. Together, the precautionary approach and ALARA (as low as reasonably achievable) principle can also be applied to save us from substantial exposures and the possible ill effects if any. The objective is to minimize EMF exposures to the greatest degree possible without significant economic cost and disturbance.

Conflict of Interests

The authors declare that there is no conflict of interests regarding the publication of this paper.

Acknowledgments

The authors are very thankful to Dr. M. P. K. Reddy and Dr. S. N. Singh, DIPAS, DRDO, for their valuable inputs in the preparation of the paper.

Mr Fox has a fantastic sense of direction as he uses the magnetic field to hunt

By David Derbyshire for MailOnline
Updated: 03:11 EST, 12 January 2011

Foxes aren't just cunning - they also have a fantastic sense of direction, scientists have shown.
A new study has found that the creatures are able to detect the Earth's magnetic field and use their navigational skills to hunt mice, rabbits and voles.
In tests, animal behaviour experts discovered that foxes tend to face north east when jumping on prey, no matter their location or the time of day.

Researchers believe they combine their acute hearing with their uncanny sense of direction to time jumps perfectly.
The discovery means foxes join other migratory animals - including pigeons, turtles and whales - in being able to sense the points of the compass.
The same team of scientists has previously shown that cattle and deer tend to align themselves with the Earth's magnetic field when resting so that herds end up pointing in the same direction.
Prof Hynek Burda, of the University of Duisburg-Essen in Germany, studied the behaviour of 84 wild red foxes at 65 locations across the Czech Republic as they pounced on food.

Foxy loxy: The predators combine their acute hearing with their uncanny sense of direction to time jumps perfectly

Safety Advice for Electromagnetic Fields

EMF*WISE*

Potential Wireless Health Effects

The following sections discuss the scientific and epidemiological studies.

- Infertility
- Cancer
- Sleep Disruption/Insomnia
- Calcium Efflux
- Arrhythmia and other Cardiac Problems
- Neurological Problems
- ADHD
- Immune System Changes
- Allergy, Asthma
- Autism
- Mercury
- Plants
- Animals

For more on the mechanisms that may explain the biological/health effects, refer to the Science Overview.

Infertility

Wireless technologies may increase the risk of infertility, by impacting human sperm count, motility, and normal morphology.[1] Five countries have now shown that cell phone use among men had negative effects upon sperm. Relevant studies were done in Ohio, Wisconsin, as well as Australia, Hungary, Poland, and Turkey.[2] Occupational exposure of Danish personnel to radar may also have resulted in lower sperm counts.[3] In animals, microwaves also affect rat sperm motility,[4]reduce the average number of fruit fly offspring (Drosophila melanogaster),[5] result in irreversible infertility in mice [6]. Female rats' ovaries are affected as well,[7] which is alarming because females, unlike males, have only one set of eggs from birth, and the genetic damage that accumulates before they give birth may affect posterity.

Power line frequencies, in addition to microwave frequencies, have similarly been linked to infertility or miscarriage, suggesting that this is not necessarily a thermal effect, and that power line and microwave frequencies may be working under similar mechanisms. Read more on powerline magnetic fields here.

Genotoxic Effects and Cancer

Genetic changes resulting from microwaves, including DNA strand breaks, double-

stranded breaks, and effects on gene expression, is another interesting area of research. There is both scientific evidence for this as well as epidemiological evidence for the increase of cancer as a result of wireless exposure.

Scientific Evidence

One of the first studies to show DNA breaks from microwaves was conducted by Henry Lai and Narendra Singh of the University of Washington.[8] Despite the industry's attempts to attack this study, this finding was later confirmed by the 7-nation European REFLEX project and a study by the University of Vienna. There are now in total at least 11 studies showing DNA breaks.[9] In addition to studies on DNA breaks, there are also now studies showing effects upon gene expression.[10] Not all studies found significant increases in DNA damage, but it's important to note that not all cell types may be equally sensitive. A paper by Phillips, Singh, and Lai further notes that the comet assay method is very sensitive and that some researchers with little prior experience made specific methodological errors, or developed versions with different detection sensitivities.[11]

The exact mechanism behind DNA breaks is under speculation. The following have been raised as possibilities:

- ***Direct Interaction with Electrons:*** Local charging of DNA caused by displacement of electrons in DNA can result in its disaggregation, and thereby impact protein synthesis.[12]
- ***Free Radicals:*** Radiation-induced increase in oxidative and nitrosative free radicals may result in DNA damage as well as hinder the repair process. There are at least 24 papers on increased free radical activity from microwaves since 1997. Researchers found that antioxidants could reduce the EMF-induced DNA damage.[13]
- ***Electrical:*** DNA happens to be a good conductor of electricity, and electrical charge transfer may be linked to DNA breaks.[14] For example, Swiss scientists at University of Basel found that DNA conducts electricity like a semiconductor. An electrical charge added to the DNA may cause a charge transfer to travel the DNA until it encounters guanine, which it oxidizes, causing strand breaks that may lead to genetic mutations.
- ***DNA as an antenna:*** Since DNA is a good conductor of electricity, it can act like an antenna, with different coil sizes responding to many EMF frequencies, according to Martin Blank, Columbia University.
- ***Calcium Efflux:*** Another mechanism proposed for DNA damage is related to the leakage of DNAase through the membranes of lysosomes, due to the calcium efflux effect (see section on calcium efflux below).[15]
- To read more about these and other potential mechanisms, see theScience Overview

Note that genotoxic effects were found for both power line (alternating current) 50/60Hz frequencies in addition to radio/microwave frequencies. Because power lines and microwaves may have different power/frequency levels, it suggests that it is not related to the thermal effect.[16]

When the rate of repair cannot keep up with the rate of DNA breaks, then there is greater likelihood of retaining mutations, which may lead to cancer. If the mutation is too great, cell death may occur, which is a partially protective mechanism, because it prevents the propagation of errors. However, at the same time, it can be dangerous for cells in the

brain, heart, and ova which are less likely to be regenerated through mitotic activity, and where cell death can possibly lead to conditions like Alzheimer's, Parkinson's, and infertility.

Corresponding Epidemiological Evidence

Given that microwaves cause damage to DNA, we might expect to see cancer increases in epidemiological studies. Indeed, cancer has been potentially linked not only to mobile phones, but also to cordless phones [17], radio towers, and TV towers (Australia, Great Britain, Rome, and San Francisco, and Lookout Mountain, Colorado).[18] Some have argued that radio and TV towers have been around for a long time and are safe, and therefore the same should be true about mobile phone masts. Nevertheless, the premise itself appears false, given the many epidemiological studies on radio and TV towers, which indicate a correlation with cancer. Although the Radio and TV transmitters are more powerful, they are also tightly regulated and so are likely to be spaced further apart than cell towers.

Cell towers and mobile phone masts, as well as cordless phones, in contrast, are now quite ubiquitous, and a lot of people are now exposed to high levels. Sometimes these masts are placed right on residential buildings, right outside of people's apartments. There appear to be multiple cancer clusters in close proximity to mobile phone masts, for example, in Israel, in Naila, Germany, in the UK, in Perez, Spain, in Taman Subang in Kelana Jaya, Malaysia, in Taiwan, and Bayville, NY (see footnotes for more information).[19] Eileen O' Connor, of the EM Radiation Research Trust, is one example of a **breast cancer** survivor who was in a cancer cluster near a mobile phone mast.[20] The high breast cancer rates of Marin County, California, were also suspected by some to be related to wireless radiation.[21] In Canada, telecommunications workers had increased rates of**melanomas (skin cancer)** [22], a cancer which is increasing in several countries.[23]**Leukemia** is another form of cancer that has been noticed with nonthermal microwave radiation, e.g., as a result of the Russian's secretly irradiating the U.S. Embassy in Moscow.

In the large Interphone multinational study on mobile phones and **brain cancer**, a link between mobile phones and cancer was found for multiple nations. The correlation was found despite poor study design that would actually grossly underestimate the risk of mobile phones. For more information on Interphone's weaknesses, including its definition of "regular user," the exclusion of children and business users, and more, see Cellphones and Brain Tumors: 15 Reasons for Concern: Science, Spin and the Truth Behind Interphone.

In the US Congressional hearing in 2008, one of the debated issues was whether the evidence points to a causal relation between wireless technologies such as mobile phones and cancer. The wireless industry representative claimed that the overall cancer statistics have not been getting worse.

> Looking at the overall statistics is not completely appropriate in this case, without considering the individual trends that are a part of this overall statistics. For example, the overall statistics includes statistics for lung cancer, one of the most prevalent cancers, whose incidence has been decreasing due to increased awareness of the dangers of smoking.[24] Instead of looking at overall statistics, it may be more instructive to look at a particular type of cancer. For example, brain

cancer has been on the rise for young adults, e.g., 20-29 year olds.[25]It is also instructive to look at salivary gland tumors among younger users.

There is approximately a ***20-year time lag***between the rise of smoking and the consequent rise of lung cancer deaths and between the decrease in smoking and the consequent decrease in lung cancer deaths. The population that began using cell phones 20 years ago is much smaller than the population using cell phones today, and these users were generally not as heavy users as today. It is possible that we will see a similar or even shorter time lag between wireless technology use and its long-term consequences. Personal home and office wireless technologies have only been around for a few decades, starting around the 1980s, with the newer and possibly more dangerous technologies like Wi-Fi and digital (as opposed to analog) cordless phone systems getting greater adoption and popularity in the ***late 1990s***. They have not been studied for long enough to establish their safety. Also, we have the difficulty of factoring in "second-hand"radiation, especially since people are not fully aware of their level of exposure, unlike with smoke.

Furthermore, the cancer statistics also suffer from omissions, e.g., the omissions of Veterans Administration cancer statistics from state registries since late 2004.[26] In some studies, business users and children have been excluded. In other studies, only short-term studies not exceeding 1 decade were performed.

Sleep Disorders

Research Studies

There is some research confirming that microwaves can impact sleep. Researchers at the University of Zurich, Switzerland found that 15 minutes of exposure affected brain waves during sleep in young male volunteers.[27] In one study, the components of sleep thought to be important for daily recovery, have been found to be adversely impacted by wireless technologies as well. A 3-hour exposure prolonged the latency to reach the first cycle of deep sleep, and decreased stage 4 sleep.[28] Studies have shown that ELF *pulse-modulated* microwaves have effects upon sleep. Furthermore, *pulse-modulated* microwaves may increase regional cerebral blood flow and enhanced EEG power. In contrast, non-pulse-modulated microwaves did not enhance EEG power. [29] Concerning the EEG effects, it has also been found that the EEG alpha band are especially affected.[30]

Corresponding Anecdotal and Epidemiological Evidence

One of the symptoms associated with microwave sickness is sleep issues, such as insomnia or frequent waking.[31] In the 1990s, an experiment was performed with a short-wave radio broadcast transmitter in Schwarzenburg, Switzerland. This study found that microwaves may result in more difficulty falling asleep as well as maintaining sleep. Sleep quality improved when the transmitter was shut down. This was not a double-blind study, however, and so does not rule out the possibility of placebo-like effect.[32] Another study by Citizens Initiative Kempten West (Germany) found that mobile phone masts resulted in a large decrease in serotonin in a majority of the participants. In any case, it is interesting to note that the use of prescription sleep aids has nearly tripled in young adults between 1998 and 2006.[33] In 1998 and 1999, were introduced cordless phones of the 2.4

GHz spectrum as well as Wi-Fi (see Appendix 1C).
In K. Crofton's book, *Radiation Rescue*, the first testimony is from someone who heeded the wireless wake-up call, following which her insomnia of 3 years disappeared, and she was sleeping well for a couple of weeks.

Calcium Efflux

Wireless radiation has been shown to remove calcium ions from membrane surfaces.[34] An experiment (Blackman et al) found calcium ion efflux from chick-brain tissue at certain field intensities.[35] This calcium efflux phenomenon may have impacts in multiple systems including the neurological and cardiovascular system. For example, contractions in the heart are influenced by calcium. Neurotransmitters in the brain are also influenced by calcium.[36] Some relevant research on cardiac and neurological effects will be discussed in the following sections.
We can further gather some insight into the importance of calcium, and the disruption that calcium efflux might have, by studying the delicate balance between Magnesium and Calcium in the body. Magnesium helps dissolve calcium and maintain calcium levels in the blood, the excess of which could effect calcification and disrupt cell function. Additionally, magnesium allows just enough calcium for electrical transmission along the nerves. Magnesium and calcium also work in opposite roles in the relaxation vs. contraction of muscles. Magnesium plays an important role as well as co-factor in chemical reactions, in the synthesis of proteins, and the the production of energy. Finally, Magnesium is also important in the detoxification process. According to *The Magnesium Miracle,* magnesium deficiency and calcium excess is potentially related to multiple conditions, including neurological, heart, infertility, osteoporosis, kidney stones, bowel disease, chronic fatigue syndrome, asthma, cramping, depression, and more. [37] Perhaps some of the symptoms of microwave sickness are related to the calcium efflux effect.

Cardiac Effects like Arrhythmia

Scientific Research

As mentioned previously, Calcium and Magnesium play an important role in the contraction and relaxation of the heart. Neuroscientist Allan Frey, who came up with a theory for microwave hearing, found that microwaves could trigger heart arrhythmia in laboratory animals or even stop hearts with the right modulations.[38] A study on frogs' hearts found a greater release of calcium ions within two intensity regions in response to electromagnetic waves.[39] Similarly, the calcium concentration in guinea pigs' heart muscle cells is also affected by low levels of microwave radiation.[40] Problems with heart rate have furthermore been observed in exposed chick embryos.[41] Chick embryos exposed to GSM mobile phone radiation during development actually had higher mortality rates.[42] With regards to humans, a study exposing ten healthy individuals to a digital cell phone for 35 minute periods in double-blind experiments found an average rise in systolic and diastolic blood pressure of 5-10 mm Hg as well as a slowing of heart rate.[43] Magda Havas has also performed a double-blind study which shows some volunteers' heart rate responding to DECT cordless phone stations without knowing whether the DECT station was plugged into a live or dead outlet.[44]

Corresponding Anecdotal and Epidemiological Evidence

People living near radio towers or mobile phone masts appear to have increased cardiac symptoms such as arrhythmia. In Switzerland, when examining adults before and after turning on a cell tower for arrhythmia, it was found that there was a significant increase in arrhythmia.[45] The example of Ouruhia, New Zealand, previously given, also included cardiac symptoms near the radio tower. Since the heart involves electrical signals, this may not be a complete surprise.

Cardiac problems have also been observed in the young. The usage of wireless technologies by pregnant women has been correlated to higher fetal and neonatal heart rate and decreased cardiac output, according to one study.[46] Since electrical disturbances in the heart may be responsible for some cases of Sudden Infant Death Syndrome (SIDS), we should also be concerned about a potential link between microwaves and SIDS.[47] The frightening thing is that people worried about SIDS often employ wireless baby monitors to check on their babies, not realizing that the monitor itself may cause electrical disturbances. There are anecdotes in which wireless DECT baby monitors gave babies more problems than the older analog wireless baby monitors.[48]

Neurological Effects

Scientific Research

Other examples of leakage across barriers include the increased permeability of the blood-brain barrier (BBB) to various substances like albumin, which could damage neurons. Neuronal damage was found in rat brains 50 days after a 2 hour exposure to a level as low as 2mW per kg.[49] This increased permeability of the BBB in rats was also found after 7 and 14 days after the exposure.[50] Other studies have suggested that other substances besides albumin can also penetrate this barrier when exposed to microwaves.[51] This BBB permeability may partly explain why some people have headaches around wireless technology.[52]

Research has also found calcium efflux in brain tissue in response to microwaves. Blackman discovered two power density windows in which calcium would be removed from brain tissue.[53] As a possible mechanism, Andrew Goldsworthy suggests that if the voltage is just right, it will selectively remove the more strongly charged ions, such as divalent ions like calcium.

Since calcium plays an important role at the inter-neuron synapse in the release of neurotransmitters, this might further explain effects related to neurotransmitters. Changes in neurotransmitter functions have been found after low intensity exposures.[54] Dopamine, norepinephrine, acetycholine levels, and 5-HT, a precursor to serotonin, and melatonin, for example, may be affected.[55] Low levels of norepinephrine may help explain feelings of **stress**. Low levels of serotonin may help explain symptoms of **depression**around mobile phone masts. Chronic exposure to GSM cell phone radiation was found to reduce synaptic activity in the hippocampus neurons, which may also help to explain **memory loss** in wireless phone use.[56] Impaired memory was also found in rats as a result of wireless exposure and is another symptom of microwave sickness.[57]

Neuron death is another concern. BBC News reports that Swedish researchers studied rats whose brains are in the same development stage of a teenager. 50 days after a 2-hour exposure to radiation equivalent to mobile phones, they found an abundance of dead brain cells.[58] Exposed brain neurons may die more rapidly because of a lower capacity

for DNA repair in brain cells. Neuron death could contribute to **Alzheimer's** disease or **Parkinson's**disease. Changes in protein folding resulting from microwaves could cause formations of long strands of proteins called fibrils which trigger heat shock proteins. Protein fibrils are likewise found in diseases like Alzheimer's and Parkinson's.[59]

ADHD and Emotional Disorders

Mobile phone usage by pregnant mothers was recently correlated to the risk of having children with greater hyperactivity and emotional problems, even to the surprise of some of the researchers who expected to find otherwise.[60] This phenomenon might explain the rise of modern day disorders such as ADHD (attention deficit hyperactivity disorder). In Switzerland, when examining school children before and after turning on a cell tower for concentration problems, academic performance, and ADD, it was found that there was a significant increase in problems.[61]A study in Latvia of children near an early warning radar station in the early 1990s, found decreased attention, memory, and learning ability in the children living closes to the radar.[62]The Skrunda radar station operated from 1971 to 1998. Scientists were invited to conduct studies due to reports of ill health. Among the many effects they found included impaired memory and attention in school children.[63]

Immune System Dysfunctions and Chronic Diseases

Unlike other particles and pathogens, microwaves can penetrate directly into the body. This is a problem for the immune system which relies a lot on skin as a barrier against pathogens. Some of the possible consequences found from microwave radiation include:

- Morphological alterations of immune cells
- Changes in lymphocytes dependent on the carrier frequency,
- Reduced T lymphocyte count, and
- Hypersensitivity manifesting as autoimmunity.[64],[65]

Johansson observed that electrohypersensitive individuals had higher densities of dendritic cells in their skin, which are reactors to ionizing radiation like X-rays and UV. Hence, electrohypersensitivity is postulated as being the result of irradiation due to effects similar to those documented of ionizing radiation like UV light. The increased numbers of mast cells could release histamines resulting in itch and pain. Mast cells are found to occur in many places, including the brain and heart. Chronic exposure to EMF was postulated to lead to chronic allergic responses and inflammatory responses.

Chronic Fatigue Immune Deficiency Syndrome (CFIDS or CFS)

The immune system dysfunctions caused by wireless technologies, may also be related to Chronic Fatigue Syndrome (CFS or CFIDS) as noted by Olle Johansson. Whereas wireless technologies may initially stimulate the immune system, they can eventually exhaust it. The depressed immune system may then make one more susceptible to ordinary bacterias/viruses. CFS was a symptom mentioned found in Ouruhia, New Zealand, correlated to a radio tower. One individual claims to have recovered from Chronic Fatigue Syndrome, by escaping from wireless technologies.[66]

Increased Asthma, Allergies and Rashes

Dr. Peter Finch discovered mobile phone frequencies increased the production of histamines, which are involved in allergic reactions and bronchial spasms. Consequently,

Dr. Finch predicted an increase in allergies and asthma.[70] It is therefore interesting that asthma, along with headaches and impaired concentration, was one of the strongest connections found in users of wireless telephones, according to a study in Örebro University, Sweden.[71] Asthma was also one of the symptoms found near the AM/FM radio towers in Ouruhia, New Zealand.
Even power frequencies may increase risk for asthma. Asthma of offspring is also being linked to the power line magnetic field exposure of mothers during pregnancy (De-Kun Li et al, 2011). Filters for dirty electricity, high frequency radiation on wires, have also reportedly reduced a number of symptoms, including headache, skin irritation, and asthma.[72]

Possible Mechanisms for Asthma:

- Impacts on the autonomic parasympathetic vs. sympathetic system by wireless technologies. The parasympathetic system results in constriction of bronchial tubes, whereas the sympathetic system results in dilation. This system is mediated by neurotransmitters like acetycholine which may be affected by wireless technologies. (Adams, The Asthma Sourcebook, p.4)
- As mentioned previously, the calcium efflux of microwaves affect might result in an imbalance of Calcium and Magnesium, which might have an impact on asthma. Calcium tends towards constriction of muscles vs. relaxation by Magnesium.
- Impacts on the immune system: Mobile phone frequencies result in an increase in histamines. Asthma may also be related to an increase in the number of mast cells, which store and release irritating chemicals. Wireless technologies may increase the number of mast cells.

Possible Mechanisms for Allergies, Rashes, Gut permeability:

One Japanese study found that microwave radiation can increase allergic responses to dust and pollen in adults with eczema, in comparison to the control group.[69] This may also be related to mast cells. Mast cells may cause other problems depending upon where they occur-- asthma related to bronchial tubes, hay fever related to the nose, conjunctivitis related to the eye, and eczema/hives related to the skin (Adams, pp8-9).
The other hypothesis for the mechanism behind allergies is that it is the result of cell membrane weakening due to the calcium efflux effect. Andrew Goldsworthy explains that when calcium ions are replaced with monovalent ions, it weakens the cell membrane, increasing the likelihood of pores.[67] This membrane weakening can affect “tight junction barriers,”such as nasal mucosa, lungs, and gut linings. Leakage through pores may allow increased amounts of toxins to enter in and damage the cell, resulting in increased allergies, multiple chemical sensitivities, asthma, skin rashes, bowel cancer, and gut permeability. Gut permeability might in turn contribute to many health conditions such as type-1 diabetes, Crohns disease, celiac disease, multiple sclerosis, and irritable bowel syndrome. [68]

The Autism Hypothesis and Other Developmental Problems

Autism arose in the 1980s and 1990s around the time that wireless technologies started becoming popular.[73] Autism has been thought to be a “geek syndrome”, rising amongst places like Silicon Valley, where a greater proportion of people are likely to be

technology lovers, and hence, wireless users.[74] According to one source, it nearly tripled between 1987 and 1998 in California. Brick, NJ, also had autism, at the rate of 8 children per 1000 between ages 3 and 5. Investigators could not find a chemical contaminant to explain it, but 10 miles away was a Doppler weather radar transmitting at an extremely high power of 750,000 watts since late 1994. [75]

Are there any studies which suggest a possible correlation between wireless technologies and autism?[76] One pilot study by **Dietrich Klinghardt** checked the body voltage and microwave power density that a person would have in the sleeping location of the pregnant mother. These numbers were compared for the sleeping location of women who later gave birth to healthy children versus the sleeping location of those who gave birth to autistic children. The study found significantly higher body voltages and microwave power density for the mothers who gave birth to the autistic child.[77]

Suggestions for the cause of autism range from mercury toxicity from vaccines to problems with neurotransmitters to genetic damage to GMO's and food allergy problems, all of which can be exacerbated by wireless technologies. Klinghardt believes that electro-smog (wireless radiation) is one of three interconnected causes of autism. This electrosmog may contribute to the growth of molds and other bio-toxins, which may also be working in autism. [78] Another study in 2007 suggested that wireless technologies could make it more difficult for autistic children to excrete heavy metals, such as mercury.[79]With regards to synergy, it is possible that EMF worsens the effects of a toxin (e.g., by opening the blood-brain barrier, letting more of the toxin in) or stands in the way of the body's natural protective mechanism against the toxin (e.g., by reducing glutathione levels). Andrew Goldsworthy also hypothesizes that microwaves can interrupt the pruning process in neuron connections, and thereby contribute to autism.[80].

The latest Bioinitiative Report (2012) notes additional clues that might link microwaves to an increased risk for autism. For example, some of these factorsinclude increased oxidative stress, reduced glutathione levels, interference with calcium signaling, cell membrane peroxidation, impacts to gap junctions like the blood-brain barrier, genotoxicity, mitochondrial dysfunction, melatonin dysregulation, disturbed immune function, and brain cell damage. The report concludes that even if these links cannot be proven, that EMF can increase the risk by worsening challenging biological problems.

An increase of**Down's syndrome** was also found amongst the children of radar operators, and amongst residents near satellite uplinks in the microwave bands in Vernon, NJ (radar and satellite also fall within the microwave band).[81] Note that radar has also been linked to "internal bleeding, leukemia, cataracts, headaches, brain tumors, heart conditions, and liver involvement with jaundice" at certain power densities.[82]

Effects on Mercury

Mercury also seems to be tied into Electromagnetic radiation. The Swedish book of testimonies of electromagnetic hypersensitivity, Black on White, includes many individuals who reported their sensitivity to microwaves following a dental appointment that impacted mercury levels.[83] Another anecdote has been provided of an otherwise normal patient who developed trigeminal neuralgia. It was suspected to be a result of this man's root canal with 2 metals and amalgam fillings in combination with the cell tower. The individual had the filling for 15-20 years before the neuralgia, but he did not become sick until after the cell tower came up. It is suggested that the amalgam fillings may act as

an antenna[84]Note that mercury also increases excretion of magnesium and calcium from kidneys. Magnesium levels are important as they can help in the excretion of certain heavy metals.[85] There is also a possibility that radiation increases mercury release, which can be dangerous since mercury is a toxic chemical.

Effects on Plants

Even plants seem to be affected by microwaves, including tomato plants, pine trees, aquatic plants, poplars, willows, and more. In Latvia, pines exposed to radar, experienced a decline in growth in comparison to surrounding trees, coinciding with the start of the emissions. Exposed pine trees were also found in other studies to have increased resin production (a possible stress response) and low seed germination. Trees near phone masts have similarly experienced deterioration.[86]

Dr. Wolfgang Volkrodt, a retired Siemens physicist and engineer, studied deforestation in the German and Swiss Alps. He noticed areas of damage that occurred even where there was no acid rain. He hypothesized the cause was the massive communication between NATO countries and the soviet block. The theory was that the pine needles absorbed electrical current, and channeled this into the soil, which was destroyed. Indeed, U.S. satellites found deforestation in areas with massive communication. Some students built a Faraday cage around whole areas of forest, and those were the areas where the forests started to regenerate[87].

Effects on Animals

Effects can be seen not only in humans, but also in animals-- including horses, cows, pigs, birds, bird eggs, rats, monkeys, amphibians, bees, worms, drosophila (fruit flies), yeast, algae, and bacteria, some of which were mentioned earlier due to laboratory studies on animals.[88]Our mobile phone standard of 1.6 W/kg was itself based on a behavioral disturbance in monkeys in response to microwaves.

One possible explanation for some of these effects is related to magnetite, which is used in many animals as a navigational tool. Bees, butterflies, birds, fish, dolphins, and magnetobacteria have magnetite. In 1992, it was even discovered that the blood brain barrier and meninges covering the human brain (Joseph Kirschvink at California Institute of Technology) also has magnetite. The sinus region was also found to have magnetic material.[89] The pineal gland, which produces melatonin, has also been found to be contain calcite microcrystals with piezoelectric properties, which might operate with a similar mechanism as the magnetite crystals in the brain.[90]

Mammals

It is interesting to consider a few case studies regarding livestock exposed to mobile phone masts or radio towers, which involve pigs, cows, and horses.

In Casaveieja, Spain, farmers blamed mobile phone base stations for **pigs'** miscarriages. Upon the disassembly of the antennae, the problems stopped.[91]

In Bavaria, Germany, a farmer started noticing problems beginning in 1992, and could not find a reason other than the radio frequency broadcasts. The **cows'** problems included conjunctivitis, itching, reproductive problems, decreased milk production, dancing or weaving in stalls, and pointing heads away from the transmission tower. When one cow was moved to a neighbor's farm 20 kilometers away, this strange behavior disappeared in

5 days. Not to mention also, this farmer's family also experienced many health issues, including headaches, non-malignant growth, aching joints, pains in bladder, head, and heart. Other animals, including birds, cats, and chickens and dogs, upon entering the farm, appeared to be strangely and negatively affected.[92]

In New Zealand, well-known horse trainer Penny Hargreaves had a small farm near a radio tower. She had some **cows** which became nervous and disoriented. All 90 of her **horses** were also affected and became nervous and jumpy. Symptoms included loss of balance, volatile behavior, more infections than ever before, and walking as if their feet hurt. Penny and her daughter also suffered health problems including abdominal pain, joint pains, heart palpitations, ringing in the ears, mental confusion, and asthma, until they moved away.[93]

Birds

Previously, negative effects were mentioned regarding exposed chick embryos. In scientific research, cell cultures of avian brain tissue subjected to cell phone frequency also had abnormal neuronal firing in over half of the cell samples, or else an abnormal shut down. In practice, around cell towers, we do see abandonment of nest sites, fewer eggs, chick deformities, a decrease of population,[94] as well as lower productivity in nests, plumage deterioration, and partial albinism.[95] The decrease in population may be in part due to cell tower collisions, but also in part due to interference with magnetic navigation.[96]

Bees, Insects, & Worms

A serious problem has afflicted bee colonies *worldwide*, called colony collapse disorder. Beekeepers have been surprised to find many beehives unusually abandoned. 25 to 50% of American bee keepers reported loss, e.g., 50% to 90% of their bees disappeared within a 6 month period .[97]While herbicides, pesticides, and GMO's may be suspected for problems with bee colonies, some also postulate that the increase of mobile phone masts (e.g., cell towers) could be related to colony collapse disorder by interfering with their navigational skills.[98]

A limited study at Landau University put DECT wireless stations at the bottom of bee hives. The ones with greater exposure to the DECT stations had greater incidence of colony breakdown. Fewer bees returned to the hive, and the exposed hives had lower honeycomb weights.[99] A study in 2009 by Pattazhy from Kerala also found that mobile phone towers could damage the navigational skills of worker bees.[100]

Another hypothesized mechanism is through the interference of the Nitrogen Monoxide (NO) system, which would disrupt not only learning capability and olfactory orientation but also the immune system. The mechanism by which this happens might be related to the sensitivity of NADH oxidase enzyme to magnetic and electromagnetic fields. As a result, not only would this interfere with bees' orientation, but also with their susceptibility to virus, fungi, and other microorganisms.[101]

Non-thermal microwave fields like that of cell phones were also found to induce heat-shock responses in the soil nematode Caenorhabditis elegans[102]as well as fruit flies.[103]

Killing With Sound: What Happens When the Whales Stop Singing?

Posted: 02/22/2013 6:26 pm EST Updated: 04/24/2013 5:12 am EDT

Close your eyes. Your world is now only sound -- the rain, the traffic, that far-off siren. In this acoustic world, how you navigate, find food, your children, or mate, all depends upon how well you hear. Imagine that as you search in the darkness for a crying child, a horrifying drone, loud as a rocket, suddenly blasts sound pulses like shockwaves through your home.

There are no noise-cancelling headphones to stop the U.S. Navy's 235-decibel pressure waves of unbearable pinging and metallic shrieking. At 200 Db, the vibrations can rupture your lungs, and above 210 Db, the lethal noise can bore straight through your brain until it hemorrhages that delicate tissue. If you're not deaf after this devastating sonar blast, you're dead.

This is the real life of marine mammals destroyed by the U.S. Navy's all-out acoustic war on the world's oceans. The collateral damage of this high-intensity military sonar is shocking. But because all these millions of dying whales or dolphins are too often out of human sight, they're also out of mind. Only when cetaceans strand on land do we witness what orca researcher, Ken Balcomb, calls, this "acoustic holocaust." Military sonar so panics cetaceans that as they try to escape the sonic violence, they rise too quickly to the surface and die of "the bends."

Ken Balcomb has researched multi-generations of the resident orca pods in the Pacific Northwest. In March, 2000, Balcomb documented a mass stranding of predominantly deep-diving beaked whales off the Bahamas that the Navy later finally admitted was a result of their LFA (Low-frequency Active sonar) tests. Balcomb told the *Los Angeles Times*, "sonar waves at certain frequencies might have resonated around the whale's ears, causing tissues to tear much as a wineglass will shatter at a particular pitch."

Scientific American calls military sonar, "rolling walls of noise." For the dolphins, whom researchers have documented as "self-aware," noting that they "call each other by name," this is a brutal and inhumane death sentence. For whales, such as the great blue, who can communicate over thousands of miles, such sonic stress affects reproduction and communication so much that some whales simply stop vocalizing. What happens to our oceans when the whales stop singing?

In the Navy's latest environmental impact statement draft, they admit that the sonar exercises planned for 2014-2018 may unintentionally "harm marine mammals 2.8 million times over five years." This estimate is up about 150,000 instances a year from their EIS statement of 2009-2013. Included in this estimate are two million incidents of "temporary hearing loss," and 2,000 are targeted for permanent hearing loss.

A deaf whale is a dead whale. Dr. Lindy Weilgart, sperm whale researcher at Dalhousie University in Halifax, Nova Scotia warns us "There are some technologies that simply should never be used. As a scientist -- and as a mother and fellow inhabitant of this fragile planet -- I am alarmed at this new threat to our oceans. The ocean gives us our air, our water, our food, and regulates our climate. The ocean literally enables human life."

Criticism of the Navy's sonar has intensified, even as the military has intensified their sonar

tests.The main concern of scientists and environmentalists is that the Navy has not done enough environmental impact research and knows much too little about the devastation they're unleashing on our marine environment to proceed with such expanded target ranges.

The Navy has paid little heed to the scientists, the lawsuits, the public outcry, and the many media storms all protesting this risky technology. Even while sometimes admitting sonar's role in mass strandings -- like those in the Bahamas, Canary Islands, Pacific Northwest, Greece, and North Carolina -- the Navy has proceeded to garner federal permits to expand their sonar tests. NMFS (National Marine Fisheries Service) just gave the Navy the go-ahead for their proposed 2014-2018 sonar exercises, targeting those two million whales and dolphins. In response, the NRDC (Natural resources Defense Council) and Earth Justice, along with several tribes have brought a lawsuit claiming that NMFS was "wrong to approve the Navy's expanded training plan," which would affect Washington, Oregon and California coasts.

The Navy has agreed only to post look-outs onboard ships to spot whales. "Visual detection can miss anywhere from 25 to 95 percent of the marine mammals in an area," says Heather Trim, Director of Policy for People for Puget Sound. The Navy should at least use common-sense precautions: declare whale sanctuaries, birthing nurseries, and whale migration paths off-limits to sonar testing. The Navy could employ their sophisticated listening devices to make sure no cetaceans are in the path of their lethal sonar. Finally, the Navy could engage in a serious and thoughtful dialogue with scientists and environmentalists about how to assure our military readiness while not destroying the very ocean they supposedly serve.

Our seas are not just a backdrop or stage upon which to practice our war games. As a recent *New Yorker* blogger wryly points out, "The cat-and-mouse games played by submarines may have made a certain kind of sense during the Cold War, but what is the point of them now? Russia is annoying, but it is no longer our mortal enemy. The Chinese have no desire to bury us, except under piles of sneakers and kitchen appliances... The terrorists have no submarines."

As we now ponder cuts to the defense budget, why not stop this military sonar's expansion until we have enough sound science and environmental research to use it judiciously and with much greater concern for all life? In this time of collapsing fisheries and disastrous marine pollution, when our oceans are more fragile and endangered than ever before, why let the Navy blast its expensive and fatal sonar through our seas?

We must not let our fear of some supposed enemy destroy our foresight. The tragedy is that in our zeal to protect ourselves, we are destroying the same life support system that we need for our own survival -- our oceans. Because when you save the whales, you also save the humans.

THE WORK OF OLLE JOHANSSON

 In the 1970s the newspaper industry was one of the first to supply its employees with computers. Complaints of visual problems and headaches, as well as clusters of miscarriages and birth defects in children born to female editors and other newspaper employees, generated some publicity. In the United States, then-Representative Al Gore held Congressional hearings in 1981 on the health effects of computer screens. In Sweden, a union activist brought the problem to the attention of Dr. Olle Johansson, a neuroscientist at the world-renowned Karolinska Institute. Johansson was the head of the Experimental Dermatology Unit at the Institute.

“For me,” said Johansson, “it was immediately clear that persons claiming skin reactions after having been exposed to computer screens very well could be reacting in a highly specific way and with a completely correct avoidance reaction, especially if the provocative agent was radiation and/or chemical emissions — just as you would do if you had been exposed to e.g. sun rays, X-rays, radioactivity or chemical odours.”

Johansson began to study the skin of these patients, and proved that they had a real skin condition that was provoked by sitting in front of a computer screen. The damage was similar to that caused by ultraviolet radiation from the sun. He also showed that the radiation from computers causes measurable changes even in the skin of “normal” people,” and also in the skin of laboratory animals.

He named the new disease “screen dermatitis.” However, since such individuals also usually complained of other symptoms, such as chest pain, memory loss, fatigue, insomnia, dizziness, nausea, and headache, the more general term “electromagnetic hypersensitivity” came into use.

Many people who worked in the electronics industry in Sweden, including an estimated 12% of the electrical engineers in that industry, became electrically sensitive, and helped form an organization called Föreningen för el-och bildskärmsskadade (Association for the Electrosensitive), or FEB. Due in part to the work of FEB and the research of Dr. Johansson, electrosensitivity is a fully recognized disability in Sweden.

 More recently, Johansson and his colleagues have conducted important epidemiological studies showing that wireless communication networks are causing significant illness throughout society. They have also shown that increased rates of asthma as well as certain types of cancer were strongly correlated with exposure to radio broadcasting during the twentieth century.

"The world may be moving inexorably," Johansson warns, "toward one of those tragic moments that will lead historians to ask: Why did they not act in time?"

EMF Research

Peer-reviewed studies from scientists over more than five decades have shown a consistent correlation between exposure to electromagnetic fields (EMFs) and negative impacts to living beings.

Biological effects from EMF exposures include damage to DNA, higher risks of cancer, Alzheimer's disease, Lou Gehrig's disease, heart disease, autoimmune diseases such as MS and diabetes, lowered sperm counts and many others.

Troubling and disabling symptoms affect a wide range of body functions. EMF exposure affects all of nature, interrupting the ability of birds and bees to navigate, causing cows to be agitated and to produce less milk, and leading to (bee) colony collapse disorder.

Importantly, many of these effects on health and nature occur at levels that are thousands of times lower than the limits set by regulatory agencies like the FCC as safe. It is now clear that safety limits are no longer sufficiently protective of public health, particularly more susceptible individuals (infants, children, pregnant women and the elderly.

EMF sources associated with adverse health effects include:

- Cellular (long-range transmission) towers and antennas in schools, neighborhoods, churches, light standards, power poles, highways and towns
- Wireless (short-range transmission) systems and devices including cellphones, cordless phones, baby monitors, computers, tablets
- Electrical production facilities, transmission lines, structure wiring, all electrically powered items and electronics
- Radar
- Radio and TV broadcasting facilities
- Smart meters, appliances and transmission systems
- Microwave ovens
- Satellites

Modern technology has stoked an unparalleled degree of innovation and improvement in our quality of life. At the same time, both wired and wireless infrastructures and the buildings, equipment and gadgets connected to them now bring electromagnetic fields (EMFs), a form of radiation, into virtually every space we inhabit, whether at work, home or play, inside or outside, in cities or rural areas.

Relatively few people in the U.S. are aware EMFs cause harm. Unfortunately, industry forces have successfully discredited a very large body of research that strongly supports significant and growing harm from EMFs.

We've seen industry oppose strong scientific evidence of harm before – with tobacco, asbestos, chemicals, fracking and other industries that have paid scientists to generate "evidence" that falsely supported their claims of product safety.

The research, articles and reports found here are arranged in the following manner:

1. Collections of EMF studies

2. EMF studies in chronological order

3. Articles, Commentaries and reports about EMF health effects

4. Effects of EMFs on plants and animals

Research studies, articles and reports on EMF health effects

1. COLLECTIONS of EMF STUDIES

1972: 2,300 studies published by the US Navy showing biological impacts of EMF: Naval Medical Research Institute 2300 Studies on EMF Health Effects.
http://www.radiationresearch.org/pdfs/20091016_naval_studies.pdf

2012 BioInitiative Report – References 1,900 new studies showing biological impacts from non-thermal EMF. Prepared by 29 authors from ten countries, ten holding medical degrees (MDs), 21 PhDs, and three MsC, MA or MPHs. Among the authors are three former presidents of the Bioelectromagnetics Society, and five full members of BEMS.: http://www.bioinitiative.org/

Comprehensive German data bank of global EMF research showing biological effects of RF/EMF. Includes summaries of over 5700 studies: http://www.emf-portal.de

WiFi in Schools. Refers to numerous studies. Includes chart showing numerous health effects from laptop and iPad radiation: http://www.wifiinschools.com/science.html

Comprehensive collection of studies, papers and commentary of how EMF pollution affects body systems and disease. Studies arranged by disease: http://emractionday.org/science

Thousands of studies showing links between EMF pollution and adverse biological effects:
http://www.powerwatch.org.uk/science/studies.asp

Collection of over 5,000 studies showing biological impacts from EMF pollution: http://justproveit.net/studies

Graph with 67 studies that show adverse health effects occur well below the limit set by the U.S. government EMF limits and the corresponding effects of smart meters – See the following PDF, as well as the graphic:

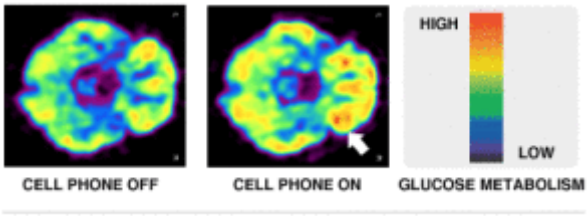
2011 Dr. Leif Salford and his colleagues at Lund University Hospital in Sweden exposed over 1,600 experimental animals to low-level microwave radiation. They then repeated the experiment in another 32 animals but waited 8 weeks before examining their brains. They found that up to two percent of the neurons in all areas of the brain were shrunken and degenerated. *Silent Wireless Spring. ArthurFirstenberg*
http://www.cellphonetaskforce.org/wp-content/uploads/2011/10/silentwirelesspring.pdf

2011 study by Nora Volkow showing that cell phone radiation increases brain glucose metabolism in areas next to antenna. Increased glucose metabolism is associated with cancer. Study shows that biological changes occur at levels lower than FCC guidelines. http://www.ncbi.nlm.nih.gov/pmc/articles/PMC3184892/



Journal of Neuroscience highly controlled double-blind study showing evidence of electro-hypersensitivity (EHS) symptoms of headache, skipped heartbeats, temporal pain and muscle twitching from EMF that was repeatedly turned off and on, in a female physician. The subject could not detect when the EMF was off or on but her symptoms began within 100 seconds after initiation of EMF exposure: http://www.ncbi.nlm.nih.gov/pubmed/21793784

2009 YouTube: "Suppressing the science on cellphones". Prominent researcher Franz Adlokofer's study funded by the European Commission found that high frequency electro-magnetic fields damage genes and gene function. He describes the attempts made by the telecommunications industry to discredit him and his research. https://www.youtube.com/watch?v=B9ycyWd8GMs

2009 Research article by Dr. Carl Blackman showing that non-thermal effects of electromagnetic radiation should be included in national and international exposure standards, which should have been lowered, not raised as they were recently: http://www.pathophysiologyjournal.com/article/S0928-4680(09)00004-2/pdf

2001 Dr. Neil Cherry discusses evidence available in 2001 that showed a causal link with EMFs and brain tumors. http://www.pathophysiologyjournal.com/article/S0928-4680(09)00004-2/pdfrozpotter@defyingdisaster.com

1995 Electrical distribution lines constitute both inside and outside homes is one of the major sources of the public's time-weighted average exposure to magnetic fields. This report provides insight into representative data on magnetic field levels inside residences and in proximity to distribution lines. EPRI *Handbook for the Assessment and Management of Magnetic Fields Caused by Distribution Lines*. Author(s): Enertech Consultants. http://www.epri.com/abstracts/Pages/ProductAbstract.aspx?ProductId=TR-106003

1994 U.S. Air Force study confirming existence of non-thermal EMF effects, including alterations to the central nervous system and cardiovascular system: Air Force Study showing non-thermal effects

1981 NASA paper showing numerous health affects from non-thermal electromagnetic fields. NASA report on EMF effects on human body

1965 Ford Motor Company commissioned this study which shows the numerous damaging biological effects of microwave radiation. It notes in particular how damaging microwave radiation is to the central nervous system.

3. ARTICLES, COMMENTARIES AND REPORTS ON THE EFFECTS OF EMF RADIATION

2002 Dr. Gro Harlem Brundtland, Director of the World Health Organization and former Prime Minister of Norway, admits that cell phones and computers make her ill. http://emrabc.ca/wp-content/uploads/2010/01/SUMMERLAND.pdf

52 Medical Doctors and Researchers respond to industry PR that "smart" meters are safe: https://maisonsaine.ca/sante-et-securite/electrosmog/smart-meters-correcting-gross-misinformation.html

Italian Supreme Court rules that brain tumor is caused by cell phone: http://www.telegraph.co.uk/health/9619514/Mobile-phones-can-cause-brain-tumours-court-rules..html

World Health Organization and IARC classifies microwave radiation as a "possible carcinogen", Class 2B, the same classification as lead and DDT– May 31, 2011: http://www.iarc.fr/en/media-centre/pr/2011/pdfs/pr208_E.pdf

"Captured Agency" report on how the FCC is completely dominated by the wireless industry that it supposedly regulates. Published June 2015 by investigative journalist Norm Alster and the Harvard University Center for Ethics. Mr. Alster also wrote about the Dot Com Crash and the 2008 Financial Crisis before they happened. Click for free PDF or Kindle versions.

2001 Cellphone manufacturers own patents that would cut radiation risks but do not use their own technology http://www.rcrwireless.com/20010604/carriers/manufacturers-own-patents-to-cut-radiation

2014 Former Nokia technology chief says cellphones wrecked his health. Nokia has held patents since 1998 that would reduce the irradiation of cell phone users – but did not utilize the technology: http://betweenrockandhardplace.wordpress.com/2014/10/20/former-nokia-ctos-multiple-sclerosis-and-nokias-patents-to-prevent-it/

2004 Electric and magnetic fields affect milk production and the behavior of cows. Donald Hillman, Ph.D. http://emf.homestead.com/files/ShockingNewsv3-072004.pdf

Open Letter to Parents, Teachers, & School Boards Regarding Wireless Utility Meters (AMR, AMI, ERT, and Smart Meters), Smart Boards, Smart Phones, 3G/4G Cell Towers and Wifi:

There has been an alarming increase in illness, disease, aggressive behavior, crime, and death since the introduction of the above mentioned technologies into our society.

Bullying and inappropriate behaviors in school districts as well as businesses and homes have been increasing steadily.

Health problems caused by continual exposure to wireless frequencies from Wifi and Smart Phones were already on the rise when the school districts started allowing installations of wireless utility meters and smart boards in their schools.

It was after these installations that we saw a sudden increase of bizarre behaviors in students and staff as well as a steady increase in illnesses and disease processes which were being continually misdiagnosed by the Medical Community.

The continual EMF/ELF/Radiation emitted by these devices has an accumulative effect on the body and disrupts its ability to heal and maintain health. The body is Electrical and these frequencies interfere with it's own electrical system causing it to break down and become vulnerable to disease.

When students are sitting in classrooms surrounded by this "soup of radiation" their entire body is being damaged! (Brain, Immune System, Heart, Lungs, etc…)

The World Health Organization has labeled this technology as a **Class 2b carcinogen** and thousands of studies have proven the EMF/ELF/Radiation to be a contributing cause to ADD, ADHD, Aggressive Behavior, Dementia, Parkinsons, MS, Heart Palpitations, Heart Attacks, Strokes, Nose Bleeds, Headaches, Flu-like symptoms, chronic coughs, unexplained rashes, severe depression, suicidal tendancies, and many, many more!

Schools are reporting severe outbreaks of Flu, Mumps, Meningitis, etc… as well as unprovoked shootings, bullying, and criminal behavior of students.

Anyone who takes the time to research the long-term effects of EMF/ELF/Radiation from the above mentioned devices and equipment will find that the sudden increase of these problems is directly related to the accumulative exposure to this "soup of radiation."

The companies that make these devices would have you believe they are safe and the media has been told to remain silent on their dangers.

The vast majority of Medical Doctors are making a fortune "mis-diagnosing" and "mis-informing" parents and students of what is truly wrong because they either refuse to pay attention to the research or they don't want to give up the financial windfall they have received due to the invention, sales, and installation of these devices and equipment.

Documentation and 1000's of Research Studies have been turned into the AMA, Kentucky Attorney General, and the Kentucky Public Service Commission under Case File 2012-00428. They may be reviewed at their website online!

The documentation is being ignored and the entire population is being "duped" into believing this technology is safe as well as believing that all the health problems and outbreaks are due to something other than the chronic exposure to this EMF/ELF/Radiation.

It is one thing to be able to turn your phone, laptop, or wifi off and on, but the above mentioned technology is not "hard-wired" nor is it analog! Everyone is being exposed constantly and the body has no recovery period from the exposure!

Parents, Teachers, Students, and the Entire Population need to stand-up and speak-out against this technology being used in the schools, businesses, and homes!

It is one thing to choose to use this technology in your home, but to expose everyone to it chronically because they have no choice for a EMF/ELF/Radiation FREE School or Work Environment, is a crime!

Children and young adults are more vulnerable to this technology because their bodies have not fully developed. (Especially their Brains and Immune Systems!)

Take a stand and tell your school board to "Hard Wire" all technology! Do not allow wireless devices such as the AMR/AMI/ERT/Smart Meters to be installed on Homes, Businesses, Schools, Hospitals, etc…

Instead of Wifi and Smart Boards, tell the School Boards that all laptops and smartboards must be hardwired.

Say "No" to the smart phones! You and your family can function just fine with the old style cell phones that use the CDMA Networks. Those phones still gave off EMF/ELF and Radiation, but the levels were half of what the smart phones put out!

It's a choice! Health or eventual illness and disease! You must control your environment and get informed before you or your children become a statistic!

There are so many more dangers associated with this technology, but there is just not enough room to list it here.

Please go to Kentucky Public Service Commission Case File 2012-00428 and see for yourself the documentation filed against wireless utility meters and the damages they are causing to property by killing trees, wildlife and making residents sick!

We are a community of Traditional Natural Medicine Doctors who have researched and understand the symptoms and illnesses caused by exposures to EMF/ELF/Radiation created by the above mentioned devices.

Our Nation is in crisis, and the most important issue at hand is not being addressed!

Increases in Cost of Healthcare, Crime, Illness and disease, is directly proportional to these exposures to EMF/ELF/Radiation. The exposure can not be controlled unless we are the ones who can individually turn it off and on! This is not an option if it is not "Hard Wired." (Our privacy is also being violated by the utilization of these devices!)

Peer-reviewed scientific studies on EMF related subjects

When it comes to EMF issues, one of the most frequently heard phrases is "There is no evidence to support EMFs having health effects" or simply "There is no conclusive evidence".

This is completely wrong; there is an enormous body of evidence out there, but public and even academic awareness seems to be very poor. Therefore, we will be presenting a list of papers and odds ratios which either show serious effects or are considered important papers on the subject which we have collected over the years. This page will be updated regularly.

P This study has found effects from the exposure or radiation category

N This study has found no effects from the exposure or radiation category

- This study has offered important insights or findings but is neither a positive or null finding

Electromagnetic Radiation in Western Canada

WI-FI Studies

EFFECTS OF 2.4 GHz RADIOFREQUENCY RADIATION EMITTED FROM WI-FI EQUIPMENT ON microRNA EXPRESSION IN BRAIN TISSUE.

Int J Radiat Biol. **2015 Mar 16**
http://www.ncbi.nlm.nih.gov/pubmed/25775055?dopt=Abstract

The results revealed that long term exposure of 2.4 GHz Wi-Fi radiation can alter expression of some of the miRNAs such as miR-106b-5p (adjP* = 0,010) and miR-107 (adjP* = 0,005). We observed that mir 107 expression is 3.3 times and miR-106b-5p expression is 3.65 times lower in the exposure group than in the control group. However, miR-9-5p, miR-29a-3p and miR-125a-3p levels in brain were not altered.

CONCLUSION:

Long term exposure of 2.4 GHz RF may lead to adverse effects such as neurodegenerative diseases originated from the alteration of some miRNAs expression and more studies should be devoted to the effects of RF radiation on miRNAs expression levels.

Study Suggests Wi-Fi Exposure More Dangerous To Kids Than Previously Thought

Most parents would be concerned if their children had significant exposure to lead, chloroform, gasoline fumes, or the pesticide DDT. The International Agency for Research on Cancer (IRIC), part of the United Nations' World Health Organization (WHO), classifies these and more than 250 other agents as Class 2B Carcinogens – possibly carcinogenic to humans. Another entry on that same list is radiofrequency electromagnetic fields (RF/EMF). The main sources of RF/EMF are radios, televisions, microwave ovens, cell phones, and Wi-Fi devices.

Uh-oh. Not another diatribe about the dangers of our modern communication systems? Obviously, these devices and the resulting fields are extremely (and increasingly) common in modern society. Even if we want to, we can't eliminate our exposure, or our children's, to RF/EMF. But, we may need to limit that exposure, when possible.

That was among the conclusions of a survey article published in the *Journal of Microscopy and Ultrastructure* entitled "Why children absorb more microwave radiation than adults: The consequences." From an analysis of others studies, the authors argue that children and adolescents are at considerable risk from devices that radiate microwaves (and that adults are at a lower, but still significant, risk). The following points were offered for consideration:

- Children absorb a greater amount of microwave radiation than adults.
- Fetuses are even more vulnerable than children. Therefore pregnant women should avoid exposing their fetus to microwave radiation.
- Adolescent girls and women should not place cellphones in their bras or in hijabs (headscarf).
- Cellphone manual warnings make clear an overexposure problem exists.
- Government warnings have been issued but most of the public are unaware of such warnings.
- Current exposure limits are inadequate and should be revised.
- Wireless devices are radio transmitters, not toys. Selling toys that use them should be monitored more closely.

Children and fetuses absorb more microwave radiation, according to the authors, because their bodies are relatively smaller, their skulls are thinner, and their brain tissue is more absorbent.

Do the benefits of immersive learning applications outweigh the dangers of increased cellular and Wi-Fi exposure for children?

More generally, the studies cited in the paper seek to link RF/EMF exposure to different types of cancer, low sperm count, and other disorders. However, it is important to note that survey articles such as these need to be taken in their proper context. This particular article is one group's perspective. It was published in a relatively new and minor journal with limited data sets. They also note that the average time between exposure to a carcinogen and a resultant tumor is three or more decades, thus making it difficult to arrive at definitive conclusions.

This is not a call to throw out all electronic devices. However, at the very least, it should open up the discussion about different safety levels for adults versus children. Hopefully more longitudinal studies will be done to verify or contradict the assumptions so far. In the meantime, are the government's current regulations adequate? The exposure levels they warn against haven't seem to have been updated for more than 19 years.

In a Network World opinion article ominously titled "Is Wi-Fi killing us…slowly?" columnist Mark Gibbs makes the point that "… laws and warnings are all very well but it's pretty much certain that all restrictions on products that use microwave technology will err on the safe side; that is, the side that's safe for industry, not the side of what's safe for society." Gibbs then added this ominous closing question, "Will we look back (sadly) in fifty or a hundred years and marvel at how Wi-Fi and cellphones were responsible for the biggest health crisis in human history?"

But, short of that worst-case scenario, the topic certainly merits more scrutiny, and perhaps some common sense limits on what devices our children use, and for how long.

Wi-Fi Makes Trees Sick, Study Says

By René Schoemaker, IDG News Service - Nov 19, 2010 1:09 PM
Editorial note: A Dutch agency that looks into the health effects of electromagnetic radiation issued a statement that the results of the research described in this story were unconfirmed. "Based on the information now available [it] can not be concluded that the Wi-Fi radio signals leads to damage to trees or other plants," it said, according to a Google translation. Radiation from **Wi-Fi networks** is harmful to trees, causing significant variations in growth, as well as bleeding and fissures in the bark, according to a recent study in the Netherlands. All deciduous trees in the Western world are affected, according to the study by Wageningen University. The city of Alphen aan den Rijn ordered the study five years ago after officials found unexplained abnormalities on trees that couldn't be ascribed to a virus or bacterial infection. Additional testing found the disease to occur throughout the Western world. In the Netherlands, about 70 percent of all trees in urban areas show the same symptoms, compared with only 10 percent five years ago. Trees in densely forested areas are hardly affected. Besides the electromagnetic fields created by mobile-phone networks and wireless LANs, ultrafine particles emitted by cars and trucks may also be to blame. These particles are so small they are able to enter the organisms. The study exposed 20 ash trees to various radiation sources for a period of three months. Trees placed closest to the Wi-Fi radio demonstrated a "lead-like shine" on their leaves that was caused by the dying of the upper and lower epidermis of the leaves. This would eventually result in the death of parts of the leaves. The study also found that **Wi-Fi radiation** could inhibit the growth of corn cobs.The researchers urged that further studies were needed to confirm the current results and determine long-term effects of wireless radiation on trees.

Plants won't grow near Wi-Fi routers, experiment finds

Friday, December 13, 2013 by: Michael Ravensthorpe

Tags: Wi-Fi routers, radiation, plant growth

(NaturalNews) It's not difficult to understand the appeal of Wi-Fi. This revolutionary technology, which has been commercially available since 1999, eliminates cabling and wiring for computers, reduces cellular usage charges and allows us to connect to the

Internet from anywhere with a signal. Despite these benefits, however, studies continue to show that the radiation generated by wireless routers is negatively affecting our health. In fact, the British activist website *Stop Smart Meters* recently published a list of 34 scientific studies demonstrating the adverse biological effects of Wi-Fi exposure, including studies linking it to headaches, reduced sperm count and oxidative stress.

The latest research into the dangers of Wi-Fi, though, comes from a surprisingly humble source: Five ninth grade female students from Denmark, whose science experiment revealed that wireless radiation is equally as devastating to plants.

Undeniable results

The experiment began when the five students realized that they had difficulty concentrating in school if they slept near their mobile phones the previous night. Intrigued by this phenomenon, the students endeavored to study the effects of cellphone radiation on humans. Unfortunately, their school prevented them from pursuing this experiment due to a lack of resources, so the students decided to test the effects of Wi-Fi radiation (comparable in strength to cellphone radiation) on a plant instead.

The girls placed six trays of *Lepidium sativum* seeds (a garden cress grown commercially throughout Europe) in a room without radiation, and an equal amount in a room next to two Wi-Fi routers. Over a 12-day period, they observed, measured, weighed and photographed the results. Even before the 12th day arrived, however, the end results were obvious: The cress seeds placed near the routers either hadn't grown or were completely dead, while the seeds placed in the radiation-free room had blossomed into healthy plants.

The experiment earned the five students top honors in a regional science competition. Moreover, according to a teacher at their school, Kim Horsevad, a professor of neuroscience at the Karolinska Institute in Sweden was so impressed with the experiment that he is interested in repeating it in a controlled scientific environment.

You can help reduce your exposure to Wi-Fi radiation by following the advice in this article.

Radiation from WiFi connections can reduce sperm activity in up to a quarter of men, study finds

By DAILY MAIL REPORTER
UPDATED: 09:50 GMT, 1 December 2011

Working on a laptop wirelessly may hamper a man's chances of fatherhood.

In a study, sperm placed under a laptop connected to the internet through wi-fi suffered more damage than that kept at the same temperature but away from the wireless signal.

The finding is important because previous worries about laptops causing infertility have focused on the heat generated by the machines.

Radiation: It may be convenient, but using a laptop on your lap could be harming your sperm, say researchers (file picture)

In the latest study, researchers took sperm from 29 men aged 26 to 45 and placed them either under a wi-fi connected laptop or away from the computer.

The laptop then uploaded and downloaded information from the internet for four hours.

At the end of the experiment, 25 per cent of the sperm under the laptop had stopped moving and 9 per cent showed DNA damage.

By comparison, just 14 per cent of samples kept away from the wi-fi stopped moving. And just 3 per cent suffered DNA damage, the journal Fertility and Sterility reports.

The wireless connection creates electromagnetic radiation that damages semen, the scientists, from the United States and Argentina, believe.

Lead researcher Conrado Avendano, of Nascentis Medicina Reproductiva in Cordoba, said: 'Our data suggest that the use of a laptop computer wirelessly connected to the internet and positioned near the male reproductive organs may decrease human sperm quality.

'At present we do not know whether this effect is induced by all laptop computers connected by WiFi to the internet or what use conditions heighten this effect.'

A separate test with a laptop that was on, but not wirelessly connected, found negligible EM radiation from the machine alone.

The findings fuel concerns raised by a few other research teams.

Some have found that radiation from mobile phones creates feeble sperm in the lab, for example.

And last year urologists described how a man sitting with a laptop balanced on his knees can crank up the temperature of his scrotum to levels that aren't good for sperm.

So between the heat and the radiation from today's electronic devices, testicles would seem to be hard-pressed.

Concern: A quarter of sperm exposed to WiFi radiation in the study were no longer swimming around after four hours

However, Dr Robert Oates, the president of the Society for Male Reproduction and Urology, has managed to father two kids despite having both a laptop and an iPad.

He told Reuters Health he doesn't believe laptops are a significant threat to male reproductive health.

Remarking on the new study, he said: 'This is not real-life biology, this is a completely artificial setting.

'It is scientifically interesting, but to me it doesn't have any human biological relevance.'

He added that so far, no study has ever looked at whether laptop use has any influence on fertility or pregnancy outcomes.

'Suddenly all of this angst is created for real-life actual persons that doesn't have to be,' said Oates, also of Boston Medical Center.

He added: ‘I don’t know how many people use laptops on their laps anyway.’

According to the American Urological Association, nearly one in six couples in the U.S. have trouble conceiving a baby, and about half the time the man is at the root of the problem.

While the impact of modern technology is still murky, lifestyle does matter, researchers say.

Earlier this month, a report in Fertility And Sterility showed that men who eat a diet rich in fruit and grains and low in red meat, alcohol and coffee have a better shot at getting their partner pregnant during fertility treatment.

http://survincity.com/2010/07/the-effects-of-electromagnetic-waves-on-human/

The effects of electromagnetic waves on human health

There are many ways to classify the effects of electromagnetic radiation on health. Here we have to distinguish between biological changes (which are proved by experimental observations at the cellular level) and pathological effects (causing or worsening of disease) proved by epidemiological studies.

Effects of radiation on the list of health, presented here is actually just a small sample of large studies, reported in the present time in the scientific literature.

Pay attention!Links to articles, reports, studies, video reports on this topic can be found in the text material, and at the end.

Biological effects of electromagnetic radiation

Here are some of the biological changes according to research vyzvannyhelektromagnitnym radiation (first — the most recent data):

Protein changes in the skin.

Ten women volunteered to participate in the proposed study in which they were EMP (900 mH) via GSM mobile phones for one hour. After the experiment, scientists seized for investigation of skin cells in order to find any stress reactions. They investigated 580 different proteins and found two that were significantly affected. (He has been increased by 89%, while the other is reduced by 32%). Source — «NewScientist» on February 23, 2008.

Anomalies of development and quality of sperm.

Researchers at the Cleveland Clinic studied 361 male sperm quality, tested in the clinic issledoaniya fertility. On average, those who have spent many hours talking on the cell phone, showed a low sperm count, and increased rates of sperm abnormality. Source — «New Zealand Herald».

Irritation of brain cells.

Researchers from Fatebenefratelli Hospital in Isola Tiberina, found that elektromagnitnoepole emitted by cell phones can cause some cells in the cerebral cortex (adjacent to the side of the head where the phone is used) is strongly excited by the hour, while others become depressed. Source — «Health24» — June 27, 2006

DNA damage.

German research group Verum studied the effect of radiation on human and animal cells. After the cells were placed in the electromagnetic field of a cell phone — they showed an increase in the gap in their DNA that are not always able to be recovered. This damage can be passed on to future cells which, in turn, could develop into malignant tumors. Source — «USA Today», December 21, 2004

Damage to brain cells.

Study the effects of cell phone frequencies (applied at non-thermal intensity) on rat brain showed damage to neurons (brain cells) in different parts of the brain, including the cortex, hippocampus and the main ganglia. Source — Newsletter "Environmental Health Perspectives", June 2003

Aggressive growth of leukemia cells.

Researchers at the National Research Council in Bologna, Italy showed that leukemia

cells exposed to cell phone frequencies (900 mH) for 48 hours, have become more active breed. Source — «NewScientist» October 24, 2002

High blood pressure.
Researchers in Germany have found that a one-time use of a cell phone for 35 minutes could cause an increase in the normal blood pressure by 5-10 mm. Source — "Lancet", June 20, 1998

The adverse effects of electromagnetic radiation.
Here are some of the pathological (bolezneobrazuyuschih) effects vyzvannyeelektromagnitnym radiation, published in the media (in reverse chronological order):

Cancer of the salivary gland.
Israeli researchers report that people who used cell phones for 22 hours a month or more, up to 50 percent more likely to develop cancer slyunnoyzhelezy than those who used cell phones rarely or never used them. Source — «Health24», February 19, 2008

Brain Tumor.
The analysis of several previous studies led to the conclusion that the use of a cell phone for more than 10 years with an increased risk of acquisition of certain types of brain tumors (2.4 times for acoustic neuroma and 2 times for gliomas). Source — «News24», October 3, 2007

Lymphatic cancer and cancer of the bone marrow.
Researchers from the University of Tasmania and the University of Bristol studied the records of 850 patients who were diagnosed with cancers of the bone marrow and lymphatic system. They found that people living within 300 meters of high voltage power lines over a long period (especially a child), 5 times more at risk of developing these diseases later in life. Sources — "Journal of Internal Medicine", in September 2007, «Physorg.com», August 24, 2007

Miscarriage.
Researchers in California have found that electromagnetic radiation from electrical appliances (such as vacuum cleaners, hair dryers and mixers) can significantly increase the risk of miscarriage in women. Source — "Journal of Epidemiology", January 2002

Suicide.
American researchers have found that the growth rate of suicide among 5000 workers operating the technical facilities related to electricity, which had been exposed to very low frequencies, doubled compared to the results of the control group of the same size. The effect was particularly expressive of young workers. "Journal of Occupational and Environmental Medicine", March 15, 2000

In addition to the above — produced a lot of other studies, but not all of them got the attention of the media.

The list of diseases caused by exposure to electromagnetic radiation on health

Life-threatening Diseases
- Alzheimer disease
- Brain cancer (adult and child)
- Breast cancer (male and female)
- Depression (suicidal)
- Heart disease

- Leukemia (adult and child)
- Miscarriages

Other conditions:

- Allergies
- Autism
- Elevated blood pressure
- Electro-sensitivity
- Headaches
- Hormonal changes
- Damage to the immune system
- Damage to the nervous system
- Sleep Disorders
- Sperm abnormalities

How Does Amy?

Some scientists previously believed that the only way by which izlucheniemoglo produce harmful effects in its intensity was sufficient to cause the effect of heating tissue. (Previously, it was reported that talking on a cell phone for half an hour can raise the temperature in that part of the brain where the head came in contact with her staff). Subsequently, this theory has been roundly condemned by many studies, which proved that the intensity of the electromagnetic radiation is not enough to harm.

The mechanisms by which electromagnetic radiation can trigger the disease, is not yet fully understood, but actively conducting experiments on the subject.

DNA damage.

Our cells have mechanisms to partially compensate the damage caused to DNA, but, apparently, the EMR may violate these mechanisms. DNA damage is involved directly in the development of several diseases, including various types of cancer.

Protective antiviral mechanism of the host cell (interference) with the production of melatonin.

Electromagnetic radiation is introduced into the process of the production of melatonin, a hormone produced in the human body. We have already proved that low melatonin levels are associated with several diseases, including cancer. (Recent research indicates that the production of seratonin can also be affected by EMI).

The effect on cell-cell communication.

Our body cells communicate internally and externally through electric signals. These signals can be changed by electromagnetic radiation through the production of electrical currents within the body, causing changes in cellular activity and cell structures.

The harmful effects of electromagnetic radiation on health may depend on …

At this stage we do not have all the answers, but the tips of various studies indicate that the health effects of EMF may depend on:

The intensity of the radiation.

Getting into the zone of strong electromagnetic waves can be harmful, even if briefly. In one study of pregnant volunteers were asked to wear a device that measures the intensity of the highest (peak) for EMI day period. The results indicated that higher peak levels of RF correlated with higher rates of damage to health (miscarriage).

Cumulative effect of radiation.

During the day the person is exposed to electromagnetic radiation of different

frequencies. For example, they may come from electric shavers and hair dryers, the equipment of cars, buses or trains, household items such as heaters, ovens and microwaves, neon lamps, home wiring, power lines, carrying and using a cell phone. These are the most common sources.
The combination of these effects can overwhelm the body's defenses and defense mechanisms.

The duration of the EMP.

Numerous studies indicate that damage to health is beginning to be noticeable only after many years of exposure EMR, such as from power lines of high voltage, or cell phones.

Transience of EMF.

More biological stress from exposure to electromagnetic radiation the body is under the instruments, with volatile, fluctuating cycle (photocopier, printer, etc.), rather than in regular employment.

Frequency EMF.

So far, not known for certain what type of electromagnetic waves cause adverse health effects, but it seems to have different frequencies cause a variety of negative effects.

Signal interference.

To produce an analog or digital signal — electromagnetic wave can be modulated in various ways. Where waves are used for communication (eg, radio, television, mobile phone, etc.), the signal is applied to the frequency of the carrier. There is evidence that, in some cases, a component of the signal can be more harmful than the EMR support.

Medical EMR danger is real.

The danger to our health caused by high levels of man-made electromagnetic fields, is real. Such a general conclusion, many of the growing number of senior scientists and professional health care workers.
Fortunately, there are many ways to protect ourselves and our loved ones, before our health will be affected.
Now absolutely certain that electromagnetic fields can exert a negative influence on your health.
If you are still skeptical — please learn on this article (effects of EM radiation on human health).
Aware — is forearmed. If you know the risks and EMI protection strategies, then you can make the best choice for the health of you and your family.
If you can not follow all the recommendations below — make at least what you can.
In this case — it helps everything.

General Rule protection from EMI # 1

Reduce exposure to electromagnetic radiation, increasing your distance from the radiation.

This — the most important rule for EMP protection, and often the easiest to use.
How much to move away from the source of radiation — depending on its intensity. For example, to reduce the intensity of the field, you may have to move to a distance:
25 meters for power lines and cell phone towers.
30 see on your computer monitor
5 cm from the electric clock next to your pillow
2.5 cm from the cell phone

Many people realize that they can increase their level of security from EMI went away for a hundred meters away from power lines or cell phone towers, but few people think that in life, you can further protect themselves by placing the computer on the floor or move a TV yet away from themselves and their children.
To understand the safety distance for different kinds of devices, study**Now this document**, but keep in mind that your EMR devices may differ from those in this list. If you have the opportunity to use fluxmeter — better to take advantage of this opportunity.

General Rule Protection EMI number 2

If you can not avoid exposure to electromagnetic radiation, try to limit it.
For many may have long been commonplace — to watch a technician at work, go by and chat with colleagues around the office printers and copiers, or stand next to the oven while cooking dinner.
In all these cases, as in many others, for your health it would be better to apply Rule # 2.

General Rule EMP protection # 3

If there is no real need to include the device — turn it off (or on).
EMP is based on the many devices that people working unreasonable to leave, for example chargers (for batteries, cell phones, laptops, etc.), as well as computers in sleep mode, and printers.
Off devices also contributes to the health of the planet and your wallet.
You also have to know and remember all sources of electromagnetic radiation in their environment, at home or in the office. This might sound strange to the background of the general behavior, but this is the only responsible approach mature and well-informed person.
Explore and all major sources of EMR in your house or apartment.
Note the location of the building in which you live. Power lines at a distance greater than 400 meters — are unlikely to have seriously impact on your health. If this distance — less — we recommend you use flowmeters.
Local power lines (supply your home with electricity) can also cause significant electromagnetic radiation.
Note the distance from your home to the transformer substation buildings or engineering. Electromagnetic radiation from the local substation can come to a distance of 5-10 meters. Do not allow children to play in this area.
400 meters — the optimal distance to be safe from the effects of cell phone towers, you know that they are there in your area.
As long as you look around the area, pay attention to how far you are from the TV and radio antennas. They may have a much stronger radiation than cell towers.
Several studies have linked increased rates of cancer and leukemia with proximity to the TV antenna, especially a very large and powerful, which increases cancer, being located at a distance of 3-5 kilometers.
Unfortunately, there is no better protection than to apply Rule # 1
Protecting your home from EMI
The house / apartment, sources of EMR is the internal wiring of appliances and all kinds. Internal wiring is essential and one of the major sources of electromagnetic radiation, but

it is rarely people think. Some companies offer expertise in the presence of electromagnetic radiation in the apartments.

Radiation protection appliances

As for appliances, some very common types of household appliances rather high level of radiation. Put them on a long distance from the people, and remember that your communication with them should not be long.

For frequent or prolonged use any device — be it makes sense to find an alternative with lower EMI (such as a laptop or phone).

For example, portable hair dryers often have high levels of electromagnetic radiation, but if you use it for just 1 minute a day, then you are unlikely to be exposed to some seriously affected.

However, if you — a hairdresser, using a portable hair dryer for a total of about 60 minutes a day, then you should consider buying a dryer with low EMI. The same applies to the sewing machine.

Technique in the bedroom — or protection from EMI in the bedroom

Try to identify your personal exposure to electromagnetic radiation. Pay particular attention to the instruments and equipment that you encounter most often during the day. Start with your bedroom, because here you spend about 8 hours a day, so even a small level of EMR in your bedroom can significantly damage your health.

Turn off the electric blanket, if they do not need or use the lowest level of the adjustment. Keep electric clock / radio as far away from a sleeping person, preferably at a distance of 60 cm or more network devices. Even hours on batteries and a clock radio does not have to be next to your head.

Pay attention to the place where electricity is opened opened in your home and on the position of the main distribution box.

If it's in the bedroom, put the bed at a distance of not less than 1.5 meters from it. Magnetic part of the electromagnetic radiation easily penetrates through walls, so also think about what is on the other side of the wall.

Radiation protection cell phones.

Cell phones are becoming a major biological threat, almost weapon possibly as harmful as smoking. In order to reduce the negative impact — use alternative means of communication (land line) when a every opportunity.

Do not use cell phones for long conversations and think about others — do not keep them on the tube more than necessary.

We recommend using a headset, or a simple tool like a speakerphone. We do not notice, but we have is really enough situations where it is convenient to use.

The children, for their own health should be protected from cell phone use, because their developing brains are particularly vulnerable to EMP cell phones, and their skulls are thinner.

Experts recommend that children under 10 years do not use cell phones. Older children also need to be subject to strict guidelines on the use of phones.

Protection from electromagnetic radiation in the workplace.

If you spend a lot of time working in the office or at work, try to be at least 1.5 meters from any electrical equipment such as heaters and air conditioners, file servers or printers. Stick to the same distance from the neon wiring connections or nodes.

If you have been working on a computer — place it as far away from you (especially the

head) shall, if the cables. If possible, give preference to the LCD monitor instead of a CRT monitor. Also stay away as far as possible, and at a distance that allows the length of the cables.
If you have installed UPS — remember elektromagnitnoeobluchenie them much higher than the computer itself. Try putting these devices at a distance of 1.5 meters from you and other people.
It should take some effort once to optimize their living space, if you spend many hours every day in this environment.
Try to avoid the location or work in an environment that uses wireless devices — networks, Wi-Fi, cordless phones and modems. Do not flatter their supposed "security". Radio and microwave radiation is more dangerous than the low frequency.
Calculate your personal exposure to low-frequency waves.
Once you have implemented the above recommendations, it is necessary to check the level of daily low-frequency radiation to which you are exposed. This will help you understand where there is a big part of the EMP.
Tolerances for EMI, in our opinion, applies only to low-frequency radiation, but not to the radio and microwave EMF (which probably are dangerous at much lower levels.)
Constant exposure to ELF (ultra-low frequency, ie, <100 Hz) and VLF (very low frequency, ie, 100 Hz-10 kHz) waves at 1.0 milligaus considered safe. This would be equivalent to 24 milligaus / h (1.0 × 24) a day.
Our recommendation for an acceptable level of EMR slightly lower — 20 mg / hour.
To correctly perform this calculation, you have to add all the calculations EMR level from all sources.
For example, if you use a hair dryer (EMP force 100 milligausov obektaizlucheniya at distances of 30 cm) for 1 minute every morning — it's 100 milligausov / minute, or 1.67 milligausov / hour (100/60).
If you sleep for 8 hours next to the electric clock, the power of EMP effects on your head is 4 milligausa, you have accumulated 32 milligausa per hour (4 × 8) and have exhausted your allowable limit EMI before you got out of bed!
To calculate the impact of EMR in milligausah per hour (mg / hours):
Make a list of all devices that you use every day, along with the duration of exposure (in minutes).
Then calculate the value for each of these items on our chart by selecting the appropriate distance for each device.
Multiply the value in milligausahna number of minutes for each item. Summarize mg / min for all the items. Then divide the total by 60 to get the value milligaus / h.
Adapt the resulting overall result to the general factors, such as proximity to the lines elektoperedach**(See table)**, the trip, and any other known sources of ELF / VLF.
This method — somewhat crude tool in order to completely and correctly determine your level of exposure to low-frequency waves. But it helps you to see how much of the proceeds of electromagnetic radiation, and the final figure helps you evaluate your risks.
By calculating your total daily dose, try to make adjustments to your lifestyle, which can help minimize exposure. Start simple. (Remove the electric clock away from your pillow!)
In short, set attainable directly to you limit the resulting exposure, say 30 milligaus per hour. When you reach it, ask to split into two your exposure. Then you can figure out

what else can be done to further reduce this level.

Table EMP effect appliances
This table shows the approximate tlko for very low-frequency waves and the sub radiation. Devices such as mobile phones and microwave ovens are included in this tablitsutolko for the reason that they produce a significant low-frequency radiation as well as radio and micro wave izluenie (the latter not shown in table). This is about values. Your equipment may have several different values.

Electrical Equipment / Appliances	The strength of the electromagnetic field in the distance millig ausah

Anthropogenic radiofrequency electromagnetic fields as an emerging threat to wildlife orientation

Alfonso Balmori

- Consejería de Medio Ambiente, Junta de Castilla y León, C/ Rigoberto Cortejoso, 14, 47071 Valladolid, Spain

Received 5 January 2015, Revised 20 February 2015, Accepted 22 February 2015, Available online 4 March 2015

Highlights

•The growth of wireless telecommunication technologies causes increased electrosmog.

•Radio frequency fields in the MHz range disrupt insect and bird orientation.

•Radio frequency noise interferes with the primary process of magnetoreception.

•Existing guidelines do not adequately protect wildlife.

•Further research in this area is urgent.

Abstract

The rate of scientific activity regarding the effects of anthropogenic electromagnetic radiation in the radiofrequency (RF) range on animals and plants has been small despite the fact that this topic is relevant to the fields of experimental biology, ecology and conservation due to its remarkable expansion over the past 20 years. Current evidence indicates that exposure at levels that are found in the environment (in urban areas and near base stations) may particularly alter the receptor organs to orient in the magnetic field of the earth. These results could have important implications for migratory birds and insects, especially in urban areas, but could also apply to birds and insects in natural and protected areas where there are powerful base station emitters of radiofrequencies. Therefore, more research on the effects of electromagnetic radiation in nature is needed to investigate this emerging threat.

American Academy of Environmental Medicine

Electromagnetic and Radiofrequency Fields Effect on Human Health

For over 50 years, the American Academy of Environmental Medicine (AAEM) has been studying and treating the effects of the environment on human health. In the last 20 years, our physicians began seeing patients who reported that electric power lines, televisions and other electrical devices caused a wide variety of symptoms. By the mid 1990's, it became clear that patients were adversely affected by electromagnetic fields and becoming more electrically sensitive. In the last five years with the advent of wireless devices, there has been a massive increase in radiofrequency (RF) exposure from wireless devices as well as reports of hypersensitivity and diseases related to electromagnetic field and RF exposure. Multiple studies correlate RF exposure with diseases such as cancer, neurological disease, reproductive disorders, immune dysfunction, and electromagnetic hypersensitivity.

The electromagnetic wave spectrum is divided into ionizing radiation such as ultraviolet and X-rays and non-ionizing radiation such as radiofrequency (RF), which includes WiFi, cell phones, and Smart Meter wireless communication. It has long been recognized that ionizing radiation can have a negative impact on health. However, the effects of non-ionizing radiation on human health recently have been seen. Discussions and research of non-ionizing radiation effects centers around thermal and non-thermal effects. According to the FCC and other regulatory agencies, only thermal effects are relevant regarding health implications and consequently, exposure limits are based on thermal effects only.[1]

While it was practical to regulate thermal bioeffects, it was also stated that non-thermal effects are not well understood and no conclusive scientific evidence points to non-thermal based negative health effects.[1] Further arguments are made with respect to RF exposure from WiFi, cell towers and smart meters that due to distance, exposure to these wavelengths are negligible.[2] However, many *in vitro*, *in vivo* and epidemiological studies demonstrate that significant harmful biological effects occur from non-thermal RF exposure and satisfy Hill's criteria of causality.[3] Genetic damage, reproductive defects, cancer, neurological degeneration and nervous system dysfunction, immune system

dysfunction, cognitive effects, protein and peptide damage, kidney damage, and developmental effects have all been reported in the peer-reviewed scientific literature.

Genotoxic effects from RF exposure, including studies of non-thermal levels of exposure, consistently and specifically show chromosomal instability, altered gene expression, gene mutations, DNA fragmentation and DNA structural breaks.[4-11] A statistically significant dose response effect was demonstrated by Maschevich *et al*. , who reported a linear increase in aneuploidy as a function of the Specific Absorption Rate(SAR) of RF exposure.[11] Genotoxic effects are documented to occur in neurons, blood lymphocytes, sperm, red blood cells, epithelial cells, hematopoietic tissue, lung cells and bone marrow. Adverse developmental effects due to non-thermal RF exposure have been shown with decreased litter size in mice from RF exposure well below safety standards.[12] The World Health Organization has classified RF emissions as a group 2 B carcinogen.[13] Cellular telephone use in rural areas was also shown to be associated with an increased risk for malignant brain tumors. [14]

The fact that RF exposure causes neurological damage has been documented repeatedly. Increased blood-brain barrier permeability and oxidative damage, which are associated with brain cancer and neurodegenerative diseases, have been found.[4,7,15-17] Nittby *et al.* demonstrated a statistically significant dose-response effect between non-thermal RF exposure and occurrence of albumin leak across the blood-brain barrier.[15] Changes associated with degenerative neurological diseases such as Alzheimer's, Parkinson's and Amyotrophic Lateral Sclerosis (ALS) have been reported.[4,10] Other neurological and cognitive disorders such as headaches, dizziness, tremors, decreased memory and attention, autonomic nervous system dysfunction, decreased reaction times, sleep disturbances and visual disruption have been reported to be statistically significant in multiple epidemiological studies with RF exposure occurring non-locally.[18-21]

Nephrotoxic effects from RF exposure also have been reported. A dose response effect was observed by Ingole and Ghosh in which RF exposure resulted in mild to extensive degenerative changes in chick embryo kidneys based on duration of RF exposure.[24] RF emissions have also been shown to cause isomeric changes in amino acids that can result in nephrotoxicity as well as hepatotoxicity.[25]

Electromagnetic field (EMF) hypersensitivity has been documented in controlled and double blind studies with exposure to various EMF frequencies. Rea *et al*. demonstrated that under double blind placebo controlled conditions, 100% of subjects showed reproducible reactions to that frequency

to which they were most sensitive.[22] Pulsed electromagnetic frequencies were shown to consistently provoke neurological symptoms in a blinded subject while exposure to continuous frequencies did not.[23]

Although these studies clearly show causality and disprove the claim that health effects from RF exposure are uncertain, there is another mechanism that proves electromagnetic frequencies, including radiofrequencies, can negatively impact human health. Government agencies and industry set safety standards based on the narrow scope of Newtonian or "classical" physics reasoning that the effects of atoms and molecules are confined in space and time. This model supports the theory that a mechanical force acts on a physical object and thus, long-range exposure to EMF and RF cannot have an impact on health if no significant heating occurs. However, this is an incomplete model. A quantum physics model is necessary to fully understand and appreciate how and why EMF and RF fields are harmful to humans.[26,27] In quantum physics and quantum field theory, matter can behave as a particle or as a wave with wave-like properties. Matter and electromagnetic fields encompass quantum fields that fluctuate in space and time. These interactions can have long-range effects which cannot be shielded, are non-linear and by their quantum nature have uncertainty. Living systems, including the human body, interact with the magnetic vector potential component of an electromagnetic field such as the field near a toroidal coil.[26,28,29] The magnetic vector potential is the coupling pathway between biological systems and electromagnetic fields.[26,27] Once a patient's specific threshold of intensity has been exceeded, it is the frequency which triggers the patient's reactions.

Long range EMF or RF forces can act over large distances setting a biological system oscillating in phase with the frequency of the electromagnetic field so it adapts with consequences to other body systems. This also may produce an electromagnetic frequency imprint into the living system that can be long lasting.[26,27,30] Research using objective instrumentation has shown that even passive resonant circuits can imprint a frequency into water and biological systems.[31] These quantum electrodynamic effects do exist and may explain the adverse health effects seen with EMF and RF exposure. These EMF and RF quantum field effects have not been adequately studied and are not fully understood regarding human health.

Because of the well documented studies showing adverse effects on health and the not fully understood quantum field effect, AAEM calls for exercising precaution with regard to EMF, RF and general frequency exposure. In an era when all society relies on the benefits of electronics, we must find ideas and technologies that do not disturb bodily function. It is clear that the human body uses electricity from the chemical bond to the nerve impulse and obviously this orderly sequence can be

disturbed by an individual-specific electromagnetic frequency environment. Neighbors and whole communities are already exercising precaution, demanding abstention from wireless in their homes and businesses.

Furthermore, the AAEM asks for:

- An immediate caution on Smart Meter installation due to potentially harmful RF exposure.
- Accommodation for health considerations regarding EMF and RF exposure, including exposure to wireless Smart Meter technology.
- Independent studies to further understand the health effects from EMF and RF exposure.
- Recognition that electromagnetic hypersensitivity is a growing problem worldwide.
- Understanding and control of this electrical environmental bombardment for the protection of society.
- Consideration and independent research regarding the quantum effects of EMF and RF on human health.
- Use of safer technology, including for Smart Meters, such as hard-wiring, fiber optics or other non-harmful methods of data transmission.

Environmental Effects

I haven't seen two bees at any time on a flower since smart meters were installed in my city.

An ever-increasing number of studies, as well as much anecdotal evidence, points to the harm that wireless frequencies are causing to our environment. The combined effects of wireless radiation on pollinators (including bees and butterflies) and food plants, along with the degradation of our food supply caused by GMOs, are creating a perfect storm for the collapse of the food supply and of the world's ecosystems.

Since the installation of smart meters in Ann Arbor in 2012, I have seen almost no bees. The numbers were already dropping precipitously, and this seems to have been their death knell. That same year, almost no toads. Every year since, the numbers have been minimal. Starting in the summer of 2012, I found that the bugs that are tiny enough to fly through the holes in your window screens were no longer a problem. *Where did they all go?* I wondered, then realized it must be the smart meters. When I go walking Bird Hills Nature Area, I see thousands of flowers but only 0–7 insects during my half-hour walk. This was *not* the case prior to smart meter installation. This year, some of the plants are bearing almost no fruit—likely because the pollinators they require are gone.

Radiofrequency affects the ability of insects to navigate. Navigation systems are critical to the survival of birds, insects, and earthworms, to name just a few.

Here we present a *few* of the scientific studies. First, a word about the environmental community and smart meters.

The earth, bathed in the smart grid.
Nothing can escape it unless we act.

Environmentalists Speak Out

Whitney North Seymour, Jr.

Sadly, most of the environmental community is unaware of the harm caused by smart meters and other forms of wireless radiation. Nonetheless, a few environmentalists both groups and individuals, have taken a stand. The co-founder of the National Resources Defense Council, Whitney North Seymour, attorney, environmentalist, and former state senator, is one of them. Sadly, the organization he co-founded, the NRDC, has jumped on the false "smart meters are green" bandwagon.

See a video of Seymour speaking about smart meters.

Jonathan Libber

Former EPA attorney Jonathan Libber has taken a strong stand against the meters as president of Maryland Smart Meter Awareness. He points out our country's spotty record of figuring out environmental hazards before they're widespread. Libber was a skeptic at first. When a concerned neighbor approached him about the meters, Libber's response was, "Ah, some kind of stuff from California. Whatever. I initially was not that impressed." That would have been the end of it for Libber, except that a friend kept pressing him on the issue, eventually getting him to read about 150 pages of documents. That convinced him, and he joins the ranks of others, like Dr. Martin Blank of Columbia University and former Microsoft Canada president Frank Clegg in opposing the meters because of the harm they cause humans and the environment. Read more at the Baltimore Sun.

Linda Kurtz

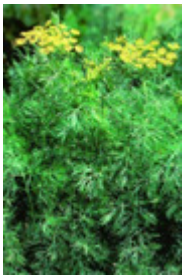
Says Linda Kurtz, head of the Smart Meter Education Network: “The larger environmental community likely has not come out against smart meters for a number of reasons. First, these meters—and all the other wireless devices—have been touted as ‘green’ and energy-saving. Nothing could be further from the truth, as we discuss on our page, “Do Smart Meters Really Save Energy? Secondly, the environmental community has not heard about the negative health and environmental impacts of wireless and digital technologies, mainly because information about these meters has largely been disseminated by conservative and libertarian groups that, in general, do not support the goals of and are not in communication with environmentalists. I feel very fortunate that I, as an environmentalist, have had the opportunity to learn about the negative consequences of these meters on our environment. Third, like most people, so many environmentalists are in love with these technologies and don’t want to give them up, no matter what harm they are causing to the environment. Therefore, they dismiss any reports they do receive about the meters. I have contacted a variety of environmental organizations about these meters. They have not even bothered to acknowledge my emails or phone calls. Finally, guess who sits on the boards of some of the largest environmental organizations? The very people who stand to make the most money from this technology. For instance, Wendy Schmidt, wife of the Google CEO, sits on the board of the NRDC. Ann Doerr, wife of venture capitalist John Doerr (who sits on Google’s board), serves on the board of the Environmental Defense Fund. I don't doubt these people’s commitment on one level, but it is a commitment that ends once their own personal pleasure or wealth is impacted.”

One of the few environmental groups that has taken a stand against smart meters is the San Francisco Sierra Club.

Plants

Scientific and Lay Studies on Effect of Microwave Frequencies on Plants

The first studies were by high school students and grade-schoolers. Now, scientists are weighing in.



Food Plants Affected by Microwave Radiation from Wireless Devices
A study published in the Journal of Plant Physiology finds that microwave irradiation of food plants results in thinner cell walls, smaller mitochondria and chloroplasts (both produce energy for plants), and enhanced emissions of volatile compounds. The frequencies studied are those emitted by smart meters, cell phones, wireless routers, and other devices. There was a direct relationship between microwave-induced structural and chemical modifications of the three plant species studied. Volatile compounds function as hormones, to repel predators, and to attract beneficial organisms. Read more...

Science Experiment by Grade-Schooler Shows That W-Fi Is Causing His Headaches and Deforms Growing Seeds

An eight-year-old boy in Almont, Michigan was getting severe headaches when seated near the wireless projector in his classroom. They were so severe, he would come home crying from the pain. When he was seated away from the projector, his headaches stopped. For many people, who are even more sensitive than he is, increased distance from wireless device

does not help, because the radiation is permeating the environment around them. See this series of pictures and explanations for more information.

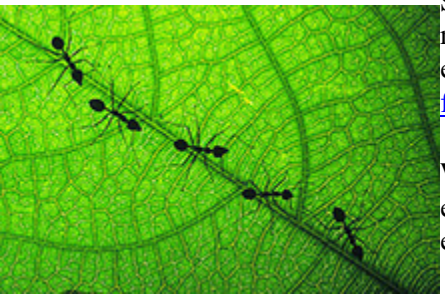
"I want to know why I get headaches when I'm around wireless devices but not the wires," Aiden Fitch says. "We use a laptop at home, and we have a television set, and it's only around wireless that I get the headaches." So Aiden did the same experiment a group of Danish high school students did last year. The Danes began the experiment with Read more...

Bees, Butterflies, and Other Insects

Bees

Study Links Bee Decline to Cell Phones. CNN Report - "Animals, including insects, use cryptochrome for navigation," Goldsworthy told CNN. "They use it to sense the direction of the earth's magnetic field and their ability to do this is compromised by radiation from [cell] phones and their base stations. So basically bees do not find their way back to the hive." Also look at this PDF file.

Honeybees' Behavior Changes When Exposed to RF.



Safe Land for Bees. Barrie Trower, retired British military intelligence officer and microwave warfare expert, asks, "Will the Communications Industry be the final straw for Our Planet's Ecosystems?"

Warning by Dr. Ulrich Warnke. The bioscientist Dr. Ulrich Warnke of Germany knows the electromagnetic workings of nature better than most. Dr. Warnke says: "Today, unprecedented exposure levels and intensities Read more...

Calcium Ions, Cytochrome P450, and the Relationships Between Wireless Radiation, Round-Up, the Decline of Bees and Other Insects, and Human Illness As you know from reading our Health page, calcium plays a critical role in neurotransmission. Studies are showing that glysophate, the main chemical in Round-up (widely used in GMO planting as well as by homeowners on their lawns), and wireless frequencies have the same effects on calcium ions, thus giving humans and bees a double whammy. Many people have reported a decline in insect populations Read more...

Ants

This study on ants regarding food collection and pheromones response showed that electromagnetic radiation causes ants to become confused and unable to collect food. Under the influence of electromagnetic radiation, ants followed trails for only short distances, no longer arrived at marked areas, no longer orientated themselves to a source of alarm pheromone, became unable to return to their nest and recruit congeners. Therefore, the number of ants collecting food increases only slightly and slowly. After 180 h of exposure, their colonies deteriorated.

Earthworms

Oxidative and genotoxic effects of 900 MHz electromagnetic fields in the earthworm. Significant DNA-damaging capacity of 900 MHz electromagnetic radiation. Results indicated the induction of antioxidant stress response in

terms of enhanced catalase and glutathione reductase activity as a result of the RF-EMF exposure, and demonstrated the generation of lipid and protein oxidative damage**.**

Birds

Department of the Interior: Cell Tower Microwave Radiation Has Negative Impact on Birds. Cell tower radiation has had negative impacts on the health of migratory birds and other wildlife, said the Department of the Interior, in a strongly worded letter dated February 7, 2014. "The electromagnetic radiation standards used by the Federal Communications Commission (FCC) continue to be based on thermal heating, a criterion now nearly 30 years out of date and inapplicable today."

The department noted that there is a growing level of anecdotal evidence showing harm to nesting and roosting wild birds and other wildlife from non-thermal, non-ionizing electromagnetic radiation from cell phone communication towers. Cell tower radiation is the same radiation as that emitted by smart meters. Read more...

Other Animals

Department of the Interior: Cell Tower Microwave Radiation Has Negative Impact on Animals. Cell tower radiation has had negative impacts on the health of migratory birds and other wildlife, said the Department of the Interior, in a strongly worded letter dated February 7, 2014. "The electromagnetic radiation standards used by the Federal Communications Commission (FCC) continue to be based on thermal heating, a criterion now nearly 30 years out of date and inapplicable today."

The department noted that there is a growing level of anecdotal evidence showing harm to nesting and roosting wild birds and other wildlife from non-thermal, non-ionizing electromagnetic radiation from cell phone communication towers. Cell tower radiation is the same radiation as that emitted by smart meters. The Interior Department criticized the federal government's proposed procedures for placement and operation of communication towers, and called for "independent, third-party peer-reviewed studies" in the U.S. to examine the effects of cell tower radiation on "migratory birds and other trust species." It said the FCC standards are no longer appropriate because they control only for overheating and do not protect organisms from the adverse effects of exposure to the low-intensity radiation produced by cell phones and cell towers.

The Interior Department's avers that the 30-year-old FCC standards are outmoded because it does not take into account the effects of lower levels of radiation output from microwave-powered communication devices such as cellular telephones and other sources of point-to-point communications (such as smart meters, which communicate point to point). It says that "very low levels of non-ionizing electromagnetic radiation" are a problem.

The letter from the Department of the Interior states in part: "There is a growing level of anecdotal evidence linking effects of non-thermal, non-ionizing electromagnetic radiation from communication towers on nesting and roosting wild birds and other wildlife in the U.S. Independent, third-party studies have yet to be conducted in the U.S. or Canada, although a peer-reviewed research protocol developed for the U.S. Forest Service by the Service's Division of Migratory Bird Management is available to study both collision and radiation impacts (Manville 2002). As previously mentioned, Balmori (2005) found strong negative correlations between levels of tower-emitted microwave radiation and bird breeding, nesting, and roosting in the vicinity of electromagnetic fields in Spain. He documented nest and site abandonment, plumage deterioration, locomotion problems, reduced survivorship, and death in House Sparrows, White Storks, Rock Doves, Magpies, Collared Doves, and other species.

Though these species had historically been documented to roost and nest in these areas, Balmori (2005) did not observe these symptoms prior to construction and operation of the cellular phone towers. Balmori and Hallberg (2007) and Everaert and Bauwens (2007) found similar strong negative correlations among male House Sparrows. Under laboratory 'conditions, DiCarlo et al. (2002) raised troubling concerns about impacts of low-level, non-thermal electromagnetic radiation from the standard 915 MHz cell phone frequency on domestic chicken embryos-with some lethal results (Manville 2009). Given the findings of the studies mentioned above, field studies should be conducted in North America to validate potential impacts of communication tower radiation—both direct and indirect —to migratory birds and other trust wildlife species."

Meta-Review of 46 Studies: Even the Lowest-Level Radiation Is Damaging to Human Health

Posted on November 19, 2012 by WashingtonsBlog

Even *Miniscule* Amounts of Radiation Can Be Dangerous

A major new scientific study proves that low-level radiation can cause huge health problems.

Science Daily reports:

> Even the very lowest levels of radiation are harmful to life, scientists have concluded in the Cambridge Philosophical Society's journal Biological Reviews. Reporting the results of a wide-ranging analysis of 46 peer-reviewed studies published over the past 40 years, researchers from the University of South Carolina and the University of Paris-Sud found that variation in low-level, natural background radiation was found to have small, but highly statistically significant, negative effects on DNA as well as several measures of health.
>
> The review is a meta-analysis of studies of locations around the globe ….
>
> "Pooling across multiple studies, in multiple areas, and in a rigorous statistical manner provides a tool to really get at these questions about low-level radiation."
>
> Mousseau and co-author Anders Møller of the University of Paris-Sud combed the scientific literature, examining more than 5,000 papers involving natural background radiation that were narrowed to 46 for quantitative comparison. The selected studies all examined both a control group and a more highly irradiated population and quantified the size of the radiation levels for each. Each paper also reported test statistics that allowed direct comparison between the studies.
>
> The organisms studied included plants and animals, but had a large preponderance of human subjects. Each study examined one or more possible effects of radiation, such as DNA damage measured in the lab, prevalence of a disease such as Down's Syndrome, or the sex ratio produced in offspring. For each effect, a statistical algorithm was used to generate a single value, the effect size, which could be compared across all the studies.
>
> The scientists reported **significant negative effects in a range of categories, including immunology, physiology, mutation and disease occurrence**. The frequency of negative effects was beyond that of random chance.
>
> ***
>
> When you do the meta-analysis, you do see significant negative effects."
>
> "It also provides evidence that **there is no threshold below which there are no effects of radiation**," he added. "A theory that has been batted around a lot over the last couple of decades is the idea that is there a threshold of exposure below which there are no negative consequences. These data provide fairly strong evidence that there is no threshold — radiation effects are measurable as far down as you can go, given the statistical power you have at hand."

> Mousseau hopes their results, which are consistent with the "linear-no-threshold" model for radiation effects, will better inform the debate about exposure risks.
> "With the levels of contamination that we have seen as a result of nuclear power plants, especially in the past, and even as a result of Chernobyl and Fukushima and related accidents, there's an attempt in the industry to downplay the doses that the populations are getting, because maybe it's only one or two times beyond what is thought to be the natural background level," he said. "But they're assuming the natural background levels are fine."
> "And the truth is, if we see effects at these low levels, then we have to be thinking differently about how we develop regulations for exposures, and especially intentional exposures to populations, like the emissions from nuclear power plants, medical procedures, and even some x-ray machines at airports."

(We will address below the question as to how most of us can remain healthy if even small doses of background radiation may be harmful.)

Numerous Other Studies Show the Danger of Low-Level Radiation

Indeed, the *overwhelming* consensus among radiation experts is that repeated exposure to low doses of radiation can cause cancer, genetic mutations, heart disease, stroke and other serious illness (and see this.)

The top government radiation experts – like Karl Morgan, John Goffman and Arthur Tamplin – and scientific luminaries such as Ernest Sternglass and Alice Stewart, concluded that low level radiation can cause serious health effects.

A 20-year study involving 110,000 workers who engaged in cleanup work related to the Chernobyl nuclear plant disaster in 1986 found that even low-level radiation causes a significant increase in the risk of leukemia.

A military briefing written by the U.S. Army for commanders in Iraq states:

> Hazards from low level radiation are long-term, not acute effects… Every exposure increases risk of cancer.

(Military briefings for commanders often contain less propaganda than literature aimed at civilians, as the commanders have to know the basic facts to be able to assess risk to their soldiers.)

The briefing states that doses are cumulative, citing the following military studies and reports:

- ACE Directive 80-63, ACE Policy for Defensive Measures against Low Level Radiological Hazards during Military Operations, 2 AUG 96
- AR 11-9, The Army Radiation Program, 28 MAY 99
- FM 4-02.283, Treatment of Nuclear and Radiological Casualties, 20 DEC 01
- JP 3-11, Joint Doctrine for Operations in NBC Environments, 11 JUL 00
- NATO STANAG 2473, Command Guidance on Low Level Radiation Exposure in Military Operations, 3 MAY 00
- USACHPPM TG 244, The NBC Battle Book, AUG 02

Many studies have shown that repeated exposures to low levels of ionizing radiation from CT scans and x-rays can cause cancer. See this, this, this. this, this, this, this, this, this and this.

Research from the University of Iowa concluded:

> Cumulative radon exposure is a significant risk factor for lung cancer in women.

And see these studies on the health effects cumulative doses of radioactive cesium.
As the European Committee on Radiation Risk notes:

> Cumulative impacts of chronic irradiation in low doses are … important for the comprehension, assessment and prognosis of the late effects of irradiation on human beings ….

And see this.
The New York Times' Matthew Wald reported in May:

> The Bulletin of the Atomic Scientists['] May-June issue carries seven articles and an editorial on the subject of low-dose radiation, a problem that has thus far defied scientific consensus but has assumed renewed importance since the meltdown of the Fukushima Daiichi reactors in Japan in March 2011.
> ***
> This month a guest editor, Jan Beyea [who received a PhD in nuclear physics from Columbia and has served on a number of committees at the National Research Council of the National Academies of Science] and worked on epidemiological studies at Three Mile Island, takes a hard look at the power industry.
> The bulletin's Web site is generally subscription-only, but this issue can be read at no charge.
> Dr. Beyea challenges a concept adopted by American safety regulators about small doses of radiation. The prevailing theory is that the relationship between dose and effect is linear – that is, that if a big dose is bad for you, half that dose is half that bad, and a quarter of that dose is one-quarter as bad, and a millionth of that dose is one-millionth as bad, with no level being harmless.
> The idea is known as the "linear no-threshold hypothesis,'' and while most scientists say there is no way to measure its validity at the lower end, applying it constitutes a conservative approach to public safety.
> Some radiation professionals disagree, arguing that there is no reason to protect against supposed effects that cannot be measured. But **Dr. Beyea contends that small doses could actually be disproportionately worse.**
> Radiation experts have formed a consensus that if a given dose of radiation delivered over a short period poses a given hazard, that hazard will be smaller if the dose is spread out. To use an imprecise analogy, if swallowing an entire bottle of aspirin at one sitting could kill you, consuming it over a few days might merely make you sick.
> In radiation studies, this is called a dose rate effectiveness factor. Generally, a spread-out dose is judged to be half as harmful as a dose given all at once.
> ***
> **Dr. Beyea, however, proposes that doses spread out over time might be more dangerous than doses given all at once. [Background] He suggests two reasons: first, some effects may result from genetic damage that manifests itself only after several generations of cells have been exposed, and, second, a "bystander effect," in which a cell absorbs radiation and seems unhurt but communicates damage to a neighboring cell, which can lead to cancer.**
> One problem in the radiation field is that **little of the data on hand addresses the problem of protracted exposure**. Most of the health data used to estimate the

health effects of radiation exposure comes from survivors of the Hiroshima and Nagasaki bombings of 1945. That was mostly a one-time exposure.

Scientists who say that this data leads to the underestimation of radiation risks cite another problem: **it does not include some people who died from radiation exposure immediately after the bombings.** The notion here is that the people studied in ensuing decades to learn about the dose effect may have been stronger and healthier, which could have played a role in their survival.

Still, the idea that the bomb survivor data is biased, or that stretched-out doses are more dangerous than instant ones, is a minority position among radiation scientists.

Dr. Beyea writes:

Three recent epidemiologic studies suggest that the risk from protracted exposure is no lower, and in fact may be higher, than from single exposures.

***

Conventional wisdom was upset in 2005, when an international study, which focused on a large population of exposed nuclear workers, presented results that shocked the radiation protection community—and foreshadowed a sequence of research results over the following years.

***

It all started when epidemiologist Elaine Cardis and 46 colleagues surveyed some 400,000 nuclear workers from 15 countries in North America, Europe, and Asia—workers who had experienced chronic exposures, with doses measured on radiation badges (Cardis et al., 2005).

***

This study revealed a higher incidence for protracted exposure than found in the atomic-bomb data, representing a dramatic contradiction to expectations based on expert opinion.

***

A second major occupational study appeared a few years later, delivering another blow to the theory that protracted doses were not so bad. This 2009 report looked at 175,000 radiation workers in the United Kingdom ….

After the UK update was published, scientists combined results from 12 post-2002 occupational studies, including the two mentioned above, concluding that protracted radiation was **20 percent more effective in increasing cancer rates than acute exposures** (Jacob et al., 2009). The study's authors saw this result as a challenge to the cancer-risk values currently assumed for occupational radiation exposures. That is, they wrote that the radiation risk values used for workers should be increased over the atomic-bomb-derived values, not lowered by a factor of two or more.

***

In 2007, **one study—the first of its size—looked at low-dose radiation risk in a large, chronically exposed civilian population**; among the epidemiological community, this data set is known as the "Techa River cohort." From 1949 to 1956 in the Soviet Union, while the Mayak weapons complex dumped some 76 million cubic meters of radioactive waste water into the river, approximately 30,000 of the off-site population—from some 40 villages along the river—were

> exposed to chronic releases of radiation; residual contamination on riverbanks still produced doses for years after 1956.
> ***
> Here was a study of citizens exposed to radiation much like that which would be experienced following a reactor accident. About 17,000 members of the cohort have been studied in an international effort (Krestinina et al., 2007), largely funded by the US Energy Department; and to many in the department, this study was meant to definitively prove that protracted exposures were low in risk. **The results were unexpected**. The slope of the LNT fit turned out to be higher than predicted by the atomic-bomb data, providing additional evidence that protracted exposure does not reduce risk.
> ***
> In a 2012 study on atomic-bomb survivor mortality data (Ozasa et al., 2012), l**ow-dose analysis revealed unexpectedly strong evidence for the applicability of the supralinear theory**. From 1950 to 2003, more than 80,000 people studied revealed high risks per unit dose in the low-dose range, from 0.01 to 0.1 Sv.

A major new study of atomic bomb data by the official joint U.S.-Japanese government study of the Hiroshima and Nagasaki survivors found that low dose radiation causes cancer and genetic damage:

And Dr. Peter Karamoskos notes:

> The most comprehensive study of nuclear workers by the IARC, involving **600,000 workers** exposed to an average cumulative dose of 19mSv, showed a cancer risk consistent with that of the A-bomb survivors.

It's not just humans: scientists have found that animals receiving low doses of radiation from Chernobyl are sick as well.

Ignore the Voodoo Science Pushers

If radiation is so dangerous, why do government and nuclear energy officials pretend that radiation is harmless?

Because governments have been covering up the danger of radiation for 67 years in order to protect the nuclear arms and nuclear energy industries.

But If Naturally-Occurring Radiation Is Bad For Us, Why Are Most of Us Healthy?

If background radiation is harmful, how have so many people remained healthy?

Initially – as we have previously pointed out – there was *no* background radioactive cesium or iodine before above-ground nuclear testing and nuclear accidents started.

Wikipedia provides some details on the distribution of cesium-137 due to human activities:

> Small amounts of caesium-134 and caesium-137 were released into the environment during nearly all nuclear weapon tests and some nuclear accidents, most notably the Chernobyl disaster.
> ***
> **Caesium-137 is unique in that it is totally anthropogenic**. Unlike most other radioisotopes, caesium-137 is not produced from its non-radioactive isotope, but from uranium. **It did not occur in nature before nuclear weapons testing began**. By observing the characteristic gamma rays emitted by this isotope, it is possible to determine whether the contents of a given sealed container were made

> before or after the advent of atomic bomb explosions. This procedure has been used by researchers to check the authenticity of certain rare wines, most notably the purported "Jefferson bottles".

As the EPA notes:

> Cesium-133 is the only naturally occurring isotope and is non-radioactive; all other isotopes, including cesium-137, are produced by human activity.

Likewise, iodine-131 is not a naturally occurring isotope. As the Encyclopedia Britannica notes:

> The only naturally occurring isotope of iodine is stable iodine-127. An exceptionally useful radioactive isotope is iodine-131…

(Fukushima has spewed much more radioactive cesium and iodine than Chernobyl. Fukushima is still spewing radiation into the environment, and the amount of radioactive fuel at Fukushima dwarfs Chernobyl.)

As such, the concept of "background radiation" is largely a misnomer. Most of the radiation we encounter today – especially the most dangerous types – did not even exist in nature before we started tinkering with nuclear weapons and reactors. In a sense, we are all guinea pigs.

Moreover, internal emitters – radioactive particles which end up inside of our lungs or gastrointestinal track, as opposed to radiation which comes to us from outside of our skin – are *much* more dangerous than general exposures to radiation. See this, this, this and this.

For example, the head of a Tokyo-area medical clinic – Dr. Junro Fuse, Internist and head of Kosugi Medical Clinic – said recently:

> Risk from internal exposure is **200-600 times greater** than risk from external exposure.

There are few *natural* high-dose internal emitters. Bananas, brazil nuts and some other foods contain radioactive potassium-40, but in *extremely low* doses.

True, some parts of the country are at higher risk of exposure to naturally-occurring radium than others.

But the cesium which was scattered all over the place by above-ground nuclear tests and the Chernobyl and Fukushima accidents has a much longer half life, and can easily contaminate food and water supplies. As the New York Times noted recently:

> Over the long term, the big threat to human health is cesium-137, which has a half-life of 30 years.
>
> At that rate of disintegration, John Emsley wrote in "Nature's Building Blocks" (Oxford, 2001), "it takes over 200 years to reduce it to 1 percent of its former level."
>
> It is cesium-137 that still contaminates much of the land in Ukraine around the Chernobyl reactor.
>
> ***
>
> Cesium-137 mixes easily with water and is chemically similar to potassium. It thus mimics how potassium gets metabolized in the body and can enter through many foods, including milk.

As the EPA notes in a discussion entitled " What can I do to protect myself and my family from cesium-137?":

> Cesium-137 that is dispersed in the environment, like that from atmospheric

testing, is impossible to avoid.

Radioactive iodine can also become a potent internal emitter. As the Times notes:

> Iodine-131 has a half-life of eight days and is quite dangerous to human health. If absorbed through contaminated food, especially milk and milk products, it will accumulate in the thyroid and cause cancer.

The bottom line is that there is some naturally-occurring background radiation, which can – at times – pose a health hazard (especially in parts of the country with high levels of radioactive radon or radium).

But cesium-137 and radioactive iodine – the two main radioactive substances being spewed by the leaking Japanese nuclear plants – are not naturally-occurring substances, and can become powerful internal emitters which can cause tremendous damage to the health of people who are unfortunate enough to breathe in even a particle of the substances, or ingest them in food or water.

Unlike low-levels of radioactive potassium found in bananas – which our bodies have adapted to over many years – cesium-137 and iodine 131 are brand new, extremely dangerous substances.

And unlike naturally-occurring internal emitters like radon and radium – whose distribution is largely concentrated in certain areas of the country – radioactive cesium and iodine are being distributed globally through weapons testing and nuclear accidents.

The Aversive Effect of Electromagnetic Radiation on Foraging Bats—A Possible Means of Discouraging Bats from Approaching Wind Turbines

Barry Nicholls*, Paul A. Racey

School of Biological Sciences, University of Aberdeen, Aberdeen, United Kingdom

Abstract

Large numbers of bats are killed by collisions with wind turbines and there is at present no accepted method of reducing or preventing this mortality. Following our demonstration that bat activity is reduced in the vicinity of large air traffic control and weather radars, we tested the hypothesis that an electromagnetic signal from a small portable radar can act as a deterrent to foraging bats. From June to September 2007 bat activity was compared at 20 foraging sites in northeast Scotland during experimental trials (radar switched on) and control trials (no radar signal). Starting 45 minutes after sunset, bat activity was recorded for a period of 30 minutes during each trial and the order of trials were alternated between nights. From July to September 2008 aerial insects at 16 of these sites were sampled using two miniature light-suction traps. At each site one of the traps was exposed to a radar signal and the other functioned as a control. Bat activity and foraging effort per unit time were significantly reduced during experimental trials when the radar antenna was fixed to produce a unidirectional signal therefore maximising exposure of foraging bats to the radar beam. However, although bat activity was significantly reduced during such trials, the radar had no significant effect on the abundance of insects captured by the traps.

Introduction

The UK government is committed to ensure that 10% of the country's electricity will be generated from renewable sources by 2010 with an aspiration to double this figure by 2020. Unfortunately the drive to ameliorate the indirect impact of energy production on the environment has led to a more immediate impact on local fauna. The exploitation of wind as a renewable and pollution-free source of energy has led to the proliferation of wind farms across the UK where 206 are currently operational, comprising 2381 turbines and with an estimated 444 sites proposed for future development [1]. Several studies have highlighted the problem of birds colliding with turbines placed along traditional migratory routes [2–6] but until recently the impact of wind turbines on bats has received little attention.

The scale of the problem became apparent in 2004 when, during a six-week period, an estimated 1,764 and 2,900 bat fatalities were recorded at two wind farms in Pennsylvania and West Virginia respectively [7]. The number of collision mortalities reported in America are greater than in Europe, where surveys have begun more recently. However, 15 of the 35 species of European bat have been recorded as regular victims of turbine collisions, and an Intersessional Working Group of Eurobats listed 20 species thought to be at risk of collision due to their foraging and commuting behaviour [8]. Currently, research in Europe is concentrated on arriving at scientifically credible mortality estimates to assess the extent of the problem. Although this is clearly important, the rapid proliferation of wind turbines requires a more urgent response. Research has to be focussed on the underlying reasons behind these collisions and potential methods of mitigation to prevent what is undoubtedly an increasing threat to bat populations.

Attempts at mitigating bird collisions with wind turbines have typically involved the application of visual stimuli to increase the conspicuousness of the turbine blades [9,10], but for bats, where audition is the primary sensory modality, this is clearly not appropriate. The design of an acoustic deterrent for bats, as used to mitigate cetacean entanglement in drift nets [11–13], is complicated by the intrinsic properties of ultrasound, which attenuates rapidly in air [14]. Despite this inherent problem, a recent study [15] revealed a significant aversive response by big brown bats (*Eptesicus fuscus*) following exposure to broadband white noise in a laboratory. However, when an acoustic deterrent was deployed at a wind farm in New York State, USA, results were more equivocal, and researchers concluded that the acoustic envelope of the deterrent system was probably not large enough to consistently deter the activity of bats within the large volume of the rotor-swept zone [16].

A more promising solution is offered by curtailing the operations of wind turbines during high-risk periods. A substantial portion of bat fatalities at operating wind farms occurs during relatively low-wind conditions during the bat migration period

[17]. Some curtailment of turbine operations during these conditions, and during this period, has been proposed as a possible means of reducing impacts to bats [17,18]. Recent results from studies in Canada [19] and North America [20] indicate that changing turbine "cut-in speed" (i.e., the wind speed at which wind generated electricity enters the power grid) from the customary 3.5–4.0 m/s, on modern turbines, to 5.5 m/s, resulted in at least a 50% reduction in bat fatalities. This requires considerable cooperation on behalf of the project operators as curtailing turbine operations, even on a limited basis, clearly poses operational and economic restrictions resulting in some loss of revenue. This method does however offer a promising solution, particularly in areas where it has been proven that bat mortalities occur over a clearly defined and restricted time period. It is not yet clear whether this method of mitigation will prove sufficiently feasible and effective at reducing impacts to bats at costs that are acceptable to companies that operate wind energy facilities. Therefore, given the problems associated with the existing proposed methods of mitigation it is essential to investigate all other alternatives.

It has been suggested that the radio frequency (RF) radiation associated with radar installations could potentially exert an aversive behavioural response in foraging bats [21]. In 2006 Nicholls and Racey recorded bat activity along an electromagnetic gradient at ten radar installations throughout Scotland. Their results revealed that bat activity and foraging effort per unit time were significantly reduced in habitats exposed to an electromagnetic field (EMF) strength of greater than 2v/m when compared to matched sites registering EMF levels of zero. Even at sites with lower levels of EMF exposure ($<$2v/m), bat activity and foraging effort was significantly reduced in comparison to control sites.

Ahlén *et al.* [22] also reported anecdotal evidence that bats foraging offshore in Sweden avoided an area around Utgrunden lighthouse where a powerful radar was in permanent operation. However, although it has been demonstrated that large air traffic control and weather radars appear to exert an aversive response on foraging bats [21], this has little practical application in preventing bats from colliding with turbine blades. It is therefore necessary to establish whether a deterrent effect can be replicated with a small, portable radar system. It is also possible that the electromagnetic radiation from the radar may not be affecting bats directly but rather the insects upon which they feed. Bat activity within an area is strongly correlated with insect density [23,24] therefore any reduction in insect density would result in a concurrent reduction in bat activity. In order to provide an efficient deterrent it is necessary to determine whether any observed reduction in bat activity is a direct result of exposure to electromagnetic radiation or an indirect result of a localised reduction in insect density.

Therefore the aims of the present study were to test the following hypotheses:

(1) Bat activity will be reduced following exposure to a pulsed electromagnetic signal from a small portable radar unit.

(2) The abundance of aerial insects will be reduced following exposure to a pulsed electromagnetic signal from a small portable radar unit.

Materials and Methods

Study sites and sampling protocol

In Britain, foraging bats are predominantly associated with areas where insect density is high: broadleaved woodland, particularly woodland edge, linear vegetation (tree lines and hedgerows) and riparian habitat. More open and intensively managed areas are avoided. In order to assess the impact of radar on foraging bats it was important to locate foraging sites with a high level of bat activity. Using existing knowledge obtained from detailed radio telemetry projects [25] in conjunction with extensive acoustic surveys, 20 foraging sites, with a high and consistent level of bat activity, were selected. All foraging sites were located within a 100 km radius of Aberdeen in northeast Scotland (latitude 57°23' N, longitude 02°45' W) and were separated by a minimum straight-line distance of $>$1 km to ensure independence. Twelve of these sites were located within riparian habitats (small ponds, rivers and streams) and the remainder along the edge of woodland where the radar signal would not be attenuated by any obstruction.

The radar used throughout the study was a Furuno FR - 7062 X-band marine radar (peak power 6 kW, beamwidth: horizontal $-1.9°$, vertical $-22°$, rotation 24 rpm or 48 rpm) with a slotted waveguide array antenna (1.2 m) capable of transmitting at pulse lengths of 0.08 μs–0.8 μs depending on the range selected. At each site the radar antenna was placed on a platform 2 m above ground level, such that the core area of bat activity was directly in line with the radar beam. At each foraging site a control (no radar signal) and experimental trial (radar switched on) were carried out. Starting 45 minutes after sunset, bat activity was recorded for a period of 30 minutes during each trial and the order of trials were alternated between nights. To avoid pseudoreplication, recordings were carried out only once at each of the 20 sites.

As in most radar systems, the antenna of the radar usually swept through 360 degrees. For the current experiment this would reduce the extent of exposure along any radius. Therefore the experiment was repeated with the antenna of the radar fixed such that the radar signal was orientated directly towards the area of highest bat activity. Similarly the duration of exposure to the radar signal is dependent on the duty cycle of the radar transmitter (pulse length×pulse repetition frequency). Therefore the experiment was repeated at each site using two different pulse length/pulse repetition rates (0.08 μs/2100 Hz, 0.3 μs/1200 Hz,) with the radar antenna fixed to maximise exposure. A portable electromagnetic field meter (PMM 8053-Accelonix Ltd.) and isotropic field probe (EP-330 Isotropic E-Field probe-Accelonix Ltd.) were used to measure the maximum value (peak hold) of the electromagnetic field strength (EMF) of the radar in volts per metre (v/m) at three distances from the radar antenna (10, 20, 30 m) for each of the two radar settings implemented throughout the study.

Bat activity recording

At each foraging site bat activity was recorded at three distances from the radar antenna (10, 20, 30 m) using automatic bat-recording stations [26]. Each automatic station consisted of a Batbox III heterodyne bat detector (Stag Electronics, Sussex, UK) linked to a count data logger (Gemini Data Loggers, UK Ltd, Chichester, UK) via an analogue to digital signal converter (Skye instruments, Ltd). The signal converter converts analogue signals from the bat detector into digital signals that can be recorded by the data logger. Every 0.5 seconds a positive or negative signal is sent to the data logger indicating the presence or absence of ultrasound respectively. Therefore the recorded number of bat active half seconds referred to as 'bat counts' over a thirty-minute trial provides a quantitative index of bat activity during that period. Most narrowband detectors will detect a range of frequencies centred on the value shown on the tuning dial. For the Batbox III this window is$\pm$8 kHz of the tuned frequency, therefore the frequency was set to 50 khz in order to effectively

detect each of the 5 breeding species of bat in Scotland (*Pipistrellus pipistrellus*, *Pipistrellus pygmaeus*, *Myotis daubentonii*, *Myotis nattereri* and *Plecotus auritus*). The component parts of the system were housed in large plastic boxes with a hole cut for the bat detector microphones. Automatic recording stations were positioned on platforms 1.5 m above the ground and orientated perpendicular to the radar signal (Fig. 1).

In conjunction with the automatic recording stations bat activity was recorded continuously during each trial using a frequency division bat detector (S-25, Ultrasound Advice, London). This method of ultrasound transformation allows calls to be recorded in real time on audiocassettes and the number of recorded passes provides a quantitative assessment of bat activity Bat detectors were linked to a tape recorder (Sony Professional Walkman, Tokyo, WMD6C) containing metal-tape cassettes. At each site the bat detector was placed at a distance of 20 m from the radar antenna and the height and direction remained constant at 70 cm. The 60 minutes recording at each site were analysed using BatSound software (BatSound Pro, Pettersson Elektronic AB, Uppsala Sweden). In addition to the total number of bat passes, terminal feeding buzzes at each site were counted. These characteristic sounds are produced by aerial hunting and trawling vespertilionid bats when prey capture is attempted [27] and can be used to quantify foraging activity within a site. Foraging rate is expressed as the ratio of terminal buzzes to bat passes; this feeding buzz ratio (FBR) provides a measure of foraging intensity per unit of flight activity [28]. The use of frequency division detectors also allowed accurate species identification at each site.

Insect Abundance

From July to September 2008 aerial insects were sampled using two identical Pirbright-Miniature light-suction traps (PMLT) [29] equipped with 8 W UV light bulbs. Each trap operated at 220 V transformed to 12 V to run from a car battery. At the base of each trap was a water-filled collecting vessel containing 2–3 drops of detergent. Most large insects were excluded by a large-mesh screen immediately above the fan and below the light bulb. The traps were deployed at 16 of the 20 foraging sites described above and were switched on for one hour prior to sunset. At each site the traps were positioned approximately 40 m apart with their trap inlets 2 m above ground level. On each sampling night the radar antenna was positioned on a platform 2 m above ground level and 10 m from one of the traps such that the antenna was orientated directly towards the trap inlet and fixed to produce a unidirectional signal. The second trap was positioned perpendicular to the radar beam to prevent any potential exposure to electromagnetic radiation and left to function as a control. To avoid any potential bias the selection of traps used as the control was alternated each night. The parameters of the radar tested were identical to those described above (Pulse length/pulse repetition rate: 0.08 μs/2100 Hz; 0.3 μs/1200 Hz,) no test was carried out with the antenna rotating.

Immediately following sampling, the insect catch was transferred from the collecting column into a 70% ethanol in water solution using a fine brush. Insects were then counted using a dissecting microscope (×30). Any insects with wingspans exceeding 20 mm were removed from the catch, as they would exceed the range of insect sizes captured by the species recorded throughout the study [30]. Following counting and sorting, the dry mass of insects was recorded by drying the samples in an oven until a constant mass was achieved (21 h).

Statistical analysis

Differences in bat activity (bat counts and bat passes), bat foraging activity (feeding buzz ratios) and insect abundance between experimental and control trials were analysed using paired t tests. To account for multiple comparisons in paired t tests, we applied a manual Bonferroni correction (*P*-values×number of comparisons). However since the application of the Bonferroni correction increases the risk of making more type II errors, i.e. not recognising

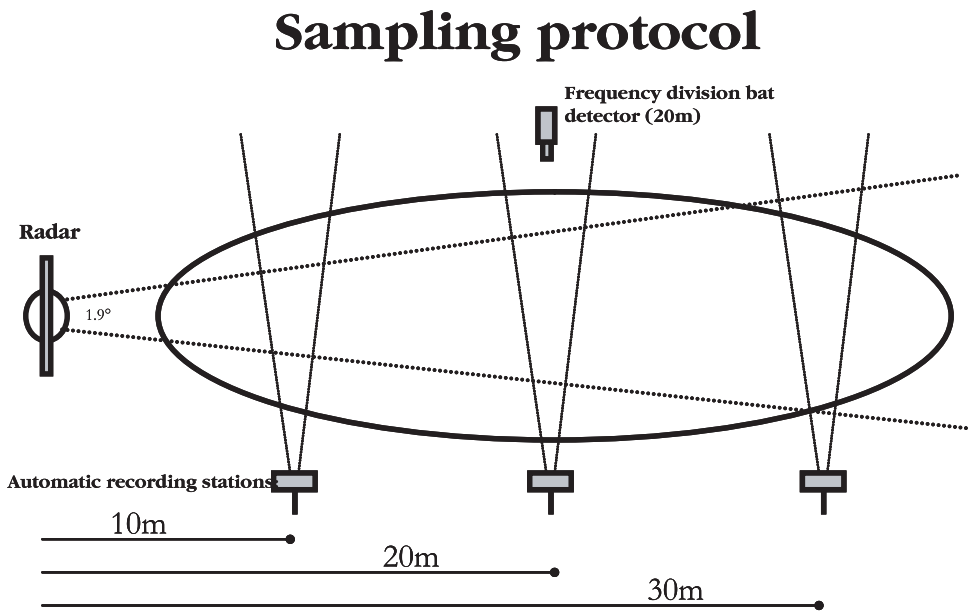

Figure 1. Sampling protocol of experimental trials carried out at 20 independent sites from July to September 2007. At each site bat activity was recorded for 1 h at three distances from the radar antenna (10,20,30 m) using three automatic bat recording stations orientated perpendicular to the radar beam. A frequency division bat detector was positioned 20 m from the radar antenna to provide further information on bat foraging activity during this period.

Results

Bat activity

Experimental trials were carried out during 58 nights from July 2007 till September 2007 representing a total of 58 hours of recording data within the following parameters:

1. Rotating antenna – pulse length/pulse repetition rate (0.08 μs/2100 Hz) – 20 h
2. Fixed antenna – pulse length/pulse repetition rate (0.08 μs/2100 Hz) – 20 h
3. Fixed antenna – pulse length/pulse repetition rate (0.3 μs/1200 Hz) – 18 h

The maximum value (peak hold) of the electromagnetic field strength within these parameters is shown in Table 1. Field strength diminished slightly with increasing distance from the antenna under all radar parameters. However when the radar antenna was fixed to emit a unidirectional signal a fourfold increase in field strength was observed at all distances (Table 1).

The three automatic stations recorded a total of 102,810 bat counts during 58 h of recording (Table 2). No significant difference was observed in the number of bat counts recorded between automatic stations positioned at 10, 20 and 30 m from the radar antenna (ANOVA, rotating antenna with pulse length 0.08 μs: $P = 0.57$; fixed antenna with pulse length 0.08 μs: $P = 0.64$; fixed antenna with pulse length 0.3 μs $P = 0.68$) therefore all further tests were carried out on the average of these three values. A further 53,731 bat passes were recorded with the frequency division detector (Table 2). As expected, the majority of passes (84%) were attributed to the two cryptic pipistrelle species: *Pipistrellus pygmaeus* and *P. pipistrellus* (51% and 33% respectively) which are the most common and abundant bats in Scotland. A further 16% of bat passes were attributed to *Myotis daubentonii*.

Total bat activity was invariably higher during the control trials when compared to experimental trials (Table 2). However paired t tests carried out on all indices of bat activity (bat counts, bat passes, feeding buzz ratios) revealed no significant difference in bat activity between control and experimental trials when exposed to a short pulse length (0.08 μs) radar signal from a rotating antenna (bat counts: $t = 1.50$; $P = 0.151$; $P_{\text{Bonferroni}} = 0.453$; Fig. 2a. Bat passes: $t = 1.89$; $P = 0.074$; $P_{\text{Bonferroni}} = 0.222$; Fig. 3a. FBR: $t = 1.80$; $P = 0.088$; $P_{\text{Bonferroni}} = 0.264$; Fig. 4a). Paired t tests carried out on all indices of bat activity (bat counts, bat passes, feeding buzz ratios) showed that bats were significantly less active during experimental trials than during control trials when exposed to a short pulse length (0.08 μs) radar signal from a fixed antenna (bat counts: $t = 2.87$; $P = 0.010$; $P_{\text{Bonferroni}} = 0.030$; Fig. 2b. Bat passes: $t = 2.54$; $P = 0.020$; $P_{\text{Bonferroni}} = 0.060$; Fig. 3b. FBR: $t = 3.82$; $P = 0.001$; $P_{\text{Bonferroni}} = 0.003$; Fig. 4b). However, following Bonferroni correction the difference in the number of bat passes between experimental and control trials was no longer significant. Bats were also significantly less active during experimental trials than during control trials when exposed to a medium pulse length (0.3 μs) radar signal from a fixed antenna (bat counts: $t = 3.95$; $P = 0.001$; $P_{\text{Bonferroni}} = 0.003$; Fig. 2c. Bat passes: $t = 3.69$; $P = 0.002$; $P_{\text{Bonferroni}} = 0.006$; Fig. 3c. FBR: $t = 6.78$; $P < 0.001$; $P_{\text{Bonferroni}} = 0.003$; Fig. 4c). A summary of these results is presented in Table 3.

Insect Abundance

Experimental trials were carried out during 32 nights from July 2008 till September 2008 representing a total of 32 hours of recording data within the following parameters:

Table 2. Total numbers of bat counts, bat passes and feeding buzzes recorded within treatment and control trials during 58 h of recording.

Index of bat activity	Rotating antenna (0.08 μs/2100 Hz)		Fixed antenna (0.08 μs/2100 Hz)		Fixed antenna (0.3 μs/1200 Hz)

1. Fixed antenna – pulse length/pulse repetition rate (0.08 μs/ 2100 Hz) – 16 h
2. Fixed antenna – pulse length/pulse repetition rate (0.3 μs/ 1200 Hz) – 16 h

A total of 10 430 insects were caught during 32 hours of sampling per trap. Ninety five percent of the insects caught had wingspans <20 mm and were dried and included in further analyses. Paired t tests revealed no significant difference in insect abundance between control and experimental traps when exposed to either a short (0.08 μs) or medium pulse length (0.3 μs) radar signal (short pulse: n = 16, t = 1.50; $P = 0.151$; $P_{Bonferroni} = 0.453$; long pulse: n = 16, t = 1.89; $P = 0.074$; $P_{Bonferroni} = 0.222$).

Discussion

Currently there is no accepted method of successfully mitigating bat collisions with wind turbines and attempts at deterring bats by the use of ultrasound have, as yet, been unsuccessful. Therefore the identification of alternative methods capable of inducing an aversive response in bats approaching turbine blades is of paramount importance. Very few field experiments have been carried out to ascertain the possible effects of high frequency electromagnetic radiation on populations of wild animals. However studies have shown that electromagnetic radiation can influence the development, reproduction, and physiology of insects [33], mammals [34], and birds [35]. Our results demonstrate that an electromagnetic signal from a small radar unit with a fixed antenna invariably reduced the foraging activity of bats within 30 m of the unit. However no significant decrease in activity was observed when the radar antenna was rotating. This is not surprising; the length of time a bat would be exposed to the radar signal is a function of the duty cycle of the radar signal (pulse length×pulse repetition rate) and the dwell time (the duration of time that a target remains in the radar beam during each rotation). The rotation of the radar antenna would reduce the time that bats were exposed to pulse-modulated microwave radiation and would therefore attenuate any potential deterrent effect. When the radar antenna was fixed to emit a unidirectional signal a fourfold increase in field strength was observed at all distances.

When foraging sites were exposed to a short pulse length signal from a fixed antenna there was a significant reduction in bat activity during experimental trials (bat counts and bat passes dropped by 15.5% and 13.3% respectively). Although once the Bonferroni correction had been applied, the difference in bat passes between control and experimental trials was no longer significant. An even greater level of significance was however observed when foraging sites were exposed to a medium pulse length signal from a fixed antenna (bat counts and bat passes dropped by 38.6% and 30.8% respectively). Clearly this represents a substantial reduction in bat activity. However, bats continued to forage at each site during experimental trials, and on no occasion were bats observed behaving abnormally or actively avoiding the beam of the radar. However, temporal and spatial fluctuations in bat foraging behaviour are common [23.24] and therefore results have to be treated with caution. Despite this caveat the significant reduction in bat activity during all experimental trials with a fixed antenna supports our hypothesis that electromagnetic radiation exerts a deterrent effect on foraging bats. This raises questions regarding the mechanisms through which bats could perceive electromagnetic fields and why they would seek to avoid them.

Nicholls and Racey [21] suggest that the aversive behavioural response of foraging bats to electromagnetic radiation may be a result of thermal induction. Studies investigating the behavioural response of laboratory animals to the presence of electromagnetic fields have shown that even short-term exposure can produce a thermal burden in an organism that can result in significant behavioural and physiological changes, some of which may be harmful [36]. Behavioural effects of such exposure include perception, aversion, work perturbation, work stoppage and convulsions [37]. The wing membranes of bats present a large surface area over which radiation might be absorbed, increasing heat load on the animal. This, combined with the heat energy produced during flight, makes bats particularly susceptible to overheating [38,39]. Furthermore, observations of captive bats have noted their aversion to even a moderate infra-red heat source [40].

However the pulsed microwave radiation characteristic of radars is a rather inefficient source of energy. The energy produced by a radar signal can reach very high values of peak power density, at relatively low levels of power density averaged over time. This is because the pulse length of the radar signal is hundreds of times shorter than the pulse repetition rate, therefore the average value of power density is hundreds of times lower than the peak value of the radiation. Therefore it would seem unlikely that the energy in the radar signal would be sufficient to induce a thermal burden in bats foraging within the beam. However several studies have reported significant behavioural and physiological effects resulting from exposure to pulsed microwave radiation even

when the average power density of the signal was relatively low [41–43]. The mechanism through which pulsed microwave radiation could affect behaviour in this manner is unclear although one possibility is an auditory response commonly referred to as the auditory microwave hypothesis.

The auditory perception of pulsed microwaves is now widely accepted. The effect is generally attributed to the thermoelastic expansion of brain tissue following the small but rapid increase in temperature due to the absorption of the incident energy. This generates a sound wave in the head that subsequently stimulates the cochlea. Repeated or prolonged exposure to these auditory effects is considered stressful [44].

Laboratory experiments have shown that the frequency of the induced sound is a function of head size and of the acoustic properties of the brain tissue. The estimated fundamental frequency of vibration in guinea pigs, cats and adult humans are 45, 38, and 13 kHz respectively [45,46]. It is therefore not only plausible but probable that bats exposed to an RF pulse of sufficient power would effectively hear this pulse and the frequency detected would lie within the range of frequencies used for orientation, prey detection and capture for the majority of bat species. It is possible that, as reported in other studies, exposure to these auditory effects may be stressful for bats or indeed it may interfere with their echolocation, inhibiting prey detection or capture. During the present study, foraging rate per unit time was significantly reduced during experimental trials indicating that bats foraging within the exposed area were feeding at a reduced rate in comparison to those foraging during the control trials. This is particularly surprising given that exposure to the radar had no significant impact on the abundance of aerial insects, and the observed reduction in foraging rate is therefore unlikely to be linked to a decline in insect abundance. It is therefore possible that the auditory perception of the radar signal during experimental trials could have interfered with the bats ability to detect or capture prey. However further experimentation would be required to accurately identify the causal relationship between exposure to electromagnetic radiation and the observed reduction in both bat activity and foraging rate.

Although we have demonstrated a clear biological effect, one of the limitations of the present study was the use of a commercial marine radar that was not specifically designed for the task. With only a limited control over the parameters of the radar signal, it is difficult to determine which parameters are most effective in deterring bats. To better understand the response of bats to electromagnetic radiation, and to identify an optimum signal capable of deterring bats, will require radar engineers to work with bat biologists to develop a portable radar which can be manipulated to produce a wider range of electromagnetic outputs. The parameters most likely to be important are the frequency, pulse length/pulse repetition rate and power output of the signal. Similarly, the radar used in the present study was only effective when the antenna was fixed to produce a unidirectional signal with a horizontal beamwidth of 1.9°. A narrow unidirectional signal is clearly not appropriate to deter bats from approaching wind turbines. In order to provide an effective deterrent it would be necessary to emit a multidirectional electromagnetic signal capable of encapsulating the large volume of the rotor-swept zone.

Conclusion

We have demonstrated that pulsed electromagnetic radiation from a small, affordable and portable radar system can reduce bat activity within a given area. Results were most effective when the radar antenna was fixed to produce a unidirectional signal therefore maximising dwell time within the beam of the radar. However although bat activity was significantly reduced during experimental trials substantial numbers of bats continued to forage within the beam. It is possible that only a particular combination of wavelength, pulse repetition rate, power output and target size or orientation may provoke a reaction and further work is necessary to elucidate this relationship further.

Acknowledgments

For different protection of mankind, environment and democracy

Preamble by the publishers at the launch of the series of papers: *Effects of Wireless Communication Technologies*

The bio-scientist Ulrich Warnke is more familiar with nature's electromagnetic housekeeping than most. In this paper, he shows how wise and sensitive nature was about using electrical and magnetic fields in the creation of life. But he can for this reason also convincingly criticise the present foolish and irresponsible interference in nature's house-keeping. It is clear from his paper that the powers that be in politics, the economy and science are in the process of destroying what nature has built up over millions of years. The traces of this destruction have long been evident in our living environment. The paper shows, however, how short-sightedly we are treating not only our health and the economy, but especially also future generations' right to life.[1] All of the above is documented not as probabilities but based on reproducible effects. This should give pause also to those who regularly justify their actions with the argument that they are unaware of any proof of damage.

Under the term "radio communication", we combine all wireless communication technology, increasingly flooding our residential zones and the environment with electromagnetic fields. A recent, comprehensive research report by the BioInitiative Working Group, a consortium of renowned international scientists, shows how many of the damaging effects of such fields have already been proven (www.bioinitiative.org). The report evaluates the present limiting values as a useless edifice, protecting nobody. Based on this, the European Environment Agency (EEA), the top scientific environment authority of the EU, has warned of the possibility of looming environmental disasters following the increasing density of electromagnetic fields. And the coordinator of the European Reflex project, Prof. Franz Adlkofer, has informed the public on the new research results, proving the high degree of gene-toxicity of UMTS radiation.

The public is little aware of these risks because they are hardly addressed in the "enlightenment" provided by officialdom and industry. The public is given the assurance that they are well-protected by the limits and the compliance-assuring measurements and that UMTS radiation is as harmless as GSM radiation – more antennae in residential areas are recommended in principle.[2] And whilst Ulrich Warnke demonstrates how vulnerable man and environment are, we are told that we are more robustly organised than our machines.[3] The original "radiation protection" has deteriorated to the protection of commercial interests.

The involvement of government in industry and the high percentage of industry-financed research and industry-beholden panels and consultants, have spawned a questionable system of environment and consumer protection. Only that which does not seriously endanger common commercial interests is noted and supported. The rights of the citizen to protection and the suffering of the people are flatly ignored. Those with political responsibility have apparently still not realised that their negligent handling of the obligation to take precautions has long since been proven to be one of the main causes of past environmental disasters and scandals.[4]

As a result of their quarrel with politics of carelessness, an interdisciplinary association of scientists and physicians founded the Competence Initiative for the Protection of Mankind, Environment and Democracy in May 2007 (www.kompetenzinitiative.de). This paper is the first in a new scientific series. The reported results are intended as a correction to trivialising "enlightenment" that does not protect, but endangers. The series intends to maintain a high level of technical information, without being unreadable to the interested layman.

Placing economic interests above culture and morality has contributed significantly to turning Germany into a country of declining education. As the journalist Hans Leyendecker so tellingly describes in his book Die große Gier[5], it started Germany too on a new career on the ladder of corruption. There is nothing that the business lo-

Lerchl at a presentation in Ritterhude acc. to a newspaper report of the Osterholzer Kreisblatt dated 16.6.2007: "More radio masts in the centre of town". Professor Lerchl appeals to all communities not to spend further tax money on mobile radio studies

cation Germany needs more, he concludes, than "new ethics". But this also requires a different perception of progress. Whether we can watch TV via our mobile telephone, is irrelevant to our future. Our future will depend on whether we can return to more human, social and ethical values again in the shaping of our lives and our relationship with nature.

Everyone who thinks beyond today and who inquires about what it means to be human is, in our opinion, called upon to contribute to this future: politicians guided by values rather than economical and tactical election issues; scientists and doctors more often remembering their obligation to the wellbeing of society and mankind; companies understanding, also in Germany, that profit and morality must be in harmony if they wish to remain successful in the long term.

But what we need above all is critical citizens, who can spot the difference between technical progress and consumer foolishness: Citizens who, in both their roles as voters and consumers, remember that democracy once meant rule of the people, not ruling the people.

The dramatic escalation of recorded degradation challenges those with political responsibility to take to heart the protection directives of the constitution and the European Convention on Human Rights. To base your actions affecting millions of your protégés on a half truth, at best, appears to us a political crime affecting health and the future – considering the state of our knowledge.
Religious and ethical cultures still profess to the mandate of conserving creation. But its actual treatment is guided by the pseudo culture of a new class of masters who ruthlessly exploit and manipulate the organisation, finally destroying it.

Electromagnetic fields as prerequisite and hazard to life

Author´s introduction to this paper

The question of causal effects and biological relevance of electrical and magnetic parameters is generally posed without simultaneous reference to their relevance to life's organisation. These questions cannot, however, be considered in isolation of each other. What role have the electrical and magnetic fields played in the evolution of life on earth? What role are they playing in the individual development and physiological capacities of an organism? Whoever investigates these questions must sooner or later conclude: Not only did the electrical and magnetic fields of our planet exist before all life, but they have had a decisive hand in the evolution of the species – in water, on land and in the near-earth atmosphere. Living creatures adapted to it in the development of their kind.

Biological experience teaches us that life will use the energy pool in which it finds itself to its best advantage. Advantageous not only because the absorbed energy is a carrier of information, useful for orientation in the environment (see glossary; hereinafter GL). But advantageous also because the organism developed to make use of gravitational and electromagnetic interactions, creating decisive functionalities of life. The biological system expresses itself just as the environment does and unity and coordination with its environment is its guiding principle.

But if bees and other insects disappear, if birds are no longer present in their traditional territories and humans suffer from inexplicable functional deficiencies, then each on its own may appear puzzling at first. The apparently unrelated and puzzling phenomena actually have a common trigger, however. Man-made technology created magnetic, electrical and electromagnetic transmitters which fundamentally changed the natural electromagnetic energies and forces on earth's surface – radically changing million-year-old pivotal controlling factors in biological evolution.

This destruction of the foundations of life has already wiped out many species for ever. Since this extinction of species mostly affected ecological niches and hardly ever own life, most of us were not interested. But now, the endangerment of animals is also threatening the survival of man in a new and unexpected way.

Animals that depend on the natural electrical, magnetic and electromagnetic fields for their orientation and navigation through earth's atmosphere are confused by the much stronger and constantly changing artificial fields created by technology and fail to navigate back to their home environments. Most people would probably shrug this off, but it affects among other one of the most important insect species: the honeybee.
Because the bee happens to be the indispensable prerequisite for fructification: without bees, the fruit, vegetable and agricultural crops will fall short.

We are, however, not only affected by the economic consequences of our actions. It can also be proven that the mechanisms evidently affecting birds and bees are also affecting the human organism. An all-round unnatural radiation with an unprecedented power density (GL) is also harming human health in a novel way.

But, unless mankind reminds itself of the basics of its existence and unless the politicians in charge put a stop to the present development, the damage to health and economic fundamentals is predictable and will fully manifest itself not now, but in the next generation.

The reasons for this are explained in this paper. It endeavours to quantify natural electrical and magnetic signals provided to men and animals as guiding signals throughout evolution. The paper, however, places particular emphasis on what happens when these natural signal amplitudes are suppressed, changed and distorted on an unprecedented scale by technically generated artificial fields. Mankind can only take successful countermeasures if the damage mechanisms are understood.

The following analyses are intended to remain readable also for interested laymen. This approach has its limits where experimental fundamentals or specific technical descriptions must be included. The following text therefore offers three options for reading. In its totality, it is intended for readers with a scientific background. It has, however, also the interested layman in mind, by allowing him to skip identified parts containing specific technical justification and arguments. And the parts against a coloured background are intended as a first overview.

I thank Prof. Dr. Karl Richter for the editorial supervision of the paper and Dipl.-Met. Walter Sönning, medical meteorologist, for his technical comments on the sferics question and the compilation of a glossary for the interested layman.

If all the functions bees perform for natural life and its preservation are observed holistically, their importance cannot be overstated. Without the bees, we humans will also suffer major deficiencies.

1. The organisation of life underlying its vulnerability

1.1 We should have known long ago

The relationship between life and the physical parameters of earth's surface and atmosphere have been known for many decades. Those responsible therefore had the opportunity long ago to question to what extent the excesses of technically created electrical and magnetic fields might have the potential to destroy nature's housekeeping.

There are only two types of energy capable of transmitting information over great distances: electromagnetic and gravitational energy. Any forces acting beyond the boundaries of an atom can be traced back to these two energies; ultimately they have an infinite reach. Both energies are universally present and can be modulated in many ways (GL). This is true, for instance for light, the earth's magnetic field, cloud charges, atmospheric electric fields and changes in atmospheric pressure. Together with atmospheric moisture and olfactory particles, they are recognised as orientation aids to mobile organisms.

In the natural environment, there are "oscillating" electromagnetic fields of many orders of magnitude and with frequencies ranging over a virtually unlimited spectrum covering many frequency decades. They manifest themselves as a continuous and enormous "hiss" – like an unlimited ocean, the surface of which is agitated by waves of any imaginable amplitude and extent. Nature has created senses that filter out very specific frequencies and intensities from this ocean of waves, analyse them and convert them to forces. These filtered frequencies identify a specific sphere of life for specific life forms.
Only those energies that are important to the life of an animal are transformed. The forces generated from these energies control nerve cell membranes and protein structures such as enzymes – creating patterns, images and impressions that we call experience. Sensory organs are organs functioning as frequency analysers (GL), information amplifiers (GL) with gains up to a million, sometimes including contrast enhancement and noise suppression. Eyes, ears, sense of smell, taste, sensitivity of touch, light, warmth, chemical, electrical, magnetic and pain receptors. The living world perceives stimuli such as light (including ultraviolet and infrared), sound (including ultrasound and infrasound), electrical fields and currents, magnetic fields and also smells and water currents. And the sensory performance of animals is often comparable to our technical measurement apparatus, sometimes even far superior. Physiologists can prove this by some astounding numbers: Snakes, for instance, can sense temperature variations of a thousandth of a degree centigrade; long-horned grasshoppers and cockroaches can register mechanical surface vibrations with amplitudes (GL) down to 1/25th of the diameter of a hydrogen atom.

The high "intelligence of the systems" is particularly obvious, however, with orientation, navigation and early warning systems. In this regard, the earth's magnetic field has an important role to play. The local geographic position and time of day can be established from the density, direction and inclination of the field lines and their temporal variation.
Every location, together with other physical information, has a specific identifiable pattern. The sensitive reception apparatus of animals use the magnetic field information for orientation and navigation, among other (WARNKE, 2006).

1.1.1 Magnetic fields as global parameter for space and time orientation of all life

To the best of our present knowledge, biological organisms depend less on static magnetic fields than on the very important intensity variations of sufficiently high frequency. If we take a closer look at such variations, the earth's magnetic field cannot be considered in isolation. Other magnetic fields must also be included in the analysis: such as the ionospheric field, for instance, and the field of the Van Allen belt – a radiation belt of very high intensity with rotational symmetry around the magnetic axis and mirror symmetry around the magnetic equator around the earth. Both the ionosphere and the Van Allen belt are held together by earth's magnetic field. The protons and electrons captured from the cosmic radiation or the solar wind (= stream of ionised particles emanating from the sun) by earth's magnetic field, create a protective shield for all life on earth – the Van Allen radiation belt.

The external magnetic fields act as moderators (GL) on the earth's magnetic field. They exhibit both a pronounced solar and also a lunar (moon-dependent) diurnal variation. The reason for the solar-induced variation lies in the diurnal warming of the atmosphere through solar radiation. This is

accompanied by horizontal eddy currents with amplitudes up to 90 000 Ampere in the ionosphere, that generate magnetic fields again. These daily variations also have a pronounced annual cycle.

The moon-dependent variations are furthermore only evident during the day. These are also generated by electrical currents at about 100 km altitude, but they have current amplitudes of "only" 10 000 Ampere. These eddy currents cannot be explained by temperature gradients as with the solar effects, but they are influenced by the gravitational remote action of the moon. The earth's atmosphere is rocked to and fro inside the earth's magnetic field in the rhythm of the tides, inducing electrical currents in the ionised layers of the upper atmosphere where the conductivity is high through the presence of the negatively and positively charged particles (ions). It appears that the conductivity of the ionosphere is too low at night to maintain induction processes (GL) – due to reduced ion densities (WARNKE 1993).

Within the realm of the conventional variations of the magnetic field that have been explained so far, electromagnetic oscillations that occur in mainly two frequency bands also deserve to be mentioned: 10 Hz and 10-25 kHz. On the one hand, there is a resonating electromagnetic oscillation between earth and ionosphere in the 10 Hz region (Schumann resonance, 7.83 Hz) and on the other, thunderstorm activities on earth constantly reinforce certain electro-magnetic oscillations. The dominant frequency of approximately 10 kHz generated by vertical lightning flashes corresponds to a transmitter dipole of cloud-to-earth length, whilst horizontal cloud-to-cloud lighting generates about 20 kHz.

These characteristics may be exploited for the design of thunderstorm warning apparatus. Our device measures the thunderstorm activity in a range of at least 800 km and simultaneously also the activity within a range of 200 km. Under favourable conditions, we can therefore register thunderstorms over the Mediterranean from our location in Saarbrücken.

Lightning also simultaneously generates very low frequency electromagnetic oscillations. Under certain conditions, these oscillations are all guided through the ionosphere along the magnetic filed lines, travel far into space and return to earth along the opposite magnetic field lines. They are reflected at the ground and the waves travel the same way again and again until their energy is dissipated. The higher frequencies are propagated somewhat faster than the lower ones. If this process is made audible through an amplifier, a whistling noise is heard, continuously decreasing in frequency down to a hum, as in a switched-off siren, but much faster, typically for approx. 1/3 of a second. This phenomenon was therefore called "Whistler".

The so-called earth-magnetic storms (magnetic induction B~1μT) are triggered by the magnetic shock waves escaping from the solar flare region at 2000 km/sec and still have a speed of 100 km/sec as they reach earth. This induces unusually high currents in the earth's magnetic field, which in turn change the earth's magnetic field and generate secondary currents. Such currents manifest themselves in long conductive paths such as pipelines, transmission lines etc. and routinely cause technical headaches.

The most important parameters, constant over millions of years, are: earth's static magnetic field: 31 μT (geomagnetic equator); resultant diurnal variation of the earth's field: 60 nT; magnetic storms: 500 nT; sferics field strengths: 0.25 – 3.6 pT per $\sqrt{Hz}$.

The natural high frequency radiation sources have far less energy than the technically generated transmission powers and energies. This is a precondition for transmission of news and communication.

The integrated power density over all frequencies up to 300 GHz is 600-800 $\mu W/m^2$ at the earth's surface. The power density of the microwave solar radiation is about 0.1 $\mu W/m^2$, escalating to several 100 $\mu W/m^2$ during solar flares.

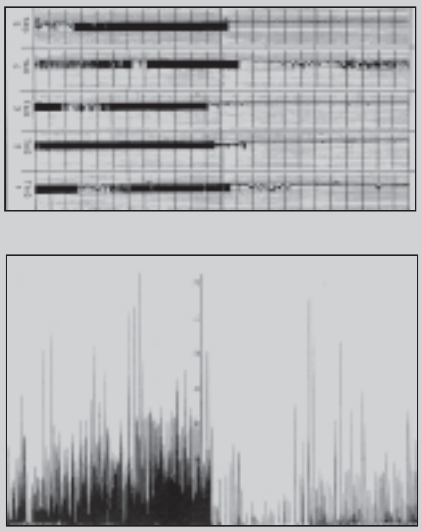

Fig. 1 *Top: The "midnight phenomenon". The activity of the electromagnetic impulses (shown on 5 different days) abruptly ends at midnight.*
Ref. Hans Baumer: (1987) Sferics. Die Entdeckung der Wetterstrahlung. Rowohlt, Hamburg

Bottom: Our original recorded activity cycles of 20 caged bees in a laboratory experiment. The vertical axis (ordinate) shows the total electrical field arising from the electrostatic charging of the wings. It is clear that the bees suddenly all come to rest at midnight.
Acc. to Warnke (1982), published in Baumer's book (1987)

1.1.2 Examples of the utilisation of earth's magnetic field parameters

For a period of millions to a billion years, life on earth had the time in the evolution of the species to adapt to the magnetic and electromagnetic conditions of their environment. They learned to use the natural magnetic field parameters also as conveyors or carriers of a diversity of information:

- The geographic location can be established by the density of the field lines, their direction and variation in time.
- Time of day and annual seasons can be deciphered in the daily, lunar and solar periodic magnetic signals.
- Frontal weather systems and air mass movements transmit characteristic electromagnetic signals, the so-called sferics. These are short oscillations comprising just a few cycles (= impulses) in the range between approx. 3 kHz and 60 kHz (= very low frequency) with a repetition frequency of up to 100/sec or more, depending on the intensity and type of atmospheric processes.

The biosphere at the earth's surface is in contact with the electromagnetic fields of the universe via two narrow frequency windows through the atmosphere. One of these windows is in the narrow medium to long wavelength UV radiation region, including the visible light spectrum and the near (short wave) infrared radiation (average 1milliwatt/m^2); another window is in the high frequency radiation region at wavelengths of 0.1 to 100 m (average 1 nanowatt/m^2 up to 1 milliwatt/m^2 (GL) during solar flares).

Effects of the earth's field and of its compensation or effects of weak artificial fields have been detected in life at all levels of development: with bacteria, single and multi-cellular algae, higher plants, protozoa, flatworms, insects, snails and vertebrates:

- Magneto bacteria (Aquaspirillum magnetotacticum) in the bottom sludge of the oceans utilise the intensity of the earth's magnetic field for orientation. Magnetite crystals (Fe_3O_4) in their bodies form a chain of "compass needles" creating a magnetic moment that the bacteria align against the thermal movement of the water molecules. (The earth's magnetic field applies an energy of 1.4 x 10^{-18} J (GL) to the bacteria – 200 times greater than the energy of the thermal movement at 22°C).
- Fish navigate in the earth's magnetic field. When sharks and stingrays, for instance, move in earth's magnetic field, they experience induced electrical fields of varying strength. The field strength is a function of the direction of movement relative to the direction of the magnetic field. Local physical water currents also generate direction-dependent electrical fields that can be detected. The sensory organ for electrical fields is highly sensitive. (So-called Lorenzian ampoules responding to voltage gradients of less than 0.1 microvolt/m).
- Compass termites (Amitermes) build their metre-high mounds in a north-south direction. With other termites and the woodlouse, the feeding activity is subject to natural magnetic alternating fields (sferics) and the earth's magnetic field.
- Bees make use of the earth's magnetic field and its daily fluctuations for their orientation and communication. They also gain information on weather developments through the natural impulse signals in the atmosphere, i.e. the sferics already mentioned above.
- Whales can sense the magnetic field of the earth.
- Carrier pigeons are affected by variations in the earth's magnetic field down to flux densities in the nano-Tesla region.
- Migratory birds have a mechanism acting like a compass.
- Humans react to atmospheric alternating electromagnetic fields between 10 and 50 kHz through various symptoms of the central nervous system. There are also correlations between activities in earth's magnetic field and sleep-affecting factors, circadian rhythms (HECHT 2005, 2006, 2007), enzyme conversion and hormone production in the central nervous system, the vitamin level in the blood serum, the average skin temperature, vision in half-light and iron content in the blood serum.

All the examples support the existence and the vital control functions of biologically active magnetic and electromagnetic fields with a specific frequency structure and corresponding information content, "arranged" to suit biological systems.

They are characterised by, among other:

- *specific flux densities and gradients ("amplitude windows"), i.e. weak fields may have a greater effect than strong fields,*
- *specific impulse frequencies and impulse sequences ("frequency window"),*
- *specific impulse shapes and a certain complexity of the impulse spectrum,*
- *specific vector characteristics with respect to the body,*
- *minimum effective duration of coherency and specific co-factors, e.g. light.*

Life forms, even of the same species, may be quite differently organised, but coordinated in a collective or social group (fish shoals and flocks of birds). In an isolated form of life, the instantaneous interaction with its environment is therefore exceedingly varied. Reproducible magneto experiments in or between individuals are therefore unlikely in the case of complex organisms, including humans; the specific metabolism parameters are, for instance, also too varied. None of these parameters can be kept as constant as required for reproducibility. "Proof", in the sense of classical scientific criteria, is therefore illusory.

1.1.3 Technical wireless communication is only possible because the transmission is stronger than the natural high-frequency radiation

Technical wireless communication such as mobile radio, radio, TV and satellite

communication is only possible because the power density of the utilised technical high frequency spectrum far exceeds that of natural radiation. Natural radiation at the surface of the earth in the 300 MHz to 300 GHz range is approximately 0.001 microwatt/m² (=0.001 µW/m²); today's typical technically created radiation level in cities is 10 000 µW/m². And the legal German limits even allow values up to 4.5 million µW/m² for the D-grid, up to 9 million µW/m² for the E-grid and up to 9.8 million µW/m² for UMTS.

As we evolved, we were of course also exposed at times to strong static and low-frequency electrical fields (typical voltages: cloud electricity up to 10 000 V, volcano electricity up to 20 000 V, lightning 500 000 V, sferics 10 V), in addition to constant static and low-frequency magnetic fields (earth's field, lonospheric field, cosmic field, lightning). But there were never fields as constant and with as many superpositions of different frequencies from different sources as we are now generating with our technology.

1.1.4 Radiation by organisms themselves could be established in the evolution, because there was no interference by continuously changing external radiation

The same high frequency radiation that technology utilises for communication is also copiously generated inside our bodies. The body also requires it for communication purposes: for biological communication through functional oscillation of our molecules.
Provided there is no interfering external radiation, the body can utilise its built-in frequencies for its internal organisation.

The body internally radiates frequencies in the 1 to 1 000 gigahertz (GHz) range at power densities of about 0.1 µW/m², i.e. lower than those of average solar radiation. If we add up the total range of high frequencies (HF and VHF) present within our organism, we arrive at natural power densities of about 10 000 µW/m². The power generated by our internal electromagnetic oscillations, that we describe as heat (wavelengths around 3 – 10 µm), corresponds approximately to that of a 100 Watt globe.

To understand the natural oscillation of our functional molecules (enzymes and other proteins, nucleic acids, hormones and many more) it is important to realise that what we generally describe as "chemistry" is actually pure physics. All the bonds and their modulations (changes) between atoms on the one hand and molecules on the other are based on physical phenomena. In this context, the electrostatic Coulomb forces (= force between different electrical charges) and the electromagnetic force (e.g. van der Waal force = force between dipoles with different moments and fast oscillations) are prominent. DNA and all the enzymes, for instance, can only carry out their functions through their natural electromagnetic oscillations.

Resonances are of particular importance here. Chain molecules, for instance, can be excited to so-called wring-resonances by high-frequency electromagnetic fields. Proteins exhibit such natural resonances in the range of 1 – 10 GHz; DNA resonates at 10 MHz to 10 GHz. Both of these therefore fall into the spectrum of common mobile radio frequencies.
Wring frequencies (modes) cause wringing of the molecular chains that directly affect the structure of the individual molecules. The structure of the molecules (conformance and configuration) is essential, however, for their specific functionality. Even minor displacements render the molecule useless. The chains may even break apart under energetic external influences.

Biological systems are obviously very sensitive in their reaction to microwave fields. For instance, Belyaev et al, 1996, reported resonance effects on the DNA structure at extremely low power densities of 0.000001 µW/m² in the 40 – 50 GHz frequency range. This surprising result must still be confirmed by other working groups. Nevertheless, it must be stated that: The ultra-weak, but biologically very effective natural electromagnetic fields are contrasting strangely with the technical radiation fields permitted in Germany. On recommendation by the ICNIRP association (Munich), technical radiation fields up to power densities of 10 000 000 µW/m² were legalised – still considered as harmless by the experts. The population, animals and plants may therefore be legally subjected to radiation in the critical frequency spectrum that is more than 10 orders of magnitude higher than the natural fields.

But organisms are not only sensitive to high frequencies; the following examples show that very high sensitivities evolved also in the low frequency ranges.

2. About the disappearing bees and birds

2.1 The bees as evolutionary force and indispensable economic factor

Honeybees existed on earth from about 40 million years ago; a "primal" honeybee encased in amber was found on the coast of the Baltic Sea. Man soon realised the usefulness of animals. And we know today that the enormous development of earth's vegetation, comprising about 200 000 species of a variety of flowering plants, is based on animals. Because about 85% of these flowers are pollinated mainly by bees and propagate through the formation of fruit and seeds.

Since also fruit trees (such as cherry, apple, pear and plum) and agricultural crops (such as rap, sunflower, red clover, lucerne, horse bean as well as vegetables such as tomato, cucumber, pumpkin) fall under these, it is not difficult to understand that bees are one of mankind's most important production animals.

In central Europe the commercial benefit of bees is estimated at 4 billion euros per annum, in the US it is estimated at over 15 billion dollars. These figures are from the New York Times. It quotes estimates by Cornell University, New York State. This included the pollination of fruit and vegetable plants, almond trees and fodder such as clover. That said, however, even the global honey production of 25 000 tons per annum is an important economic factor already.

But if we aggregate all the functions the bees are performing for nature's life and the preservation thereof, their significance can hardly be overestimated. Their industry cannot be substituted either by other insects or by technical measures. If the bees should disappear, we humans will also suffer major deficiencies.

2.2 No chance of survival: ‚Colony Collapse Disorder' CCD

In some countries there are reports of mysteriously dying bees. It appears as if the losses are at their worst in the northern American states and in neighbouring Canada. 25% to 50% of the American bee-keepers report losses through "Colony Collapse Disorder" (New Scientist, 2007). They reported 50% to 90% of their bees to have disappeared within the previous 6 months, and the remaining bee colonies were said to be so weak they can produce hardly any honey (CNN, 2007).

But unusual losses are also reported in Germany, Switzerland, Austria, South Tyrol, Spain, Poland and New Zealand. In Germany, for instance, the beekeeper associations last winter recorded a loss of about 13% in over 7 000 bee colonies - double the previous year's figure (http://orf.at/070416-11296/-index.html). In accordance with a report in the Stern magazine edition 34/2007, German bee monitoring did not confirm this number, only acknowledging an average loss of just on 8%. A 10% loss over the winter months is not regarded as unusual. What is completely unusual, however, is the statement by the president of the DBIB (German Federation of Occupational and Purchasing Beekeepers), Manfred Hederer, in the Deutschlandradio Kultur, on the Federal territory: "The beehives are empty." He paints a picture of bee colonies reduced by 25% - in some cases even 80% (Spiegel 12/2007).

In 2006, the Swiss federal research institute for production animals and dairy farming, Agroscope, (Federal office for agriculture), reported that also all of Switzerland was affected by bee deaths, to a regionally more or less severe degree (Zürichseezeitung, 5. May 2006). Roughly 30 percent of the bees were lost without a trace after winter – about half a billion animals in this year alone (http://www.heute-online.ch/wissen/play/artikel 60601).

Beekeepers from Styria are also reporting a mysterious disappearance of bees. Beekeepers in Vienna estimate a 30% loss. They agree on the following: "The bees are not developing properly anymore. They do survive the winter, but in spring they disappear as if by magic. The hives are simply empty." (This according to beekeeper Hermann Elsasser of Fladnitz in the Raab valley; http://oesterreich.orf.at/steiermark/stories/184609/). Only the brood remains in the hives, and without the care of the older bees, they will die.

Ferdinand Ruzicka, scientist and beekeeper himself, reports: "I observed a pronounced restlessness in my bee colonies (initially about 40) and a greatly increased urge to swarm. As a frame-hive beekeeper, I use a so-called high floor, the bees did not build their combs in this space in the manner prescribed by the frames, but in random fashion. In the summer, bee colonies collapsed without obvious cause. In the winter, I

observed that the bees went foraging despite snow and temperatures below zero and died of cold next to the hive. Colonies that exhibited this behaviour collapsed, even though they were strong, healthy colonies with active queens before winter. They were provided with adequate additional food and the available pollen was more than adequate in autumn. The problems only materialised from the time that several transmitters were erected in the immediate vicinity of my beehives" (RUZICKA, 2003).

Ruzicka organised a survey through the magazine Der Bienenvater (2003/9):

- Is there a mobile radio antenna within 300 m of your beehives? - This was confirmed in 20 replies (100%).
- Are you observing increased aggressiveness of the bees compared to the time before the transmitters were in operation? – 37.5% confirmed this.
- Is there a greater tendency to swarm? – 25% confirmed.
- Are colonies inexplicably collapsing? - 65% confirmed.

Such colony collapses, heralded by "angry" swarming of the bees, were also reported in New Zealand (FIRSTENBERG, 2007).

Other reasons possibly explaining the disappearance of the bees are also under discussion: Monocultures, pesticides, the Varroa mite, migratory beekeeping, dressed seed, winters too severe, genetically modified plants. There is no doubt that some problems can be attributed to this. But the fairly sudden and country-spanning appearance two to three years ago of the dying bees phenomenon cannot be convincingly explained by any of the aforementioned causes. Should the bees simply be too weak or ill, they should also die in or near the hive. But no ill bees were found in the research into this phenomenon.

About 85% of these flowers are pollinated mainly by bees and propagate through the formation of fruit and seeds. We have the utility of animals to thank for the enormous development of earth's vegetation, comprising about 200 000 species of a variety of flowering plants.

2.3 Some bird species are disappearing

But not only are bees and other insects disappearing – birds as well. The house sparrow, for instance, has become clearly scarcer in England and some western European countries. An investigation carried out between October 2002 and May 2006 in Valladolid in Spain, was launched to examine whether this decline in the sparrow population was related to electromagnetic radiation by mobile base stations. The result showed with a high decree of statistical confidence that the number of sparrows was reduced when the electrical field strengths of the antennae exceeded certain values. (BALMORI, HALLBERG, 2007).

A similar investigation was carried out in Belgium. The numbers of house sparrows were counted in the vicinity of several mobile radio base stations, during their breeding season. This confirmed a significant relationship between the electrical field strength in the 900 and 1 800 MHz bands and the diminishing numbers of birds (EVERAERT, BAUWENS, 2007).

It was noticed even earlier that storks that built their nests within a 200 metre radius of base stations could not rear any chicks, remaining without offspring. The results improved at distances of 200 to 300 metres. From a distance exceeding 300 m, the storks bred with a success rate of 96.7%. The electrical field strength at a distance of 200 metres averaged 2.36 $\pm$ 0.82 V/m, and only 0.53 $\pm$ 0.82 V/m at 300 metres. From their results, the authors concluded that the electrical fields of base stations are damaging to the reproduction of the white stork (BALMORI, 2005).

3. Mechanisms of disorientation and damage

3.1 Magnetic field sensitivity in the animal world

Birds, insects, fish and snails are assumed to have a specific organ for sensing magnetic forces. It is questionable, however, whether it is always necessary to assume such a specific magnetic sense. Electrical fields do not penetrate deep into living organisms and currents follow only certain paths. A magnetic field, however, fully penetrates the organism, without major changes. It is too short-sighted to conclude from this that such fields have no effect because they are not absorbed. To start off with, even weak magnetic fields in the body are more energetic than strong electrical fields. As such, the energy in earth's magnetic field inside us is 10 000 times stronger than the strongest possible electrical field in the atmosphere (3 Megavolt/m; WEISS, 1991). Such penetrating forces as the quasi-static magnetic field and the low-frequency electromagnetic field do not theoretically need an own amplifying reception organ. Inside the organism, they can also directly couple into aggregates of orderly paramagnetic molecules or into the electro-mechanical (photon-phonon) code of the endogenous information transmission and storage.

Magnetite was found in all animals that can navigate using their own compass, sometimes in the form of ferritin-proteins (KIRSCHVINK et al. 1981). But it is also present in our brains (KIRSCHVINK et al. 1992). And it reinforces the external magnetic fields in both cases. In the tissue of birds, bees, fish and whales (WALKER et al. 1992), the magnetite concentration exceeds that in the human brain. Most areas of our brain nevertheless contain about 5 million magnetite crystals per gram and even 100 million in the brain membrane.

Because magnetite reacts about 10 000 000 times stronger to external magnetic fields than normal dia- and para-magnetic tissue, the transmission of information separate from the neurons must be considered. Oscillating magnetite excited by ELF fields could, for instance, play a role in transport channels or cell-interconnection channels, raising the possibility of interference by communication and other negative effects of technically created electro-/magneto-smog.

It is easy to prove mechanically acting forces in insects subjected to relatively strong magnets. Own experiments with bees and flies yielded the following results (WARNKE, not published):

- *A newly captured swarm of bees is exceptionally sensitive to magnetic forces. If a magnet with only a few mT field strengths is brought close to the swarm in a dark wooden hive, the entire swarm becomes excited.*
- *Captive bees assume a horizontal rest position at night, aligned to an artificial magnetic field of several mT in the environment.*
- *Dead bees, flies and a range of other insects can be made to float on an electrostatically neutral water surface and in this condition an electrostatically neutral strong magnet can be used to attract them, drag them across the surface and in some cases repel them.*

In the laboratory, bees can sense not only the compass direction but also the intensity and the gradient of this magnetic field (SCHMITT et al. 1993). It was found in a 1982 publication (KUTERBACH et al. 1982) already that the magnetite found in bees is the source of this sensitivity to magnetic fields, and this theory was recently checked and finally confirmed (HSU et al. 2007). We also found ferrite particles together with pollen lodged in the bristles of the body surface; these might also be responsible for the above-mentioned magnetic moment.

It has been demonstrated that the birds' magnetic compass only functions in a certain range of intensities between 43 μT and 56 μT – precisely in the range of the earth's magnetic field intensity. After a three-day adaptation period the animals could, however, also orientate themselves in fields of 16 μT and 150 μT (SCHNEIDER et al. 1992) – interpreted as an adaptation to the environment.

The platypus of Australia (Ornit-horhynchus anatinus) has the electrical receptors for detecting its prey, in its bill. The receptors can sense direct and alternating voltages in the range of 20 mV and have a connection to the Trigeminus nerve. Fish with similar receptors use the acoustical nerve for transmission of the electrical stimulus. This shows that evolution exploited the electrical and magnetic environment in different ways. The Lorenzian ampoules of fish are capable of distinguishing between stimuli of magnetical or electrical origin (BROWN et al. 1978). It has not been established whether the receptors of platypus also have this capability. This question is of interest because ducks also have bill receptors. Although these are specialised to react to mechanical stimuli, they are so sensitive that the mechanical Coulomb forces accompanying electrical fields might well be detectable as well.

When magnetic fields penetrate an organism, two fundamentally different aspects must be clarified:

1. *Is the organism merely subjected to a large increase in energy - or*
2. *does the organism gain information?*

In various insect species we are aware of a time function based on magnetic field variations. In particular, the feeding habit of termites is correlated with the 27-day solar cycle (BECKER, 1973), and there is also an increased building activity for a few days around new and full moon in laboratory experiments – as it is with bees. It is also known that termites show directional behaviour under the influence of extremely low field strengths (BECKER 1976, 1979). Time triggers via similar channels sensing sun and moon appears a reasonable assumption.

The changes to the circadian activity rhythm of the house sparrow (Passer domesticus) can be correlated with cyclical changes of the earth's magnetic field. The sparrow reacts down to 200 nT in laboratory experiments.

Without doubt, light is the dominant timing mechanism of life. But also the earth's magnetic field is meanwhile recognised as a timing mechanism.

3.2 Bees and other small life forms under investigation

Insects have many aids for their navigation and orientation in space: sunlight, also polarised (WARNKE, 1975), gravity, aromatic molecules, colour as electromagnetic oscillation in a specific frequency range, variations in air pressure, occasionally also the degree of ionisation of the air (ALTMANN et al. 1971, WARNKE, 1976). Many species, however, cannot do without the magnetic field.

In this respect, bees are welcome objects for experimentation. Because different modalities of their orientation are inseparably linked to the magnetic field of the earth and to electromagnetic oscillations (LINDAUER and MARTIN 1968; HÜSING et al. 1959, SCHUA 1952, WARNKE, 1976).

In our working group, we recorded the directional behaviour of captive bees in an artificial field and during the night. A preference to assume rest positions with the body either parallel or orthogonal to the field lines was evident.

They share this alignment reaction with other insects such as various termites (BECKER, 1963), diptera (BEKKER et al. 1964) and Drosophila (WEHNER et al. 1970).
The behaviour of termites (BEKKER, 1963) was studied particularly intensively in Germany, that of the Christmas beetle (SCHNEIDER, 1961, 1963) in Switzerland and that of insects, worms, snails, snakes and other small creatures in the USA. The investigations concentrated on the influence of cosmic physical fields in which the magnetic field time and again played a pivotal role. All experiments confirmed the existing relationships. They also all showed, however, that constant laboratory conditions are impossible in practise, because cosmic influences change the magnetic component in any normal room and cage, thereby affecting the orientation behaviour of the animals.

The experiments with Christmas beetles and termites may be termed spectacular. In accordance with the above literature, Christmas beetles not only determine their rest position by magnetic and electrostatic fields, but also by interference patterns of gravitational waves of terrestrial and cosmic matter. In the final analysis, the evidence points to the influence of a physical field or radiation, varying in space and time in accordance with an unknown programme, that is registered through an unknown organ in the Christmas beetle for an unknown purpose, but the existence of which physicists doubt because it cannot be measured by any instrument. The Christmas beetle therefore becomes the instrument for measuring this unknown agent. The effect is often intimately coupled to that of the magnetic fields (SCHNEIDER, 1974). The orientation at rest is based on the Christmas beetle choosing the position of least or most symmetrical stimuli when awakening from the rigor of cold. Using interference patterns and models resonating with gravitational Earth-Sun waves, complex combinations of dynamic stimuli were constructed, to which the Christmas beetle responded by changing its position (SCHNEIDER, 1972).

Also termites (Isoptera), whose feeding activity and O_2 consumption are important indicators, react to more than just magnetic components. Their communication modes also include natural electromagnetic sferics impulse patterns, gravitational influences and electrical fields. The statistical correlation between the feeding activity of termites in the laboratory and the number of deaths in Berlin is described in detail; the consequences of this are as yet unfathomable. There is an increased frequency of human deaths on the days on which termites feed less. The authors point to the magnetic field of the earth and its variation with solar influences as the common factor linking the apparently unconnected facts. Further down, other and earlier literature is cited in which an increased incidence of human death is described during unusual variations in the magnetic field.

3.3 Birds as prototypes of magnetic field orientation

This research shows that birds' orientation by magnetic fields has been a frequently discussed topic for decades. Thanks to the thorough and meticulous work of a number of researchers (WILTSCHKO, WALCOTT, MERBEL), it is today beyond doubt that several species of birds sense the earth's magnetic field and use it to establish their position during migration. As described for insects and snails, some species of birds are also particularly sensitive to a range of magnetic field strengths corresponding exactly to the earth's magnetic field – the robin, for instance. When the field is attenuated or amplified, the birds become disoriented. Setting on a certain field range could, however, change through adaptation.

The mechanism by which birds sense magnetic fields has meanwhile been largely explained. An area with iron-containing tissue was discovered in the skull of pigeons. Strangely, only one half of the skull contains material that is permanently magnetic. But opposite to this, material was found that is only very weakly permanently magnetic. Measurements indicate magnetite inclusions - the same crystal that was found in bees, bacteria, snails, whales and humans. The magnetite-containing tissue of the pigeons is even supplied with nerve ends that can sense the orientation changes signalled by the crystals (WARNKE, 1993).

It could be demonstrated at the Zoological institute of the University of Frankfurt/Main that the top half of the pigeon's bill has three magnetite-containing bodies, with a neuron ending at each of these. They constitute a three-channel system enabling the brain to construct a spatial picture of the surrounding magnetic field the pi-

geon can use to orientate itself in flight (source: TV programme *Planet Wissen* in BR on 18.09.2007 at 16.15 on carrier pigeons. Reference by W. Sönning).

Birds also have magnetite in the edge of the bill. In addition, light and magnetic fields result in an increase of certain free radicals in the eye, the concentration of which can obviously be accurately registered by the animals (WARNKE, 1995). This relationship will be dealt with again further on.

3.4 Animals with a navigation system are extremely sensitive to electrical and magnetic fields

Birds having a navigation system are extremely sensitive to the weather. A thunderstorm changes the magnetic field, light and many other characteristics – potentially causing the orientation to collapse. Birds and other animals are particularly sensitive to a solar eclipse. They exhibit an abnormally changed behaviour: sometimes lethargic, sometimes restless. Research attributes the reactions to the suddenly occurring electromagnetic long and medium wave radiation, typical for night time, but surprising with the suddenly occurring darkness of a solar eclipse. The lack of ionisation in the ionosphere by light has the effect of many oscillating impulses propagating 100 times better on the surface of the earth.

This unexpected electromagnetic impulse effect may also, in principle, explain the early warning system animals have for earthquakes. The so-called sensitivity to weather or inclement weather, traceable to short electromagnetic impulses with a certain frequency content and rapidly decreasing amplitudes, has also been known for a long time.

These impulses originate at frontal weather systems, where colder air from sub-polar regions undercuts warm subtropical air masses. In the regions where warm or cold fronts mix, thermodynamically driven turbulent air currents with vertical and horizontal components are created. This is in essence where the abovementioned natural electro-magnetic impulse radiation of the atmosphere, also known as sferics, is created. Many life forms such as insects, frogs, birds and various mammals react to this meteorologically based impulse activity in the atmosphere. By receiving and frequency-analysing these "weather code" signals of changes in the weather or approaching thunder-storms, they can then dive for cover or fly around these thunderstorm regions (WARNKE, 2006).

Walter Sönning: "These weather signals or sferics are indicators of unstable processes in the troposphere – the weather-creating layer of the atmosphere -, since their source is in the weather centre. They originate in invisible discharges between positive and negative space charge clouds, created and maintained by different processes of ionisation such as cosmic radiation, UV radiation, natural radioactivity or the Lenard effect (= spray electrification or break-up of droplets or ice crystals with opposite charges). In terms of physics, our air could therefore also be described as a "plasma" gas. When differing space charges of possibly predetermined magnitude are electrically equalised, the ion-front of this basic plasma or gas discharge propagates at velocities of about 200 km/s along a tubular channel of about 40 cm diameter in the direction of the maximum potential difference, covering distances between 40 and 100 metres, until the electrical potentials are equalised. If the ion density in the air is sufficiently high, the following discharge impulse follows immediately. Each of these invisible and "quiet" discharges that occur at varying intensities in all weather conditions, is the source of an electromagnetic, three-dimensional impulse or space wave, a so-called EMP or primal impulse, similar in its waveform to impulses from other sources (nerves, atmospheric nuclear explosions etc.). This 3-dimensional wave propagates at the speed of light. When recorded on an oscilloscope, for instance, it vaguely resembles a sinusoidal half-wave, but has a steeper rise time and an exponential decay of the amplitude. In a Fourier analysis, it is therefore not equivalent to a sine wave of a certain frequency.

Depending on the meteorological and atmospheric electrical propagation conditions, these EMP's are dampened at a distance of 60 to 100 km from the source to lower frequency sinusoidal Fourier components with a continuous spectrum between approx. 3 kHz and 60 kHz. True to their origin in an impulse discharge, these "impulses" have waveshapes of a few oscillations with rapidly decaying amplitudes from a maximum down to zero. Particularly well-defined impulse shapes in the total collection of atmospheric impulses convey, through their resonating sinusoidal oscillations at certain frequencies and also in the subsequent impulse frequencies up to 100 Hz, the meteorological information on their origin and propagation conditions – like a kind of code. These impulses can be displayed after suitable electronic filtering and are known in the technical literature as CD sferics a.t.B. (CD = convective discharge, i.e. created in atmospheric convection or turbulence without luminosity; a.t.B. = according to BAUMER). They gained special significance, however, at the beginning of the eighties in the context of industrial four-colour copper gravure printing. In this context, their highly differentiated effectiveness in the diffusion capability of bio-chemical biological membrane systems, in dependence on characteristic weather processes, was also shown.

The signals of visible lightning, occurring over the period of the main lightning discharge comprising of virtually uninterrupted sequences of such EMP's, together showing impulse periods up to tenths of seconds with a continuous spectrum into the MHz range, are a strictly different phenomenon.

As such, however, they are suitable as a special weather or thunderstorm signal for the animal and possibly the plant world, i.e. for any organism fitted with the corresponding reception sensors.

Sferics or atmospherics of the various kinds could therefore deliver an almost complete picture of the weather of the day, including prognostic clues, for a biological strategy, considering that the sferics propagate from a weather front at the speed of light and are travelling for hundreds of kilometres, always clearly recognisable as encoded weather to those who have the reception sensors. This can be proven by the example of the reactions of the biochemical membrane system of dichromate gelatine. Also: throughout evolutionary time, both the constant impulse frequency spectrum of the CD sferics a.t.B. and the

daily excursions, constant in their climatological average, have provided a wealth of precision information on the meteorological and geophysical environment to those equipped with the receptors for the signals and the experience; which is more than today's weather services can achieve with the most modern high-tech equipment." (End of the contribution by Walter Sönning).

Animals have a typical electrical charge pattern for each weather phase. Since all movement of charge is associated with forces, animals can analyse the approaching weather via the electrical quantities, even long before the arrival of a thunderstorm.

As a function of special electrical weather events, the bodies of the animals are therefore affected through a complicated interaction of different components: charged, reverse charged, discharged, dielectrically polarised. Polarisation is by a natural electrical DC field. It can be shown that animals are slowly electrically charged in good weather, whilst approaching thunderstorms cause a rapid discharge due to a high concentration of small ions in the atmosphere and charging changes rapidly between positive and negative as the thunderstorm approaches.

Insects such as bees receive these oscillations and recognise them as storm warnings. We were able to show that bees return in great numbers when these oscillations are simulated and transmitted, using a highly amplified signal generator signal. If the amplitudes of the artificial oscillations overlap with the natural signals, however, the return rate rapidly decreases. The bees fail to find their way home.

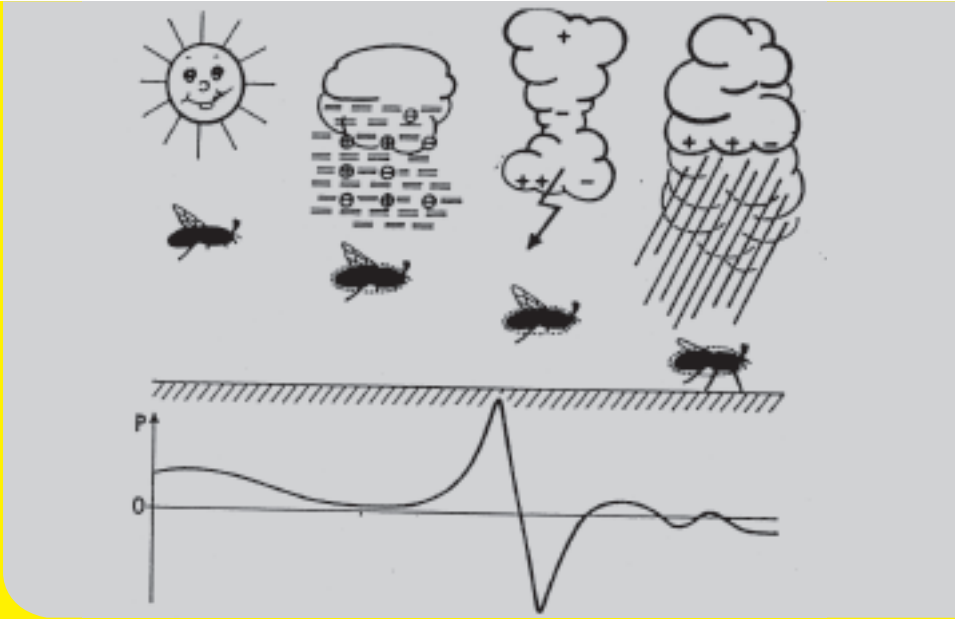

Fig. 2: Top sketch: *The electrical charging of the insects changes typically as the weather parameters change. The bottom curve shows the changes in the electrical field of a freely flying bee as a function of the weather condition.*
Warnke 1989, Copyright Ulrich Warnke

The sensitivity of the honeybee to weather is based mainly on electromagnetic information. When an approaching thunderstorm threatens the bees, flying bees return en masse when the natural 10 – 20 kHz component of the sferics activity increases within a radius of approx. 200 km (WARNKE 1973). The suction performance of the bees also correlates with the approach of the front and the associated sferics (SCHUA, 1952).

And ultimately, bees even use the receptor channel for electromagnetic waves for communication. Russian researchers found in 1975 already that bees generate electromagnetic signals with a modulation frequency between 180 and 250 Hz as they perform their communication dance. Hungry bees react to the frequencies by holding their antennae erect (ESKOV et al. 1976).

Such electromagnetic communication impulses of the antennae when touching another bee can be measured with an oscilloscope (WARNKE, 1989).

Some bird species, such as carrier pigeons, are sensitive to exactly the same electromagnetic oscillation amplitudes as the bees. Birds, particularly species of duck, also communicate by means of electrical fields (WARNKE, 1989). This interesting aspect will be dealt with in more detail below.

3.5 Humans are also sensitive to weather through electromagnetic pulses

The interest in sferics and their effect was greater in the sixties than it is today. In those days, a number of valuable overviews were compiled of their effects on the organism (REITER, 1960; ASSMANN, 1963).

Mammals and man are also influenced by sferics.
Sferics impulses change the tissue pH independent of the amplitude of the field. This is true in the minimal field strengths occurring in nature and also in the laboratory with simulated impulses and increased field strengths. Especially in the frequency band between 2 and 20 kHz, in which the energy of the atmospheric-electrical waves is at a peak, the effect is the strongest. Pain associated with amputations and with brain injury also correlates with the presence of sferics both in the laboratory and in nature (REITER, 1960). The paper by Reiter also contains notes on the triggering of bronchial asthma, heart and circulatory disorders, insomnia, headaches, glaucoma, gall and urinary convulsions, heart attacks and strokes – among other by sferics.

Reiter, R. 1960 Meteorobiologie und Elektrizität der Atmosphäre. Akademische Verlagsges. Geest & Portig, Leipzig

It has been known for a long time that certain weather conditions give rise to thromboses, heart attacks and embolisms; the correlation is statistically significant (ARNOLD, 1969; BREZOWSKY, 1965). A significant increase in platelet adhesion could be shown with certain electromagnetic oscillations such as those generated by exchange of electrical charge in the frontal regions of the atmosphere. These longwave sferics easily penetrate into buildings. The mean impulse repetition frequency is in the region of 5-15 imp/sec, i.e. in the biologically active window. Thrombocyte adhesion was measured in subjects in a controlled laboratory study using a sferics stimulator (JACOBI et al. 1975). The result was a highly significant ($p < 0.0005$) increase in adhesive property at a carrier frequency of 10 kHz and an impulse repetition frequency of 10 Hz. The thrombocyte adhesiveness was reduced at repetition frequencies of 2.5 and 20 Hz and with no electrical signals. Pharmaka (75 mg Dipyridamol plus 300 mg Acetyl salicylic acid) prevents sferics-related thrombocyte adhesiveness. Mentally unstable subjects were more affected by the change in adhesiveness than stable ones.

The daily work performance is also correlated with diurnal sferics activity (RANTSCHT-FROEMSDORF, 1962).

After further investigation by Jacobi (1977), the physiologic detector location was found to be in the head. If the head is largely screened from sferics, the thrombocyte adhesiveness disappears under otherwise equal experimental conditions – a result that is not in agreement with the effects of screening found by other researchers.

The fundamental sferics frequency is 7.5 Hz, considering the speed of propagation of the electromagnetic oscillations generated by the lightning discharge and the resonant path given by the circumference of the earth between the earth's surface and the ionosphere. The bandwidth of the fields is several kHz.

The correlation between heart attacks and weak magnetic field variations has been described in 1979 in Nature, one of the foremost scientific magazines.

This result is not an isolated case. Other experiments even found a correlation between the average number of deaths and earth's magnetic activity.

3.6 Bees transmit electrical fields

Electrical fields with high amplitudes are always in evidence when the unipolar charge accumulations creating the fields cannot be repeatedly neutralised. Charges are easily neutralised when they are highly mobile.

All land-based insects with rigid body shells (cuticula) and also animals with scales, shields, feathers and hair have used these structures to form surfaces that have excellent electrical insulating properties. These body parts have semi-conducting properties and are piezo-electric and pyro-electric – distortion and temperature changes therefore both create electrical effects. The conductivities are therefore subject to the well-known laws of semiconductor theory: temperature changes, light effects, microwave effects, changes to atmospheric ion concentration – all these parameters change the conductivity pattern.

The areas of different conductivity can be shown in a visually impressive way – demonstrated here on a bee's wing - by using a scanning electron microscope with sample current imaging.

In terms of electrostatic charging, it is also important whether the animals are in flight or on the ground. Animals having sweat, scent and adhesion glands afford excellent galvanic contact. Animals walking on hoofs, toes or claws are largely isolated from earth, however.

There is a salient point about different insects. Flies, bees and others have a glandular adhesive pad (arolium) between two toes on their feet. This adhesive pad can be folded in or folded out when walking.

When the arolium is folded in, the animals walk on their claws, insulating them electrically from the environment allowing them to get statically highly charged up. If the arolium is folded out and touches the surface on which it is walking, however, the in-

sect is instantly discharged, assuming the electrical potential of the surface. In bees, this happens just prior to taking off from a flower, in which case certain parts of the animal are discharged or obtain a different charge or sometimes even reverse polarity. Since flowers normally are at earth potential, the "arolium switch" effectively standardises the insect's potential to zero. When the bees arrive at the hive, they carry different charges that they picked up in flight and that cannot dissipate that fast (WARNKE, 1977).

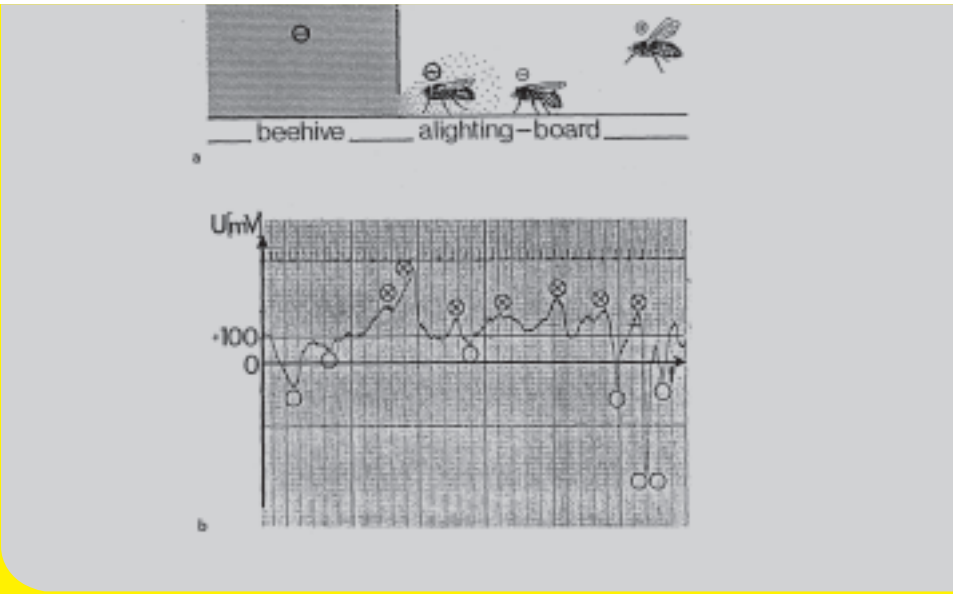

Fig. 10: *Every bee landing at the hive carries a specific charge (circle with cross) thereby changing its pattern of charge at the hive entrance, determined by the total electrical charge of the colony. Every departing bee carries with it electrical charge from the hive (circle).*
Warnke 1989, Copyright Ulrich Warnke

When two surfaces make contact on the molecular level (10 to the power of minus 10 m), positive and negative charges are separated at the point of contact through charge transfer. Many such points are activated in a short space of time by friction. Frictional electricity is one of man's oldest observations and has lent its name to the entire electrical discipline (electron: Greek for amber). It is therefore surprising that we thus far hardly spared a thought for the significance of electricity in animals.

Especially in flight, animals could become statically highly charged through friction between air molecules and body tissue – up to electrical field strengths in excess of 1 000 V/cm.

To increase these field strengths, animals have various aids such as protruding spikes on insect wings, but especially the field focussing effect of insects' antennae is measurable, developing appreciable Coulomb forces.

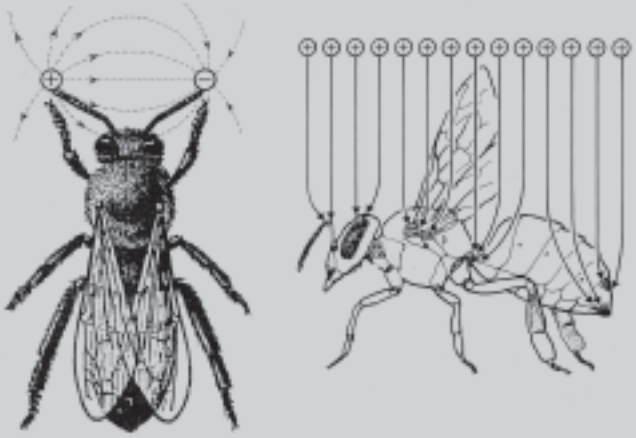

Fig. 14.1: *Representation of a measurable "dipole effect" on the antennae of the honeybee. Bees are able to change the polarity of their antennae at will (e.g. from positive to negative charge) – within a second. The dotted lines are an indication of the forces in the field.*

3.7 Effects of technically generated fields on bees

We investigated the reaction of bees to artificially created electrical fields in the laboratory (WARNKE 1975, 1976, WARNKE et al. 1976) and found the following: 50 Hz AC fields with field strengths of 110 V/cm cause significant restlessness of the bees in their enclosure. The colony temperature increases greatly. The defence of the social territory is uncontrollably increased to the point where individuals in a colony stab one other to death. They no longer recognise one other.

After a few days in the field, the bees tear their brood from the cells; no new brood is reared. Honey and pollen are also depleted and then no longer collected. Bees that were newly established in their hives shortly before the start of the experiment always abandon the hive again and disappear when the electrical field is switched on. Bees that have lived in their hive for a long time, plug all the cracks and holes with propolis, including the entrance. This otherwise only happens in winter in a cold draught.

Since an acute lack of oxygen develops when the cracks and the entrance are plugged, the bees attempt to introduce air by intensive fanning. In this process, the wing muscles generate temperatures high enough to melt the wax. The animals attempt to fight the temperature increase by more fanning. In the end, the colony burns itself out. This implies the death of all members of the colony – which we could obviously prevent in future.

With very sensitive colonies, the reaction signal was measurable from field strengths of 1 V/cm and frequencies between 30 Hz and 40 kHz. When the field is switched on, the animals suddenly move their wings and buzz at frequencies of 100–150 Hz (WARNKE 1973, 1976, WARNKE et al. 1976).

With signals in the frequency range of 10 to 20 kHz, the aggressiveness was increased and the homing ability much reduced even though the natural meteorological and electromagnetic environment was intact in the flight space (WARNKE, 1973).

Fig. 15: *Wing section of bees enlarged with scanning electron microscope. Observe the special structures serving to focus the electrical field.*
Warnke 1989, Copyright Ulrich Warnke

Scientists from the University of Koblenz-Landau conducted several experiments, looking at different aspects and questions, to measure the homing behaviour of bees (Apis mellifera carnica) as well as the development of mass and area of the combs under the influence of electromagnetic radiation (KUHN et al. 2001, 2002, STEVER et al. 2003, 2005, HARST et al. 2006).

They recorded an increase in agility, an increased swarming drive and no winter clustering when under the influence of EM radiation of cordless telephones.

In other experiments with base station fields of the DECT cordless telephones (1 880-1 900 MHz, 250 mW EIRP, 100 Hz pulsed, 50 m range, permanent exposure), the weight and area development of the colonies was slower compared to the colonies that were not exposed to a field.

The homing ability of the bees was tested from five days after the DECT telephones were introduced. There were significant differences in the return times of the colonies that were in the field and those that were not. No more than six of the bees exposed to the field ever returned – sometimes none returned. With the bees not exposed to a field, there were returning bees at any point in time of the experiment.

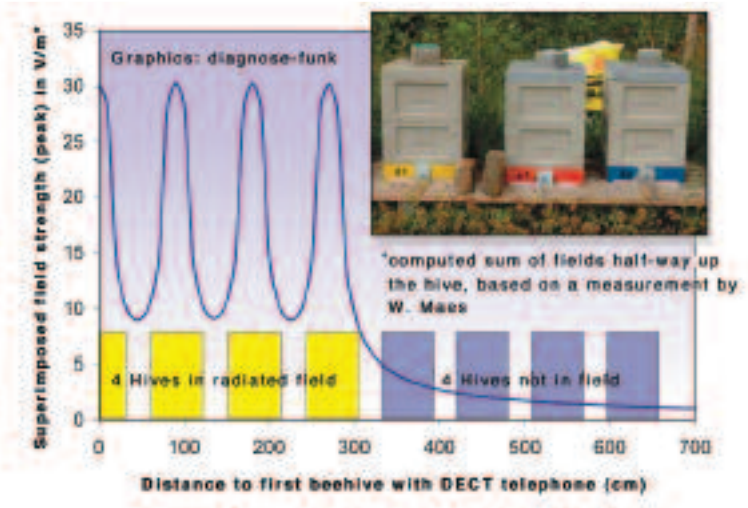

Fig. 16: *Estimated diagnosis radio field strength in the four beehives with and four without DECT telephone installations at the University Koblenz-Landau. The beehives were not electromagnetically screened, implying that the control colonies were also subjected to some field strength.*

Harst et al. 2006

Two earlier NASA financed studies by one of their working groups found neither an increased fatality rate of bees in high frequency fields (2.45 GHz, CW) nor diminished orientation (WESTERDAHL et al. 1981a/b).

3.8 The highly sensitive region for interference of bees

If a new food source is discovered within 80-100 m, the bee performs a circular dance on the comb in the hive. If the food source is further away, communication is by means of a waggle dance. This waggle dance of the honeybee communicates information on the direction and distance of the new food source relative to the hive. In this dance, the returning worker bee initially traces a straight line and then dances sideways and down in a semi-circle. She then again starts along the straight and dances a semi-circle downwards again, but to the opposite side. The distance to the food source is given by the number of deflections of the abdomen on the straight (waggling). These waggles can also be measured in the form of electrical and magnetic alternating fields.

The distance to the food source is registered by reference to optical features of the landscape over which the bees are flying. The information on the direction to the food source is given by the angle between the straight line to the food source and the azimuth of the sun in each case. This angle is conveyed in the darkness of the hive via the direction of the dance with respect to the vertical (gravitational vector).

All this can be proven. The credit for discovering this evolved strategy of bee communication goes to the Austrian Karl von Frisch (FRISCH von, 1967). But we know in the meantime that the communication processes are associated with far more complicated mechanisms.

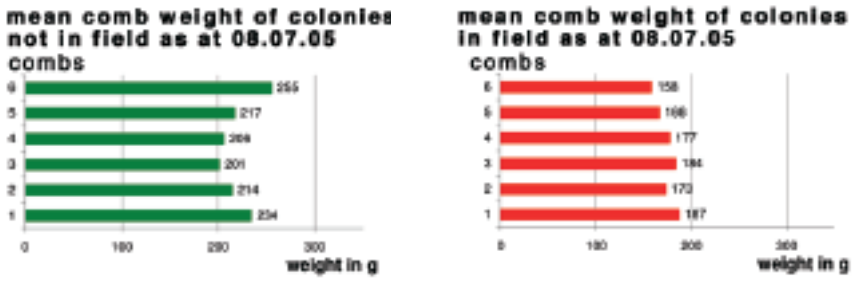

Fig. 20: *Starting with the same comb mass, the average values of the total mass of the colonies subjected to a field and those that were not, were 1326g and 1045g at the end of the test. The difference is therefore 281g (21.1%)*
Harst et al. 2006

Warnke 1989, Copyright Ulrich Warnke

Apart from the position of the sun, the bees can also identify polarisation of the light. And in case of overcast skies, the positions of permanent landmarks are memorised (DYER, 1981).

Navigation to the food sources and back to the hive makes use of other physical quantities, however: these are exactly those quantities that have existed on the surface of the earth for millions of years –taking us back to our subject. How does the bee know the azimuth of the sun at any given moment?

She needs this information to recognise the time of day. And she needs to know about time because many flowers only open at a particular time of day and because navigation is coded via the position of the sun.

The answer to this question illustrates how finely nature has analysed the naturally occurring energies and forces, making these available to the organism. The higher the sun in the sky, the more the atmosphere heats up. The higher the atmospheric temperature, the faster the atmospheric molecules move. The faster the molecules, the more energetic the collisions between them. The larger the collision forces, the larger the air volume and the more intense the turbulences manifesting themselves also as eddies. These eddies ultimately also affect the ionosphere. The increased movement of ions in the ionosphere generates huge electrical currents. These directional electrical mass-flow currents in turn generate strong magnetic fields.

These magnetic fields reach the earth's surface and have a typical diurnal pattern – analogous to the described effect of solar radiation. They are characteristic diurnal magnetic field variations, superimposed on the largely uniform magnetic field of the earth. Exactly these variations can be measured by the bees. And they use these measurements to calculate the azimuth of the sun and the time of day.

In the experiments on navigation and orientation, this magnetic field component is recognised as a so-called "precision error" in the performance of the waggle dance. The expression "precision error" was created when a deviation of the dance direction from the principle described above was noticed, but the influence of the magnetic field was as yet unknown. Since a few decades we now know: the reason lies in the consideration of the magnetic field variation which modulates the direction angle of the waggle dance (KIRSCHVINK, 1981). The "remaining precision error" in the dance disappears if the entire magnetic field is compensated to 0-4%.

The maximum sensitivity of the bee to earth's magnetic variations is around 26 nT. It must be emphasised here already that the system is particularly sensitive in the naturally existing physical range. Significantly amplifying the magnetic field compared to the normal biological range, causes a stronger variation in direction communication. If the field is amplified to 10-times that of the earth's magnetic field, the colony swarms, away from its hive.

The question of how bees sense these magnetic field variations has been investigated in a number of studies (GOULD et al. 1978, 1980, GOULD 1986, FRIER et al. 1996, HSU et al. 1994, KALMIJN et al. 1978, KIRSCHVINK 1992, KIRSCHVINK et al. 1981, 1991, 1997, WALKER et al. 1985, 1989 a/b/c, COLLETT et al. 1994).

To summarise, it may be said that (HSU et al. 2007): The construction of combs and the homing capability of bees change if the bees are subjected to magnetic fields superimposed on the earth's magnetic field. Bees in free flight can sense extremely slight variations of the magnetic field intensity - in the range of 26 nT. They can be trained to magnetic anomalies, but only provided the changes remain stable for a longer period.

Many experiments proved that an accumulation of bio-magnetite particles (Fe_3O_4) serves as receptor of the magnetic field. These iron granules are arranged in a band in the abdomen of the bee. They have a diameter of only about 0.5 µm and are located in special cells, the trophocytes. Magnetite has the effect of amplifying the magnetic variations. If 30% of the intensity of the horizontal earth field component is modulated, the activity of the neurons in the ganglion of the abdomen changes (SCHIFF, 1991).

Apart from super-paramagnetic magnetite, FeO-OH was also found in the abdomen. Magnetic material was also shown to be present in the antennae, head and claws of stingless bees.

The iron granulates are enclosed in small vesicles, touched by a cell framework. As in higher organisms, microscopic filaments (micro-tubules) serve as the cell framework. The vesicles also contain some phosphorus and calcium together with the iron. The density of the iron granules is 1.25g/cm³, that of the Fe_3O_4 magnetite is 5.24g/cm³.

Where does the magnetic material come from? Most of the iron originates from pollen (approx. 0.16 µg/mg) (BOYAIN-GOITIA et al. 2003). If an additional magnetic field is applied to the bee, the size and shape of the biomagnetic granula changes (HSU et al. 2007). These changes are detected by the micro-tubules and micro filaments, and the trophocytes thereafter secrete more Ca^{2+}. The fat cells of the bee also show this effect, but much less so than the trophocytes. It has been known for a long time that cells secrete Ca^{2+} under the influence of a weak magnetic field; macrophages, for instance (FLIPO et al. 1998), astrocytoma cells (PESSINA et al. 2001, ALDI-NUCCI 2000) and chrome-affine cells (MORGADO-VALLE et al. 1998).

It is also known that the Ca^{2+} secretion can be triggered by many different cell changes such as changes to the structure of membranes, changes to the electrical membrane and cell surface potential and changes to the structure and distribution of protein within the membrane. The magnetic field can stimulate two mechanisms for increasing the Ca^{2+} content in the cells: firstly by opening Ca^{2+} channels and by increased flow of external molecules into the cell; secondly by an increased release of Ca^{2+} from storage inside the cell (IKEHARAA et al. 2005, PETERSEN 1996). This explains the increased accumulation of Ca^{2+} in fat cells.

The magnetite mechanism amplifies the effects tremendously (SCHIFF, 1991). The property of the granules, to expand in an external magnetic filed, turns them into magnetic field sensors (TOWNE et al. 1985). The affected micro filaments make contact with the cell membrane (HSU et al. 1993, 1994), affecting signal transfer into the cell.

If the colchicine and latrunculin B toxic substances, known to shut down the micro-tubules and micro filaments, are administered, then an additionally applied magnetic field will not increase the Ca^{2+} in the cells.

A model of the magnetic field orientation is therefore as follows: If the bee flies parallel to the magnetic field lines, the magnetic granule vesicles will expand; if she flies vertically to the field lines, the granules contract. This change of shape is sensed by the cyto-framework and communicated to the membrane.

That is where Ca^{2+} channels are correspondingly opened or closed. This signal transfer results in a

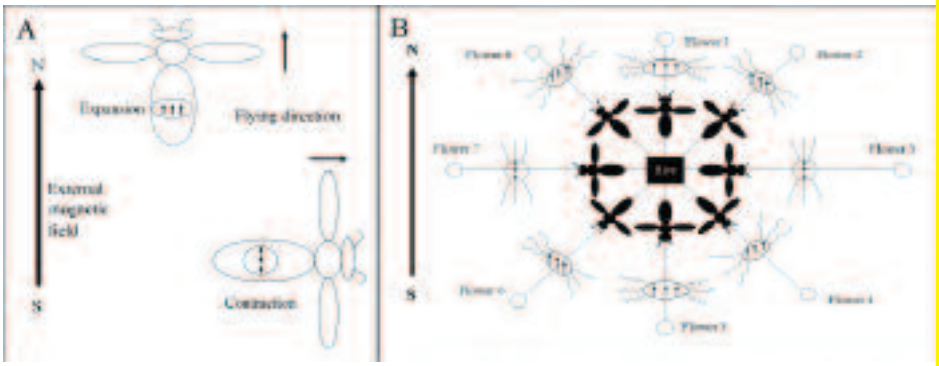

Fig. 24: Schematic of the magnetic field orientation of a bee through use of the magnetic granules.

magnetic field map for the duration of a flight, that can be used for orientation – particularly also for returning home, by reversing the time sequence of the magnetic field (RILEYet al. 2005, MENZEL et al. 2005). It is extraordinary that, in this process, variations of 26 nT can be sensed against the background of earth's 45 000 nT.

This model explains:

1. *The flight from the hive to the food source must be in a straight line. Bees navigate by means of a memory map (RILEY et al. 2005, MENZEL et al. 2005).*
2. *During the known circular orientation flights, the magnetic field is mapped over 360°. It is known that the orientation flight is indispensable for successful return to the hive (BECKER 1958, CAPALDI et al. 2000, WINSTON 1987). Nature arranged this similarly to the pigeons, who also circle several times before flying to wards their goal.*

3.9 Constant change in the magnetic environment makes learning impossible for the bees

Bees learn the patterns of the landscape they fly over and also use the magnetic field to differentiate. This is always the case when other orientation aids such as sunlight are covered by clouds. The optical patterns are therefore also associated with a magnetic coordinate (FRIER et al. 1996).

Bees may be conditioned to magnetic deviations from the normal earth magnetic field (WALKER et al. 1989a); they can also be trained to recognise small changes in the earth's magnetic field (WALKER et al. 1989b). It is a prerequisite that the change in the magnetic field remains constant over the learning period. If the field varies continuously, learning becomes impossible.

But this is exactly the situation the bees find themselves in, with wireless communication fields. The magnetic component is continuously changing – during the day and at night.

3.9.1 HAARP changes the natural diurnal variation of the magnetic fields

The information on the HAARP project is thanks to Guy Cramer (USA); it was made available to me by Joris Everaert (Belgium).

HAARP (High-frequency Active Auroral Research Project) is the abbreviation for a military project of the US Air Force and Navy. 180 towers have been erected in an uninhabited area near the city of Gakona in Alaska, together constituting an antenna complex. The frequency is around 2.5-10 MHz and the power is extremely high at 3 million Watt ("high power, high frequency phased array radio transmitter"). This is the strongest technical transmitter on earth. Its effectiveness is increased by linking the antenna array with another antenna array in Alaska, via HIPAS (High Power Auroral Stimulation). The transmitters communicate with submarines deep in the ocean and scan the horizon as a type of deep earth radar.

But the frequencies are also absorbed by the ionosphere. They heat up certain layers, creating ion turbulences by day, that are modulated onto the earth magnetic field as unnatural magnetic fields. This masks the regular effects the sun has on the ionosphere. As such, the bees lose an orientation that served them for millions of years as a reliable indicator of the time of day – encoded in the regular variations of the magnetic field changes as the sun rises and the ionosphere temperature rises.

The effects of the HAARP transmitter activity should be further investigated especially in Canada, the USA and Europe. Since the disappearance of the bees was first documented in precisely these countries, a causal relationship can no longer be excluded. The following simultaneous events tend to confirm this: In 2006, the increase of the transmitting power from 960 000 Watt to four times that power (3 600 000 Watt), was approved for the first time. Exactly in this year, reports originated in all the "scanned" transmission regions of the disrupted homing ability of bees.

Another disruptive effect may play a role. Through the irregular heating of the ionosphere, the air at great heights begins to "glow", with visible frequencies in the near infrared region (630 nm) and the associated magnetic field can be detected at the earth's surface (PEDERSEN et al. 2003, RODRIGUEZ et al. 1998).

Since the bees use not only the UV component of sunlight for orientation, but also the longer infrared wavelengths (EDRICH et al. 1979, VAN DER GLAS 1977) the new light in the sky may also be a new disrupting stimulus to them.

Fig. 25: *HAARP location and construction.*

3.10 Disrupted NO system damages learning ability, olfactory orientation and the immune system

In following, we will further detail the significance of the (NO) system and the consequences of its disruption – in other experimental animals and particularly also in humans. The salient fact is that the NO system is affected by magnetic and electromagnetic oscillations and may in the worst case become totally disrupted - finally destroying molecular functions.

As in mammals, nitric oxide (NO) normally acts as a carrier of information in insects as well. The synthesis and excretion of NO is particularly high in the insect brain. In bees, NO plays a role in the ability to smell and in learning processes (MÜLLER, 1997).

As proven in humans, if the NO system of bees is disrupted through the effect of technical magnetic fields, they lose the ability to orientate themselves by smell and the vital learning programme also becomes defunct. But since NO also materially controls the immune system, disruptions to the NO household always affect the immune defences of the organism as well.

Dennis van Engelsdorp of the American Association of Professional Apiculturists (University of Pennsylvania), in his report on the investigation into the disappearance of bees, says:

"We have never seen so many different viruses together. We also found fungi, flagellates and other micro-organisms. This multiplicity of pathogens is confusing." It is also striking that the excretion organs of the bees are affected. Dennis van Engelsdorp suspects that a weakened immune system may be behind the mysterious phenomena (VAN ENGELSDORP 2007). But he rightly asks: "Are these agents the causative stress factor or the consequences of a totally different stress?"

Diana Cox-Foster, a member of the CCD working group, says: *"It is very alarming that the deaths are associated with symptoms that have never been described before".* It appeared that the immune system of the animals had collapsed and some bees suffered from five or six infections simultaneously. But dead bees are nowhere to be found (Spiegel 12/2007).

3.11 Birds sense high frequency transmitters

Birds also sense high frequency transmitters very clearly and belong to the group of animal species that reacts very sensitively to electromagnetic fields. They absorb the impinging energy particularly intensively via the feathers of their wings (CHOU et al. 1985, VAN DAM et al. 1970, BIGU-DEL-BLANCO et al. 1975 a/b).

How sensitively and promptly they react can be demonstrated by an example. Chicks exposed to a high power microwave field flee within seconds (TANNER, 1966). Investigations have, in particular, also shown how strongly microwave radiated fields affect the behaviour within a flock (WASSERMANN et al. 1984). It has repeatedly been observed that flocks of migratory birds split up when nearing a power station, to circumvent the station as if avoiding an invisible obstacle, only to re-unite again in flight afterwards. Technical disturbances in the frequency range of natural sferics, but with higher amplitudes, cause massive loss of orientation in migrating birds. The V-formation of cranes, for instance, is disrupted as they fly over transmitter stations. This phenomenon is particularly pronounced over water surfaces parallel to the flight path, which reflect electromagnetic waves.

Researchers have for a long time been pondering on how flocks of birds and also insect swarms and schools of fish stay together. It is surprising, for instance, that large flocks of starlings in an area of an estimated 500 m^2 or more, packed with birds, can perform complex flying manoeuvres within 5 milliseconds. But how can the animals, each at a different location in the flock, receive and react to signals in a short time? Transmission by sound would require more time and visual observation of a lead animal is blocked by other animals.

A hypothesis that the flying manoeuvres were coordinated by electromagnetic signals therefore appeared reasonable. Such a signal, propagating at approximately the speed of light, could reach all individuals at the same time and independent of their position. This hypothesis appears more plausible when taking into consideration that the flying animals are highly electrostatically charged.

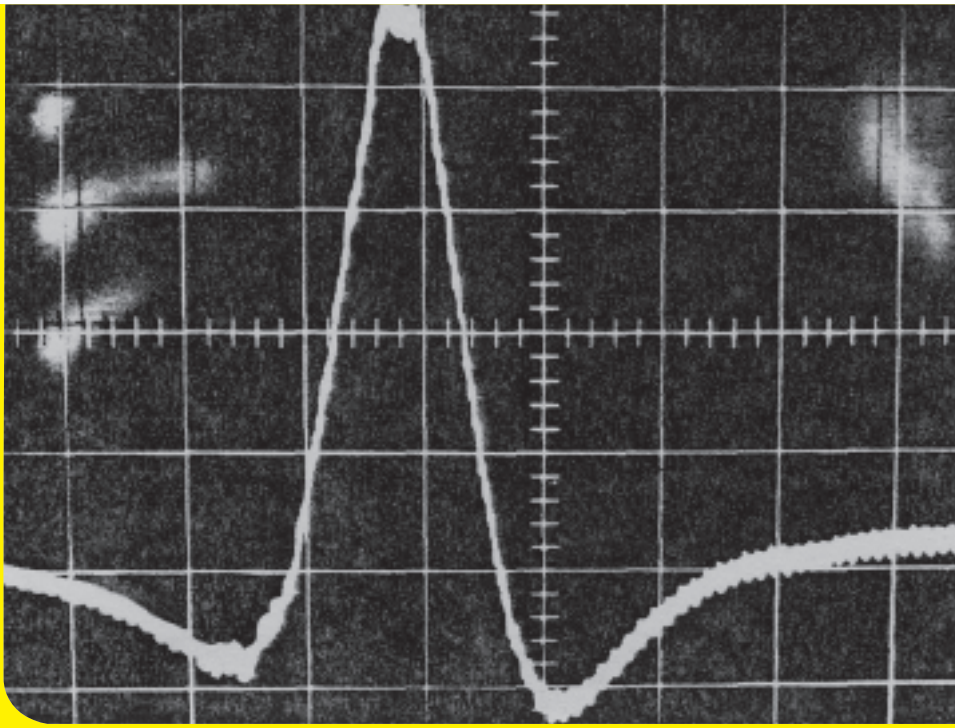

Fig. 26: *Electrical field of a passing flock of birds. The small superimposed oscillation is interpreted as interference by the beat of individual wings.*
Warnke 1989, Copyright Ulrich Warnke

We were able to record by oscilloscope that the electrical field caused by the aggregation of animals resulted in a predominantly positive overall electrostatic field. The figure also shows the very small wing beat modulation compared to the total electrical field. This modulation can be explained as a "beat" resulting from all the individual wing beats.

This beat frequency is always smaller than the wing beat frequency of an individual. The maximum beat amplitude is always much larger than the individual wing beat amplitude, however. The measured values are dependent on meteorological conditions and the geometry around the measurement.

These data allow us to conclude that flocks of small birds flying at a height of about 40 metres are electrically charged to more than 6 000 Volt. We can only speculate about the type of coded signals given for direction changing manoeuvres. It appears that each individual bird has a set beat frequency and amplitude that is corrected immediately it weakens, by changing the direction of flight.

There are presently two theories explaining the typical wedge-shaped flight formation of larger birds:

One of these assumes unhindered contact and simultaneously minimum danger of collision. The other relates aerodynamic advantage to energy economy. The first theory is based on experience with formation flying of military aircraft; the second is based mainly on calculations.

Both theories leave a couple of questions unanswered, however. How sensitive is the system to cross-winds? When a critical wind speed is exceeded – should turbulences behind the wings not distort the formation or even break up the flock? Why do the members of the flock not permanently remain in the minimum energy zone? And why is there never a formation in reverse – open to the front? Can the recognisable geometric particularities of the total formation, considering species-specific bird size and typical distances, be explained by wing-induced updrafts?

In the following, our theory of biologically sensible formations, published 25 years ago, is repeated. It describes a functional system of nature that is largely immune to meteorological interference parameters. Electrical and magnetic external fields can, however, completely destroy the formation by superposition on the biological system's own fields.

The system we are discussing allocates a position to each animal, but also considers all the flying members of the formation. It could also be identified by the analysis of formations filmed in nature. Let us inspect some facts in more detail.

Bird species flying in formation generally maintain a typical order, even in the case of only two birds flying:

The second bird flies laterally displaced behind the first. The electrical force relationships in space are in agreement with the electrical forces determined experimentally and depicted schematically in Fig 27. The highest field strengths are at the bill, the tail and the wing tips. Referring to the bird at the back, the bill-head region is charged in the alternating field of the wings of the first bird, creating an increased force field. Simultaneously, however, the wingbeat of the bird at the back induces charges in the tail region or the extremities facing backwards and resting against the body of the first bird. There is therefore a force field between these body parts as well. The respective induced charges are coupled - as shown in the model – by the electrical field. The balancing charges of opposite polarity, released from the former equilibrium, are free to move. They generate an effective new and measurable field. The bird under consideration, i.e. the second one, therefore not only received induced charges from the first bird but also indirectly - i.e. via the tail end of the first bird – originating from itself. The field strength diminishes approximately as the square of the distance from the inducing charges. The magnitude of the active forces is therefore a function of the distances. Each bird is connected to every other bird via electrical fields of a certain amplitude and direction. These fields can be calculated for each species of bird – yielding the typical formation.

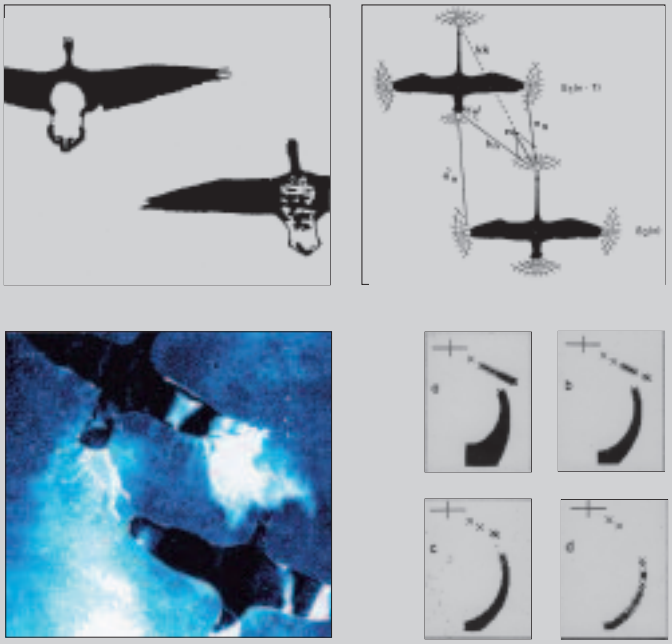

Fig. 27: *Birds use electrical fields for formation flying. Top left: Two geese in formation flight. Bottom left: Experimental model to visualise the electrical field forced between these birds. Top right: Vector diagram of the field distribution. Bottom right: Calculation of the position of the bird behind with reducing degrees of freedom a-d.*

Warnke 1989, Copyright Ulrich Warnke

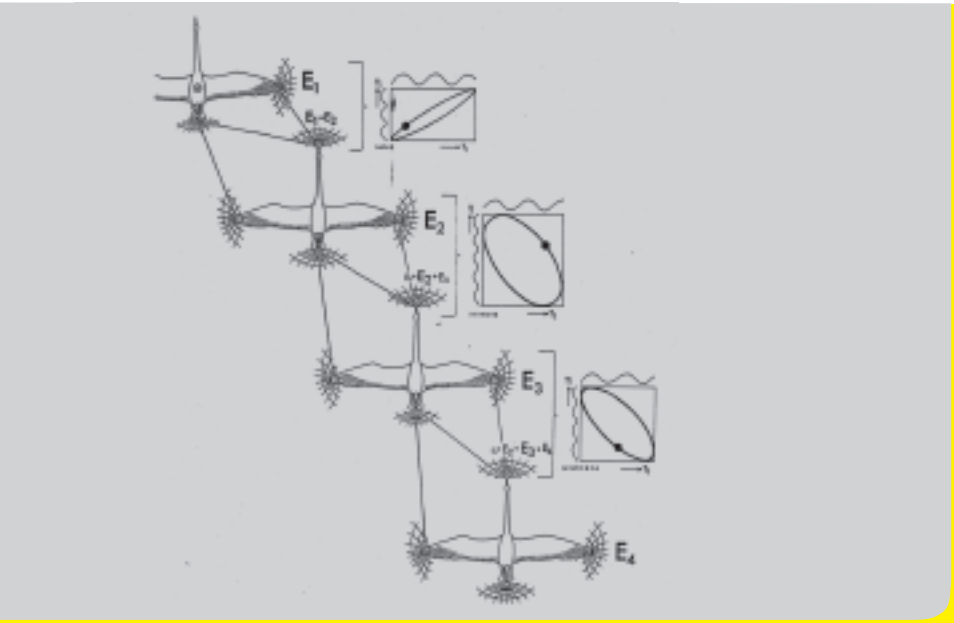

Fig. 28: *V-formations can be constructed by means of an equation that I developed on the basis of physical laws. Comparisons with photographs of natural bird formations show that the assumptions are correct: The formations are given by the Coulomb forces between birds that are electrically charged in flight.*
Warnke 1989, Copyright Ulrich Warnke

It is significant that long necked birds in particular, tend to fly in formation. Their long neck offers the advantage that the detectors in the head region – such as the highly sensitive mechanoreceptors, which also respond to the electrical field forces, can receive signals in flight largely free from the interference of their own body. Observations of their flight behaviour show that the head region compensates for all the movements of the body itself, thereby not having any own oscillations.

Electromagnetic fields therefore have a role to play in formation flying of birds as well. They serve as orientation and navigation aid and determine the position of a single animal in the flock. Depending especially on wing width, wing span and body length, our observations and calculations show that the biophysical relationships influence the species-typical V-formation flying of flocks. Computer calculations of the flight order allow us to predict natural formation flights. And photographic records, vice-versa, also agree well with computer simulations.

The observations demonstrate a unique information and orientation system of the animal kingdom. But they also explain why this is destroyed by the interference of technically generated electrical and magnetic fields.

Due to interference, it would not be possible to measure the magnetic field of the earth inside a flock of birds and its periodic variations caused by the individuals. The reason lies in the moving electrical wing charges, not only generating a weak magnetic field component (induction B approx. 0.01 pT), but also inducing voltages in neighbouring matter – like an AC generator. Only the bird flying at the tip of the formation will perceive a largely undisturbed earth magnetic field component for navigation, independent of changing superpositions - provided it is sufficiently far removed from its compatriots. The remaining animals must therefore do without own navigation mechanisms and couple themselves to the birds flying in front via an electromechanical reception channel.

The birds fly straight ahead, i.e. in the desired migration direction, if the direction of the total electrical force corresponds to the direction of the connection to the head of the bird flying in front. The connecting line between heads is visible by day and can be localised by night through calls.

The recognition of direction and magnitude of the electrical total force vector is by highly sensitive mechanoreceptors at the circumferential edge of the bill. Magnetite was also found here: Through ferromagnetic resonance, magnetite is an excellent absorber of microwaves in the 0.5-10.0 GHz band. Superimposed modulations can be transformed into acoustic vibrations via the magneto-acoustic effect (KIRSCHVINK, 1996).

Correspondence of the direction of the electrical force with the head-head line assigns to each bird a prescribed position in his flock; this position can be mathematically expressed and accurately calculated. All the results of the 22 formations investigated so far confirm the theory. It may be concluded from these data that the birds' electrical characteristics have an important biological function for transfer of information (WARNKE, 1978, 1984, 1986, 1989).

3.12 Magnetite and free radicals as a magnetic compass

Artificial oscillating magnetic fields deny migrating birds the possibility to orientate themselves. The investigation covered the effect of either an electromagnetic frequency band of 0.1 – 10 MHz, or a single frequency of 7 MHz, both superimposed vertically on earth's magnetic field. These investigations again showed that not only magnetite was required for orientation and navigation but that other mechanisms such as free radicals, played an important role as well.

Because the frequencies used in the experiments correspond to the transition energy from singlet to triplet in free radicals-pairs. The animals can obviously utilise this mechanism for orientation by targeted control (RITZ et al 2004).

The following overall picture emerges: The magnetite crystals found in the bill of the animals indicate the intensity of the magnetic field. But the animals receive complementary information on the direction of orientation via the free radical levels. Using these data, they are able to know at each stage of their flight what their instantaneous location is with reference to their biological magnetic field (WILTSCHKO et al. 2005) map.

If migrating birds are subjected to a stronger magnetic impulse, they will change their direction of flight. They can even be sent in the exact opposite direction with artificial fields superimposed on earth's magnetic field. Magnetic impulses convey information on the direction of migration; generated false impulses can also corrupt the migration direction (WILTSCHKO et al. 2006).

Summary

Bees and other insects, also birds, utilise the magnetic field of the earth and electromagnetic high frequency energy such as light. Through free radicals and simultaneously reacting magnetite conglomerates they can orientate themselves and navigate. Technically generated electromagnetic oscillations in the MHz region and low frequency magnetic impulses consistently disrupt the natural orientation and navigation mechanisms they were given through evolution.

The following can be concluded from the results of studies by other working groups and from own investigations:

1. The chitin shell of bees' and birds' feathers are semi-conducting and have piezo- and pyroelectrical properties. These body parts transform pulse-modulated high frequency into mechanical acoustic oscillation frequency. One of its important functions is the dielectric sensitivity to electromagnetic fields in the microwave region.

2. The presence of magnetite particles in the nano-range was shown in the abdomen of bees and the head region of birds. Through ferromagnetic resonance, magnetite is an excellent receiver of microwave radiated fields in the 0.5 to 10.0 GHz frequency range. In this way, pulsed microwave energy is transformed into acoustical vibrations (magneto-acoustic effect).

3. It was shown that free flying bees are capable of detecting magnetostatic fluctuations and extremely low-frequency magnetic fields with very weak inductions (from 26 nT) against the background of the 30 000 – 50 000 nT magnetic field of the earth.

4. Magnetic field impulses oriented parallel to earth's magnetic field lines, with repetition frequencies in the region of 250/sec. are responsible for clear precision errors of up to +10% in the orientation dances of bees.

5. The levels of magnetic induction in today's technically distorted environment are generally between 1 nT and 170 000 nT in the low frequency region and between some nT and a few thousand nT in the high frequency region. These values therefore generally exceed the threshold sensitivity of bees for magnetic field changes.

6. In honeybees, the NO system in the antennae has a function in the sense of smell and in learning processes. Disruptions of NO production through magnetic fields and electromagnetic oscillations have thus far been proven only in mammals. Expectations are, however, that the mechanism of disruption is the same in insects. In this case, the sense of smell and learning processes in the orientation of bees would be severely impaired.

In any event, if all the scientifically proven facts are considered, it is clear why wireless communication technologies, with their overall density of superimposed electrical, magnetic and electromagnetic fields, should disrupt the orientation and navigation of many birds

4. Humans suffer functionality disorders

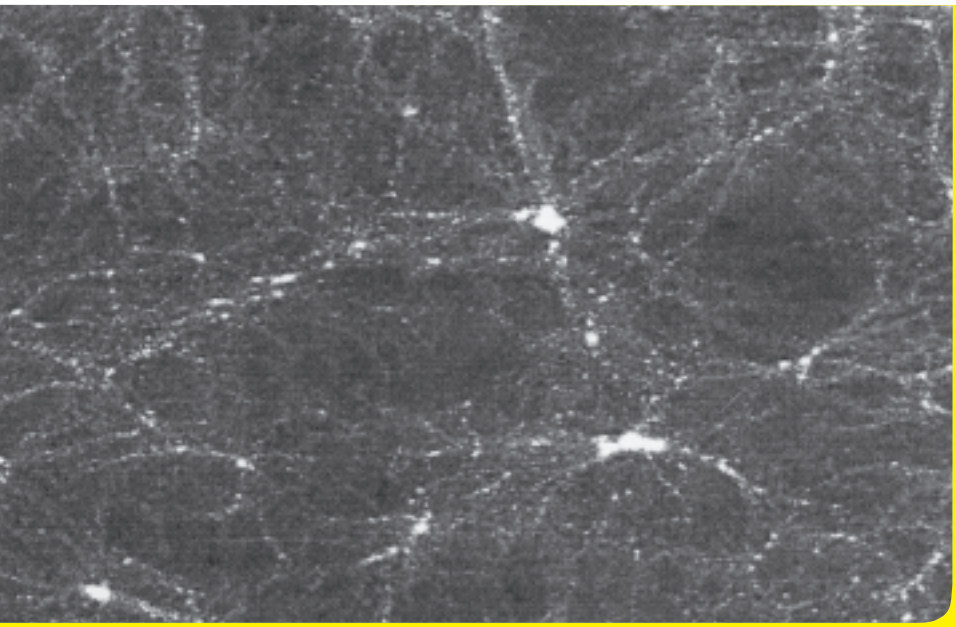

Fig. 29: *All flying organisms and also other animals, including humans, are caught up in an "impenetrable" network of electromagnetic oscillations and fields. The superpositions illustrated in this model result in points of particularly high power density or field strengths.*

Humans do not have sensory organs via which electrical and magnetic energies can be detected. But these energies nevertheless envelop humans as a tightly woven net of electromagnetic oscillations and radiating fields.

We recognised the problem in the seventies already in connection with our bee experiments and called it, in our laboratory jargon, "electrosmog". The name has established itself, also via the media.

It has in the meantime been proven that humans too can transform the specific energies and forces into information, without having a specific sensory organ to do this. But the question up to now has always been: How do they do it? And to what extent can the fields damage our health?

Let us first ask what the direct effect is on humans of the high frequency energy that is spread almost uniformly across the globe for communication purposes, and then investigate whether the subjectively frequently repeated claim that this is damaging our health can possibly be true.

This requires the following steps:

1. **Finding trends:** Do we have scientific literature causally correlating the epidemiologically recorded data on functional disorders and symptoms of disease in a human study group with the exposure to electromagnetic fields in the mobile radio and wireless communication range?

2. **Finding a causal mechanism:** Can a plausible mechanism be found that can explain functional disorders and disease systems as the result of exposure to these electromagnetic fields?

3. **Proof of health disorder and subsequent damage:** Can the function disorder as described be scientifically proven to be the result of subjectively described disease symptoms?

4. **Excluding a nocebo effect** (unfounded expectations that negatively affect health): Do we have sound scientific procedures, such as the double-blind method, showing that the symptoms of illness are not "imaginary" and are generally rapidly reversible after the physical stress fields have been "switched off"?

The answer to these four questions will determine whether subjectively described symptoms of illness can be ascribed to a collective nocebo effect or whether those responsible are required to face consequences.

4.1 On the question of finding trends

Do we have scientific literature causally correlating the epidemiologically recorded data on functional disorders and symptoms of disease of an organism with the exposure to electromagnetic fields in the mobile radio and wireless communication range?

The answer is not treated in detail here, because it has been dealt with on several occasions elsewhere (WARNKE, 2005).

To summarise, it must be noted: There is a body of differentiated scientific literature that identified a causal correlation between epidemiologically recorded data on functional disorders and symptoms of illness of the human organism, and exposure to electromagnetic

fields in the range of mobile radio and wireless communication. We therefore have an unassailable trend result.

4.2 On the effective mechanism

Can we identify a plausible effective mechanism that causally explains functional disorders and symptoms of illness as the result of exposure to electromagnetic fields?

The answer to this question does not only affect humans but analogously also birds and bees in many respects. It exposes an effective mechanism that has attracted our attention on several occasions before: The disruption of the nitrogen monoxide (NO) system. There are probably other effective mechanisms as well. But we shall only differentiate and elucidate the effective relationships of this mechanism at this point.

Nitrogen monoxide (NO) is a gas and free radical (contains unpaired electrons) that evolution has deployed as a regulator of vitality very early already – even in bacteria. This extremely important and indispensable gas is only beneficial to the organism, provided a) a certain concentration is not exceeded and b) there is no degeneration to so-called reactive nitrogens and reactive oxidative species (RNS and ROS) – i.e. no cascade-like release of newly formed free radicals and poisonous substances.

4.2.1 Disruption of the redox balance

The NO system is closely related to the so-called redox system, which is extremely important to our molecular functions. What does this mean? Every organism needs a balanced ratio of electron excess and electron deficiency. This is also called redox balance. Oxygen compounds neutralise electron charges, causing "oxidant stress". Oxidant stress is particularly intensive if free radicals and reactive oxygen species (ROS) (e.g. superoxide anion, hydrogen-peroxide) and reactive nitrosative species (RNS) (e.g. peroxinitrite) largely prevent the antioxidative processes from re-establishing an adequate electron charge.

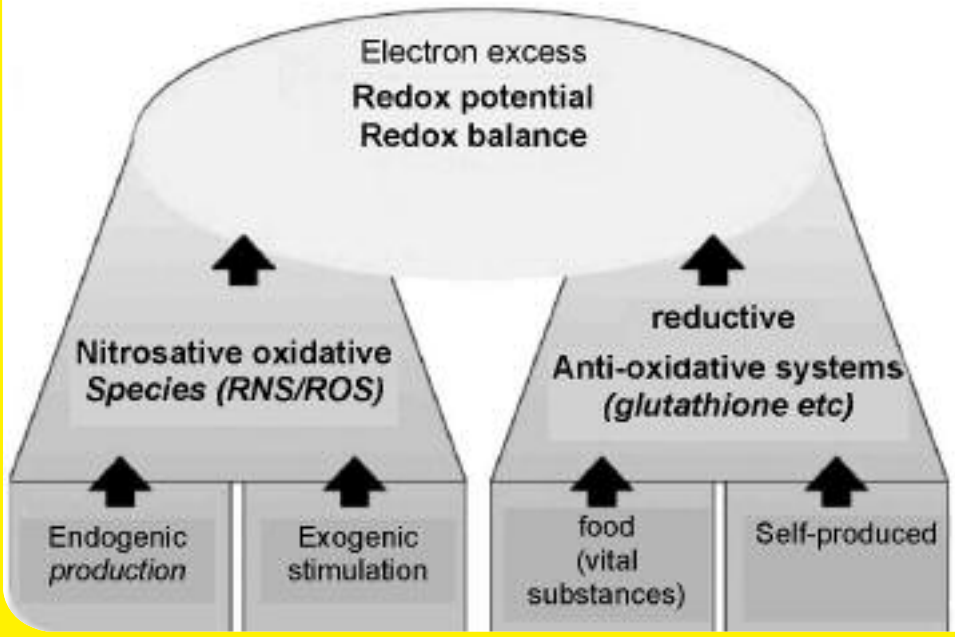

Fig. 30: *Substances with an excess of electrons are indispensible for metabolism if humans and many animals want to remain healthy. Electromagnetic oscillations destroy this electron excess and form nitrosative-oxidative species (RNS/ROS). The situation is fatal to a person if anti-oxidants are also absent in the diet.*

Shifting the redox balance towards oxidation may now result in cell damage. Oxidation may, for instance, damage unsaturated fatty acids, proteins and DNA, but particularly also the membrane – with serious consequences for heredity, energy creation and immune response.

Exposure to electrical, magnetic and electromagnetic fields disrupts the redox balance through oxidant/ nitrosative stress. This can no longer be denied in the face of many in vitro and in vivo experiments – also in humans.

Latest results on the creation of oxidant/nitrosative stress through mobile radio frequencies

Human blood cells exposed to mobile radio in standby mode show increased quantities of free radicals, resulting in lipid peroxidation (MOUSTAFA et al. 2001).

In rabbits and cells of other origin, the activity of the SOD enzyme, which neutralises free radicals, increases when exposed to mobile radio (IRMAK et al. 2002, STOPCZYK et al. 2002).

The damaging oxidative processes and NO are increased in rat brains exposed to mobile radio fields; they can be alleviated again by administering antioxidants (Ginko biloba) (ILHAN et al. 2004).

The damaging oxidative activity is increased in the skin tissue of rats exposed to mobile radio fields; this can be alleviated by administering the melatonin hormone (AYATA et al. 2004).

Acute exposure to unmodulated 930 MHz electromagnetic fields in vitro, increases the oxidant stress level in rat lymphocytes treated with iron ions (ZMYSLONY et al. 2004).

Kidney tissue of rats shows increased levels of free radicals when exposed to mobile radio fields. The damaging effects can be alleviated through various antioxidants (OZGUNER et al. 2005). The destructive effect can be neutralised by administering melatonin hormone (OKTEM et al. 2005).

Heart tissue exposed to mobile radio fields shows an increase in the activity of free radicals. This can be reduced through antioxidants (OZGUNER et al. 2005).

When exposed to mobile radio fields, eyes show an increased activity of free radicals; this can be alleviated through administering antioxidants and melatonin hormone (OZGUNER et al. 2006).

Melatonin can limit the lipid peroxidation caused by 900 MHz mobile radio fields in the hippocampus of rats, but not in the cortex (KOYLU et al. 2006).

When exposed to mobile radio fields of base stations (SAR 11.3 mW/kg), the oxidant stress level increases; the neutralising enzyme activity is simultaneously reduced (YUREKLI et al. 2006).

Compared to controls, the mobile radio signal (GSM-DTX 2W/kg) creates increased oxidative species levels in immuno-relevant human cells (LANTOW et al. 2006).

Electromagnetic high frequencies and magnetic low frequencies create stress symptoms in lymphocytes that are similar, but not identical to heat shock (BELYAEV et al. 2005).

The effect of a 890-915 MHz mobile radio field (with 217/sec. impulse rate, 2 W max. power, SAR 0.95 W/kg) was tested on guinea pigs. The setting was on 11hr 45min stand-by and 15 min talk mode. The malonaldialdehyde (MDA), Glutathion (GSH), Retinol (Vitamin A), Vitamin D3, Vitamin E und catalase enzyme activity (CAT) content in the brain tissue and in the blood was chosen as the effective indicator. The MDA level rose in the brain tissue; the GSH level and CAT activity were reduced. In the blood, the MDA levels increased, as did the Vitamin A, E and D3 levels, and the CAT activity rose. The GSH level simultaneously decreased here as well. The authors conclude from this that mobile radio produces oxidant stress in the brain tissue of test animals (MERAL et al. 2007).

These results are also confirmed for the kidney in a further study (TOHUMOGLU et al. 2007).

Stimulation of the nitrogen monoxide NO free radical by electrical, magnetic and electromagnetic fields, observed for a long time, is of importance in these effects. A chronological listing below:

Electromagnetic and magnetic radiated fields promote the production of nitrogen monoxide (NO) in organisms. A chronological literature compilation

WARNKE 1979, 1980, 1984, 1993, 1994
Weak pulsating magnetic fields create an immediate effect and stimulate NO production in humans.

MIURA et al. 1993
NO increases when a weak field of high frequency radio signals is switched on; measured directly in the brain.

LAI AND SINGH 1996
DNA destroyed through electromagnetic influence; later (2004) traced back to NO stimulation.

BAWIN et al. 1996
Magnetic fields (1 or 60 Hz, 5.6, 56, µT) had no effect when the NO synthase enzyme was pharmacologically inhibited. The effect could, on the other hand, be forced by binding NO to haemoglobin.

ADEY 1997
NO is a normal regulator of EEG rhythms and, in pathological cases, of epilepsy.

Weak magnetic fields (1 Hz, 100 µT), modulate the NO action.

KAVALIERS et al. 1998
A 60 Hz, 141 µT magnetic field affects the NO and NO synthase actions.

SEAMAN et al. 1999 and SEAMAN et al. 2002
Provided the body has sufficient supplies of nitrite, rapid increase of NO production when exposed to radio frequency pulses (SAR of 0.106 W/kg).

ENGSTRÖM et al. 2000
NO plays a role in the pathophysiology of oxidative stress, including Parkinson and Alzheimer disease through electromagnetic impulses.

YOSHIKAWA et al. 2000
A low frequency electromagnetic field increases the generation of NO.

PAREDI u.a. 2001
The production of NO also increases under exposure to the electromagnetic fields of mobile phones.

DINIZ et al. 2002
The increased proliferation of cells exposed to pulsating electromagnetic fields is caused by NO.

KIM et al. 2002
Pulsating electromagnetic fields amplify the neuronal NO synthase expression.

LAI AND SINGH 2004
Inhibitor of NO synthase (7-nitroindazol) blocks the effects of weak magnetic alternating fields (60 Hz, 10 µT).

ILHAN et al. 2004
Frequencies used by mobile radio (900 MHz) cause increased activity of NO levels, increase malondialdehyde, increase xanthin oxidase, decrease superoxide dismutase and glutathione peroxidise - thereby destroying the brain of rats. Antioxidants (Ginkgo biloba) counter this.

YARIKTAS et al. 2005
The NO level in the mucosa of the nose increases when exposed to mobile radio fields (900 MHz).

AKDAG et al. 2007
The long-term effect (2 hours per day for 10 months) of a low frequency pulsed magnetic field on rats reduces the NO production below the nominal values.

It has been known for many decades already that weak low frequency magnetic fields increase the levels of free radicals. It is therefore not necessary to quote further literature at this point.

4.2.2 Primary mechanism found: Enzymes transferring electrons are magneto-sensitive

Stimulation of free radicals – including NO – through physical fields and radiated fields is therefore scientifically and reliably proven. But viewed critically, this is no proof of damage unless the underlying primary mechanism is identified.
For this reason, we searched for a long time for a link to explain the damaging effect. And we have found it in one of the latest studies: The NADH oxidase enzyme exhibits a high – and quite reproducible – sensitivity for magnetic and electromagnetic fields of mobile phones (FRIEDMAN et al. 2007).

This sensitivity had been known for quite some time in connection with other oxidases such as cytochrome oxidase (BLANK et al. 1998, 2001 a/b). For a long time, it was believed that NADH oxidase was active only in certain cells such a phagocytes. But it was known for quite some time that it was sensitive to gravitation (NASA, 2006). In the meantime, homologues of NADH oxidase were discovered in various tissues and were collectively included in the NOX family (NOX1, N0X3, N0X4, N0X5, DUOX1 and DU0X2).

The NOX family is also responsible for a large range of pathological processes, especially neurodegeneration and heart diseases (BEDARD et al. 2007).

These oxidase enzymes are magnetically sensitive due to their capability of shepherding electrons through plasma membranes. When electrons move, an electrical current flows that in turn builds up its own magnetic field and also generates electromagnetic high frequency oscillations through acceleration and deceleration of electron movement. All these processes create sensitivity to external fields.

The electron transfer is finally responsible for the production of superoxide radicals and other reactive oxygen species (ROS). The consequences of this are far reaching in completely different areas, because radicals and ROS are very aggressive. In this way, the destruction of viruses and bacteria is promoted, the creation of proteins is forced through reinforced gene expression and finally cell proliferation is supported at the cost of cell differentiation.

Over-stimulation is a threat. It is analogous to a drug or medicine: Dosed correctly, the substance can be beneficial; but overdosing can be poisonous. This is exactly what happens with permanent exposure to magnetic and electromagnetic fields.

In detail, this process is as follows: It is a fact that the NADH oxidase enzyme also produces the superoxide anion (O_{2^-}°) free radical. Superoxide anion is damaging to the NO budget, among other. NO may be deactivated and may subsequently degrade, negatively affecting various vital parameters (WARNHOLTZ et al. 1999).

What is new is the realisation that NADH oxidase also forces the generation of NO by stimulating the eNOS enzyme (SUZUKI et al. 2006, RACASAN et al. 2005). This stimulation of eNOS then becomes a further source of increased superoxide anion radical generation (SEINOSUKE et al. 2004). This is not the end of the list in this fatal loop of overstimulation, because the NADH oxidase system also stimulates the formation of toxic hydrogen peroxide (H202), which also increases NO production by up to 100% (LI et al. 2002). These two additional NO stimulants explain the abovementioned increased NO production under the influence of magnetic fields and electromagnetic radiated fields – also through mobile radio communication.

But this is the start of a vicious circle. Because overstimulation of the eNOS enzyme, that in the final analysis is also an agent for increased NO production, also increases superoxide anion radicals on its own (SEINOSUKE et al. 2004). Nature, however, also has a cleverly devised countermeasure against excessive and dangerous NO production threatening overproduction of a radical: The more stimulated hydrogen peroxide, which also increases the NO production, is an agent for de-activating eNOS co-factors, which finally prevents the NO production by affecting the membrane receptor (JAMES et al. 2001). Such a reduction of NO has also been found before under long-term exposure to stronger magnetic fields (AKDAG et al. 2007). Even if the NO now appears to be regulated, the damaging effects of ROS remain intact.

The real pathological effects arise afterwards. We have to consider, in addition, that both the NO and ROS, which includes superoxide anion, are important modulators of the vascular tonus and are architects of the adhesive interaction of leucocytes, platelets and endothelium. The two molecules of NO and of superoxide anion, however, have opposite effects: NO is normally beneficial in a healthy life cycle; ROS, however, prepares the system for special regulation when disruptions occur.

The functions are thereby flexibly adjusted. This allocation of functions disappears, however, under the influence of an external magnetic and electromagnetic field: NO and ROS now react together. In this event, their specific effective potential is destroyed and toxic substances are created, such as peroxinitrite (0N00-) (MÜNZEL et al. 1999). This peroxinitrite in turn reacts with hydrogens, creating more hydrogen peroxide.

Because this mechanism is so important, we shall summarise it in one sentence: The serious pathological disruption is caused by exposure to magnetic and radiated fields resulting in the creation of additional reactive oxygen species (ROS) such as superoxide radicals and hydrogen peroxide, that combine with the increasingly produced NO to form extremely toxic peroxinitrite, that in turn reacts with hydrogens to form more hydrogen peroxide. The consequences of the pathological process are listed further down.

Many vital substances, required for functioning of the body, are rendered useless.

If the cascade of effects is disrupted, the normal and healthy effects of NO are restored (HORNIG et al. 2001).

The NADH oxidase is important in another sense as well. It is also found in the cell nucleus where it can – depending on the redox system – control the gene expression, but can also damage genes (MASUKA, 2006).

Let us therefore state in response to the question of a conclusive effective mechanism: The existing scientific literature abundantly documents disruptions of the redox

balance in organisms through reactive oxidative and nitrogenous species (ROS/RNS), causally connected to the exposure to electromagnetic fields of mobile radio and wireless communication.
An unambiguous effective damaging mechanism has therefore been found.

4.3 On the question of deterioration of health and damage

Can the functional disruptions thus explained be considered the scientifically proven reasons for the subjectively described symptoms of disease?

The proven effective mechanism is important also because it shows that the subjective ailments of many people are based on biological facts that can be explained. If you are aware of the cascades of effects described hereunder, you will better understand why "electrosmog" is damaging.

4.3.1 Functional disruptions and symptoms of disease

Electromagnetically induced excessive ROS/RNS stimulation may be differentiated into three effective phases that are passed through sequentially:
1. Stimulation of free radicals,
2. Stimulation of highly toxic peroxinitrite,
3. Stimulation of highly toxic peroxide radical.

The following processes are serious: Cell components are destroyed; the antioxidants absorbed with the food and the substances with excess electrons produced by the organism itself are spent; the harmful cholesterine increases. People feel tired, tense, battle various inflammations.

Pain is felt in places. More detail on the individual steps is given below.

First complex: Stimulation of free radicals such as superoxide O_2-° and NO leads to
- activation of protooncogenes
- damage to the mitochondria genome
- damage to the cell nucleus genome
- damage to the membranes
- oxidation of the polyene fatty acids of the membranes; release of cardiolipins (auto antibody formation)
- oxidation of SH groups, causing enzyme blocking
- activation of proteases (cell damage)
- activation of transcription factors.

Second complex: Stimulation of highly toxic peroxinitrite from superoxide anion O_2° together with NO (O_2° -+ NO = ONOO°)
NO has three times the affinity for superoxide O_2-° that O_2-° has for the neutralising superoxide dismutase; the peroxinitrite
- oxidises vitamin C
- oxidises uric acid
- oxidises cholesterine
- oxidises sulfhydryl groups (destroys thioles)
- oxidises polyene fatty acids of the membranes (initiates lipid peroxidation)
- causes DNA breaks
- activates kinases (phosphor lipase 2)
- activates polymerase (PAPP); this destroys NAD+, leading to a cellular energetic catastrophy.
NO and peroxinitrite react to form nitrogendioxide (NO_2); this deactivates superoxide dismutase (MnSOD), i.e. inhibiting the neutralising enzymes of the mitochondria (mt-Mn-SOD). These reactions alone result in massive metabolism disruptions already.

Third complex: Stimulation of highly toxic peroxide radical (HO_2°-) from superoxide and peroxinitrite with the involvement of hydrogen
Peroxide H00° has a redox potential of +1000 mV, making it highly oxidising.. An addition to the listing in complex 2, peroxide also oxidises:
- Polyene fatty acids
- Tocopherol (Vit E)
- Lycopene
- Co-enzyme Q 10

The functional disruptions are manifest in disease symptoms, as described in more detail below.

4.3.2 The "Acquired Energy Dyssymbiosis Syndrome" (AEDS)

The clinical picture of the "Acquired Energy Dyssymbiosis Syndrome" describes a deficiency of cell energy – with simultaneous derailment of the cell environment. This leads to "mitochondropathy": energy creation is blocked; the power generators for cell energy are transformed into copious sources of free radicals.

The changes have serious consequences:

1. Inflammation processes spread and release further substances that are harmful when overdosed (tumour necrosis factor TNFα and time and again nitrogen monoxide). We must also not forget that inflammations are on the increase in our industrial society and that arteriosclerosis and heart attacks – the primary cause of death – are ultimately caused by inflammations. This point of view has already been accepted among the scientifically active medical fraternity today.

2. Aerobic glycolysis (glycolysis despite the presence of oxygen) is activated as "emergency power generator" – which is in turn associated with:

- stimulation of proto-oncogenes (precursors to cancer genes)
- increased release of superoxide radicals
- lactate acidosis (excessive acidification)

3. The mitichondric genome finally mutates. But especially this pathological change can be hereditary via the female gender. It burdens the progeny for the generations to come.

Overview: Physiopathological consequences of nitrosative/oxidative stress

I. Disruption of mitochondrial activity
II. Disruption of sugar utilisation (pathological lactate acidosis)
III. Disruption of the neurotransmitter function
IV. Disruption of the cholesterine metabolism
V. Disruption of the steroid hormone synthesis (corticoids)
VI. Disruption of the haem system
VII. Generation of mutations, esp. the mitochondrial DNA (hereditary)
VIII. Disruption of apoptosis

Catalogue of symptoms and diseases (excerpt), derived from the known effective mechanisms of nitrosative/oxidative stress

- Sleep disorders
- High level of fatigue: no relaxation, recuperation times ineffective
- Psychosomatic performance lapses
- Major phases of restlessness and "panic disorder"
- Corpulence
- Chronic hypoglycemia
- Increased cholesterine and triglycerid values
- Lactate acidosis
- Fibromyalgy FMS (nitroso serotonin auto-antibody formation)
- Autoimmune diseases
- Arteriosclerosis
- M. Parkinson
- Chronic inflammation processes, especially in the nervous system, with multiple sclerosis and amyotropic lateral sclerosis
- Haem synthesis disruptions (porphyria)
- Lactose intolerance
- Pathological energy deficit PED (WARNKE, 1989)
- Chronic immune insufficiency (high infection susceptibility)
- Functional disruptions of the thyroid
- Myopathy
- Encephalopathy
- Polyneuropathy
- Enteropathy
- Cancer
- AIDS

To summarise, we can answer the question as to whether subjective reports of illness have an objective basis as follows: The redox balance is disturbed via the direct influence of weak magnetic and electromagnetic fields on the NADH oxidase. The result is oxidative/nitrosative stress. It leads to disruptions and prevention of vital functions. In the course of these processes, exactly those disease symptoms subjectively described by those affected and exposed to radiated fields, are in evidence.

Hereditary pathological changes passed on via the mother should, in particular, draw our attention to the effects that will only manifest themselves in generations to come.

4.4 On the exclusion of a nocebo effect.

Do we have scientifically designed methods, such as the "double blind" method, proving that the symptoms of disease cannot be attributed to fears but that they are generally reversible after "switching off" the physically stressing fields (unbeknown to the participants), after a short period of time?

All the scientific investigations that addressed this question reply to this question with "yes":

The various problems disappear if the influence of the radiation or the ROS/RNS formation is "switched off" (e.g. ABELIN 1999, ABELIN et al. 1995, HORNIG et al. 2001, PETROV1970, TNO study 2004).

Health is not, however, restored if the disruptions have already led to serious damage such as DNA destruction or tumours.

5. Summary

For many decades, research results showing that the natural electrical and magnetic fields and their variation are a vital precondition for the orientation and navigation of a whole range of animals, have been freely available.

What has also been known to science for many decades is that we as humans depend on this natural environment for many of our vital functions.

Today, however, this natural information and functional system of humans, animals and plants has been superimposed by an unprecedented dense and energetic mesh of artificial magnetic, electrical and electromagnetic fields, generated by numerous mobile radio and wireless communication technologies.

The consequences of this development have also been predicted by the critics for many decades and can now no longer be ignored. Bees and other insects disappear, birds avoid certain areas and are disoriented in other locations. Humans suffer from functional disorders and diseases. And those that are hereditary are passed on to the next generation as existing defects.

Glossary (GL)

Information: This concept is generally understood in everyday life and has gained a position of central importance, especially in modern bio-sciences. "Informed society" demands to be in a position to inform itself about everything if possible, at any time and any place in the world. Analogously, it is of cardinal importance to a living organism of any kind, not only to be in a position to communicate with its environment via information carriers, but the control of its internal vital functions must also be assured, which is again possible only through the exchange of "information".

Electromagnetic (EM) fields of all kinds and magnitudes (including light, UV and infrared radiation, microwaves, etc.) were chosen by evolution as particularly suitable carriers of information because they are able to flood the living space of organisms spontaneously and fully, affording every individual immediate access to its information content.

This is available in the ordered structure of the EM fields themselves, described in physics as waves, which propagate at the speed of light with alternating electrical and magnetic field components. Because, in accordance with Faraday's law of induction (1831), the changes in a magnetic field induce changes in an electrical field.

The force/field lines of magnetic and electrical fields are in the form of vectors between positive and negative poles and we can therefore describe them as electrical or magnetic flux and a flux density orthogonal to a unit surface area, e.g. 1 m^2.

The actual information in an EM field resides – similar to acoustics – in the number of oscillations per second (=frequency) and also in the amplitude of the oscillations. If an EM field of higher frequency is interrupted at a certain rate (facilitated only through modern digital technology), low frequency pulsed high frequency radiation is created, whereby the cyclic rate can also be used for information purposes.

The traditional technical method of transmitting "information" is called modulation. In this way, a continuous low frequency carrier wave, subject to less interference during propagation in space, is overlaid (modulated) with the higher frequencies of music and voice, allowing the information to be transmitted over large distances.

EA few common physical units:

Ampere (A): current amplitude
Volt (V): electrical voltage
V / meter (E): electrical field strength
Watt:(W): power (=VA)
Joule (J): electrical energy (=W sec)
Tesla (T): magnetic induction (=V sec/m^2)

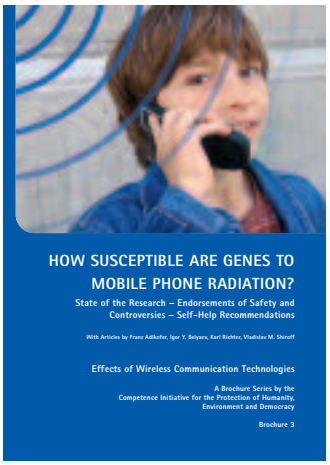
How Susceptible Are Genes to Mobile Phone Radiation?

State of the Research – Endorsements of Safety and Controversies – Self-Help Recommendations

With Articles by Franz Adlkofer, Igor Y. Belyaev, Karl Richter, Vladislav M. Shiroff

2008



In their articles, the experts in biomedicine and biosciences Prof. Franz Adlkofer, Prof. Igor Y. Belyaev, and Vladislav M. Shiroff show the broad range of international research efforts that document DNA and chromosome damages as well as chronic diseases resulting from electromagnetic radiation exposures. This is about non-thermal effects well below current exposure limits. UMTS radiation turns out to be especially hazardous.

"The endorsement of safety by the German Mobile Telecommunication Research Programme regarding the health risks of mobile phone radiation is based rather on wishful thinking than facts," says Franz Adlkofer. Exposure limits that do not account for non-thermal effects or the exposure duration do not provide protection but are rather unsafe. In commissions and research programs, which are paid by the public for the protection of its health, those scientists set the tone whose main objective it is to issue endorsements of safety and support existing exposure limits. They pursue "witch hunts" against allegedly fraudulant laboratories. But obviously they do not realize that their denial of the international body of evidence is the most offensive of all scientific frauds possible. Since this turns the entire population into potential victims.

As long as this is supposed to be the "independent" research the public and environment is at the mercy of, we should not expect any protection or precaution from the government, reasons Prof. Karl Richter. It seems to be more imperative than ever before that independent scientists and responsible citizens—with the support of foundations and environmentally minded sponsors—take the organization of independent health protection projects into their own hands, as a program for self-help. The brochure provides recommendations to this end.

About this Brochure

The bioscientist Ulrich Warnke knows the electromagnetic workings of nature better than most. In this brochure, which opens a new science series by independent scientists, medical doctors, and technicians, he shows how nature uses much wisdom and sensitivity in employing electric as well as magnetic fields in the creation of life. But, therefore, he is also in a position to convincingly criticize how foolish and irresponsible we are as we interfere with this delicate natural balance today. According to the findings of this brochure, we are currently in the process of destroying in less than a few decades what nature took to create over millions of years.
The outlook is all the more worrisome because it is not based on hypotheses and probabilities but the work of verifiable and reproducible effect mechanisms. We think that the protective provisions of the German Constitution obligate the responsible elected officials to draw the necessary conclusions. Anybody who still relies on downplaying the risk, the most convenient of all strategies used most frequently to pretend that there were no known serious risks, only signals that short-term economic interests are more important to this person than the future of the coming generations.

Ulrich Warnke summarizes the findings of his brochure as follows:
"Today, unprecedented exposure levels and intensities of magnetic, electric, and electromagnetic fields from numerous wireless technologies interfere with the natural information system and functioning of humans, animals, and plants. The consequences of this development, which have already been predicted by critics for many decades, cannot be ignored anymore. Bees and other insects vanish; birds avoid certain places and become disorientated at others. Humans suffer from functional impairments and diseases. And insofar as the latter are hereditary, they will be passed on to next generations as pre-existing defects"

Prof. Dr. K. Hecht, Dr. med. M. Kern, Prof. Dr. K. Richter, Dr. med. H.-Chr. Scheiner

About the Author
The main research areas of Dr. rer. nat. Ulrich Warnke, an internationally renowned bioscientist at Saarland University, include biomedicine, environmental medicine, and biophysics. For decades his research interest centered especially on the effects of electromagnetic fields.

The scientific jigsaw puzzle: Fitting the pieces of the low-level radiation debate

The scientific jigsaw puzzle: Fitting the pieces of the low-level radiation debate

Jan Beyea

Abstract

Quantitative risk estimates from exposure to ionizing radiation are dominated by analysis of the one-time exposures received by the Japanese survivors at Hiroshima and Nagasaki. Three recent epidemiologic studies suggest that the risk from protracted exposure is no lower, and in fact may be higher, than from single exposures. There is near-universal acceptance that epidemiologic data demonstrates an excess risk of delayed cancer incidence above a dose of 0.1 sievert (Sv), which, for the average American, is equivalent to 40 years of unavoidable exposure from natural background radiation. Model fits, both parametric and nonparametric, to the atomic-bomb data support a linear no-threshold model, below 0.1 Sv. On the basis of biologic arguments, the scientific establishment in the United States and many other countries accepts this dose-model down to zero-dose, but there is spirited dissent. The dissent may be irrelevant for developed countries, given the increase in medical diagnostic radiation that has occurred in recent decades; a sizeable percentage of this population will receive cumulative doses from the medical profession in excess of 0.1 Sv, making talk of a threshold or other sublinear response below that dose moot for future releases from nuclear facilities or a dirty bomb. The risks from both medical diagnostic doses and nuclear accident doses can be computed using the linear dose-response model, with uncertainties assigned below 0.1 Sv in a way that captures alternative scientific hypotheses. Then, the important debate over low-level radiation exposures, namely planning for accident response and weighing benefits and risks of technologies, can proceed with less distraction. One of the biggest paradoxes in the low-level radiation debate is that an individual risk can be a minor concern, while the societal risk—the total delayed cancers in an exposed population—can be of major concern.

Keywords

atomic bomb, debate, dose, linear no threshold model, low level radiation, one time exposure, protracted exposure, radiation, risk

To those outside the scientific community, it might come as a surprise that, until 2005,[1] essentially no large-scale epidemiologic studies directly demonstrated the existence of risks related to protracted radiation exposures—the kind that would be expected from releases from nuclear reactors or dirty bombs. Historically, atomic-bomb data—which look at the one-time exposures to Hiroshima and Nagasaki survivors—have dominated

quantitative risk estimates for any type of low-level exposure to ionizing radiation, including protracted exposure. The standard approach to calculating risk estimates for long-term exposure has been to use biologic arguments—that is, concepts of cancer initiation, promotion, and repair, coupled with data from cellular experiments—to conclude that long-term exposure entails lower risk than sudden exposure, by a factor of two to ten (Healy, 1981); only in the last decade has the scientific community unofficially settled on a factor of two (Preston, 2011; UNSCEAR, 2006).

Presumably, a factor of two should have had a rather minor impact on policy, which should have meant a quick end to this portion of the story on low-dose radiation risks. No such luck. In fact, there has been, and continues to be, considerable debate among members of the scientific community, political and industry leaders, and the public around the claim that atomic-bomb data is relevant to estimating risks from *protracted* exposures. This debate has contributed to the delay in updating some US regulatory dose limits that are based on a pre-1990 understanding of radiation risks.

Three new studies could very well change the balance of the debate, as knowledge of them—one on off-site citizens and two on radiation workers—percolates into the wider discussion.

Deconstructing the debate

The debate over radiation risks has many tentacles that extend into the fields of biology, epidemiology, medicine, sociology, and political science. The biggest tentacle penetrates directly into the political sphere, wrapping itself around arguments on energy policy and the consequences of radioactive releases like those at Chernobyl and the Fukushima Daiichi Nuclear Power Station. Quantitative estimates of health risks affect public policy, although sometimes it takes many decades before scientific studies affect regulations (see Brock and Sherbini, 2012, in this issue of the *Bulletin*). Likewise, it also may take years before these studies trickle down to the public and industry stakeholders.

To some in the public, the quantitative aspects determined by experts are irrelevant; they argue that experts are not to be trusted and that the existence of *any* imposed risk of cancer is unacceptable. Others believe that evolution has provided humans with repair mechanisms that protect against natural background radiation; they reason that the radiation risk at doses close to the background is, in fact, zero. But for researchers in the field, and committees of scientists trying to reach consensus and assemble what amounts to a scientific jigsaw puzzle, reaching quantitative conclusions about risk is not so simple. Researchers cannot solely rely on gut instincts; they must analyze data, scrutinize their findings, and rigorously defend these findings.

Though the debate takes on many shapes, it always revolves around one magical number: 0.1 sievert (Sv), the dividing line between what is considered high and low exposure today. It is equivalent to about 40 cumulative years of the average unavoidable background radiation and to about 40 years of average medical diagnostic radiation in the United States (Einstein, 2009; NCRP, 2009).[2] And from this magical

number, more disputes spring, specifically on the radiation risks below 0.1 Sv, as well as the risks from protracted radiation exposures above and below this number. The debates can be brutal—so much so that, at times, they make the spats between William Jennings Bryan and Clarence Darrow look tame.

One-time exposure above the dividing line

Since the United States dropped atomic bombs over Hiroshima and Nagasaki in 1945, it has worked with Japan to produce 14 periodic joint reports, known as Life Span Studies, on the fate of more than 80,000 bomb survivors. What makes these regular reports so formative—and why analysis of the atomic-bomb data continues to dominate quantitative risk estimates today—is that the vast data set, including regular follow-ups on the study population, has produced consistent epidemiologic results, providing little room for contention on the radiation risks related to acute exposures above 0.1 Sv. Despite some limitations (see Richardson, 2012, in this issue of the *Bulletin*), analysis of the atomic-bomb dose data presents a clear picture that a linear no-threshold (LNT) model—the theory that radiation risk declines in proportion to dose, but never goes to zero— holds for a large range of survivor doses (see Figure 1).[3]

But atomic-bomb data, some argue, focus on high doses and are therefore irrelevant to the low-dose debate.[7] However, as Figure 1 shows, the data set contains a wide-range of doses—including those that are quite relevant to

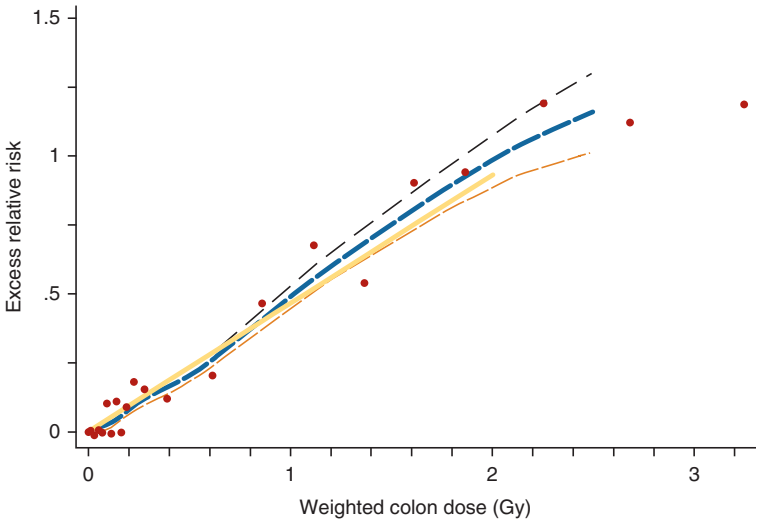

Figure 1. Solid cancer-incidence dose response for atomic-bomb survivors.
Source: Preston et al. (2007). This figure is reproduced with permission from the Radiation Research Society.
Notes: This figure shows excess relative risk versus "weighted colon dose" in units of gray (Gy)—these units are equivalent to Sv.[4] The solid line represents a smoothed version of the data that does not assume the data are linear.[5] Dashed curves represent one standard deviation. Note the tight error bands around the central curve. The horizontal access on the chart refers to colon dose, which is taken as a surrogate for the tissue dose to all organs; this may differ slightly. Each small tick mark corresponds to 0.2 Gy; half of this is what is considered to be low-dose radiation today. The vertical axis has units of excess relative risk (ERR) that have been found to fit radiation data better than absolute risk models.[6] It is important to note that this figure illustrates a dose response for an entire population.

occupational exposure limits, as well as those that match accumulated background radiation and medical-diagnostic doses, which are normally considered to be low. Bear in mind that these doses are *in addition to* the natural background radiation that the survivors had already received.

Over the decades, as new excess cancers have emerged in the atomic-bomb cohort at lower and lower doses, the number that defines "low dose" has shrunk fivefold to its current value of 0.1 Sv. At the same time, the estimated risk has risen tenfold since 1980;[8] thus, it is of little surprise why there is continuing concern about low-dose radiation. So the natural question is: When will the estimated-risk increases *stop*? Fortunately, further dramatic changes are not expected in the atomic-bomb data—certainly not for adults at doses above 0.1 Sv—because a sufficient number of excess cancers has ensured tight confidence bounds, or limits.[9]

Epidemiologic data can include many individual variations, including subgroups of people with different genetic susceptibilities (see Greenland, 2012, and Richardson, 2012, both in this issue of the *Bulletin*). These variations are too often lost in the debate over low-level radiation effects. For instance, some researchers argue that raw, dose-category data, specific to children, indicates an LNT response down to 0.01 Sv. Further evidence of a strong difference in susceptibilities among groups—such as from DNA sequence variations—may lead to calls for tighter health and industry regulations (Locke, 2009).

The LNT theory predicts that background radiation exposure and medical diagnostic exposures slightly increase a population's future cancer rates. The cancers don't appear immediately but are diagnosed five years to more than 50 years after exposure. Delayed cancers are the usual focus of the low-level radiation debate, but delayed stroke and heart disease account for "about one third as many radiation-associated excess deaths as do cancers among atomic bomb survivors" (Shimizu et al., 2010).

Protracted exposures above the dividing line

For years, nuclear power advocates have argued that the atomic-bomb cancer data were insignificant to nuclear reactor regulations and irrelevant to nuclear reactor risk assessments—not just because the atomic-bomb doses were supposedly too high, but because the bomb exposures occurred suddenly. These advocates, along with a number of researchers, argued that the body's DNA repair mechanisms assist in the recovery from slow exposures caused by routine reactor releases. Even doses from accidental releases would not be as bad as atomic-bomb doses, these advocates claimed, because radioisotopes in the body or on the ground decay with predictable half-lives, protracting the radiation dose.[10] But conventional wisdom was upset in 2005, when an international study, which focused on a large population of exposed nuclear workers, presented results that shocked the radiation protection community—and foreshadowed a sequence of research results over the following years.

15-country nuclear worker data

It all started when epidemiologist Elaine Cardis and 46 colleagues surveyed some 400,000 nuclear workers from 15 countries in North America, Europe, and Asia—workers who had experienced

chronic exposures, with doses measured on radiation badges (Cardis et al., 2005). The prediction of total excess cancers for these nuclear workers was striking: Cancer deaths in this population increased by 1 to 2 percent, making past nuclear work a rather dangerous industrial occupation relative to others. (It should be noted that Cardis's study looked at workers exposed many years ago, when efforts to reduce workers' radiation exposure were less effective than they are today.)

This study revealed a higher incidence for protracted exposure than found in the atomic-bomb data, representing a dramatic contradiction to expectations based on expert opinion. Further, this challenged the relevance of cell dose-rate experiments to human epidemiology. However, the dose response did not include as tight error lines as in the atomic-bomb data. Even though the incidence data were statistically significant, some researchers, along with industry and medical radiation advocates, quickly attacked the study.

Seizing on the data from Canada—the country with the highest excess relative risk (ERR)-per-Sv rate—the critics contended that the study was flawed; they charged that it be repudiated by the authors, which it never was. Atomic Energy of Canada Limited's industry consultants continue to focus on the Canadian segment of the data, particularly on the reliability of the dose estimates.[11] Their relentless attacks have been effective in neutralizing the study, despite the authors' defenses.[12]

UK radiation workers

A second major occupational study appeared a few years later, delivering another blow to the theory that protracted doses were not so bad. This 2009 report looked at 175,000 radiation workers in the United Kingdom, and was an update to earlier reports of the same data set. Sufficient diseases had appeared since the previous assessment, making the cancer risk statistically significant and the same as in the atomic-bomb data. Again, protracted exposures did not turn out to be less dangerous than acute exposures.

12 worker studies combined

After the UK update was published, scientists combined results from 12 post-2002 occupational studies, including the two mentioned above, concluding that protracted radiation was 20 percent more effective in increasing cancer rates than acute exposures (Jacob et al., 2009). The study's authors saw this result as a challenge to the cancer-risk values currently assumed for occupational radiation exposures. That is, they wrote that the radiation risk values used for workers should be increased over the atomic-bomb-derived values, not lowered by a factor of two or more.

If history is any guide, it is questionable that this analysis and the results of other studies will lead to actual changes in what defines worker-exposure limits. Industry pushback is very strong, as can be seen by the efforts of the California-based Electric Power Research Industry (EPRI), a nonprofit energy consortium. In 2009, the group issued a damning report that dismissed all of the new, high results in the 12 occupational studies, citing the work as either flawed or irrelevant to the exposures received by the most exposed nuclear workers (EPRI, 2009), which, EPRI says, are

around 0.02 Sv per year. Their concerns about the irrelevance of protracted studies are puzzling, because an annual exposure at 0.02 Sv over a period of 10 years would be 0.2 Sv—an accumulated exposure well above the low-dose dividing line of 0.1 Sv.

Techa River data

So what about the risks to the general population? In 2007, one study—the first of its size—looked at low-dose radiation risk in a large, chronically exposed civilian population; among the epidemiological community, this data set is known as the "Techa River cohort." From 1949 to 1956 in the Soviet Union, while the Mayak weapons complex dumped some 76 million cubic meters of radioactive waste water into the river, approximately 30,000 of the offsite population—from some 40 villages along the river—were exposed to chronic releases of radiation; residual contamination on riverbanks still produced doses for years after 1956.

Here was a study of citizens exposed to radiation much like that which would be experienced following a reactor accident. About 17,000 members of the cohort have been studied in an international effort (Krestinina et al., 2007), largely funded by the US Energy Department; and to many in the department, this study was meant to definitively prove that protracted exposures were low in risk. The results were unexpected. The slope of the LNT fit turned out to be higher than predicted by the atomic-bomb data, providing additional evidence that protracted exposure does not reduce risk.[13] Furthermore, as seen in Figure 2, the raw data showed cancer excess around 0.1 Sv of protracted exposure, before any linear fit is made. The distinction between acute and chronic exposures no longer exists in epidemiologic data. But as with the 15-country study, the Techa River study was attacked, particularly on the reliability of doses. EPRI discounted the study, claiming it contradicted other studies on low background-radiation areas in India and China. However, EPRI failed to mention in its 2009 report the limitations of such studies in high-background-radiation regions,[14] not to mention that the confidence bounds around the estimate were consistent with the risks from the atomic-bomb study (Tao et al., 2012).

Too much is at stake in terms of the cost of worker and public protection to expect the nuclear industry to be anything but skeptical of studies that undermine past practices and positions. The industry will want unequivocal evidence. Thus, the debate over protracted exposures will continue, probably even after the next US National Academy of Sciences and the Institute of Medicine's Biological Effects of Ionizing Radiations (BEIR) scientific committee issues a communal judgment five to ten years from now.[17]

Protracted exposures below the dividing line

Though they inspire and instigate forward-thinking research, the above studies do not put the debate over low-risk radiation to rest. In fact, the debate goes beyond this, to an even thornier issue: namely, the dose response *below* the divide at 0.1 Sv.[18] The debate over low doses is as intense as the debate over protracted-versus-acute exposure. Why? Because doses in this range are

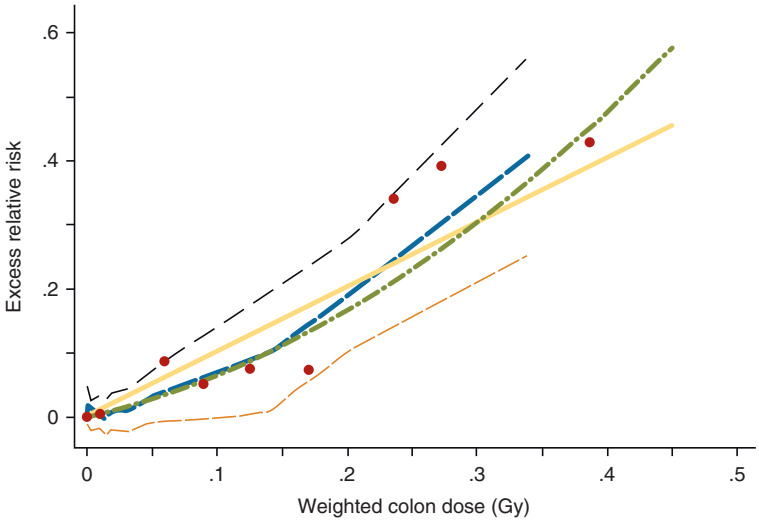

Figure 2. Solid cancer-incidence dose response for the Techa River cohort.
Source: Krestinina et al. (2007). This figure is reproduced with permission from the authors; © Oxford University Press.
Notes: This figure shows excess relative risk versus weighted dose in units of Gy (equivalent to Sv for the purposes of this article).[15] The solid line represents the linear fit. The thick dashed line represents a nonparametric fit to the data.[16] The thinner dashed curves represent one standard deviation. The scale of the dose axis is expanded compared with Figure 1, with tick marks in this graph set to intervals of 0.1 Gy. The bounds on the curves are quite wide. And the slope is higher than for the atomic-bomb survivor curve in Figure 1.

those of most concern to a public skeptical about nuclear power's side effects. Without low-dose risk estimates, it is not possible to predict the full consequences of events like Fukushima and Chernobyl; it is not possible to make estimates of the consequences of relying on nuclear power; nor is it possible to understand the consequences of relying on a high-level waste-storage site like Yucca Mountain.

Medical-diagnostic doses also often fall in this range, although the public is less concerned about them than doses from nuclear power or nuclear waste (see Slovic, 2012, in this issue of the *Bulletin*). Still, doctors, public health officials, emergency planners, and responders need to understand the risks at these doses.

Some public officials and nuclear energy supporters say doses below 0.1 Sv, particularly below 0.01 Sv, are nothing to worry about, while nuclear activists contend they are very dangerous. Personal interests can play a role in fanning the flames of the debate. In summary, there are scientific, medical, governmental, and political reasons for knowing the risks below 0.1 Sv: for example, creating an informed public, choosing energy sources, advancing scientific knowledge, facilitating an appropriate balance of risks from medical diagnostics. But there are obstacles, as well: like sabotaging lucrative business ventures and potentially amplifying risk perceptions.

Setting the record

Experts, governments, industry, and the public aren't left to their own devices to settle this debate. Due to the complex

nature of the issue—and the many opinions that it elicits—two major scientific committees oversee this matter, periodically reporting on new evidence related to quantitative risk estimates. They are the BEIR committee and the UN Scientific Committee on the Effects of Atomic Radiation (UNSCEAR).

UNSCEAR's reports are compiled by staff and a small group of knowledgeable consultants (UNSCEAR, 2006). The BEIR reports, on the other hand, have a more elaborate procedure that has a more transparent process (National Research Council, 2006).[19] The reports' conclusions usually agree, but the UNSCEAR report, being a product of the United Nations, must be cognizant of national politics in UN countries—this means that the report never states that some risk continues down to zero dose. Such careful phrasing ensures that the LNT, and the risk numbers associated with it, can be used around the world for cost–benefit analyses and other regulatory purposes. Agencies can justify the use of the LNT solely on the basis of adopting a conservative or precautionary approach, thereby escaping strong objections from industry leaders and dissenting researchers.

In the UNSCEAR reports, for example, the dose models have risks going toward zero dose, but the authors do not write that the risks definitely reach zero—rather, they provide an obtuse explanation that "the inability to detect increases in risks at very low doses using epidemiological methods does not mean that the cancer risks are not elevated." No doubt, there is concern at the United Nations that too much talk about cancer risk at low doses will amplify risk perception (see Kasperson, 2012, in this issue of the *Bulletin*).[20]

The BEIR committee, which does not answer to any government, is more direct in its pronouncements. Based on their extensive review of the biologic evidence, including epidemiology, animal data, cellular data, and cancer theory, they conclude that the risk decreases with dose, but never goes to zero. In fact, their exact words are:

> A comprehensive review of the biology data led the committee to conclude that the risk would continue in a linear fashion at lower doses without a threshold and that the smallest dose has the potential to cause a small increase in risk to humans. (National Research Council, 2006)

Still, science is a contested territory, so scientific dissent from these reports is to be expected. For the sake of understanding how layered the arguments are, it is worth exploring these theoretical dissents.

Supralinear response

One theory that uses biologic evidence to predict a response greater than the LNT is a supralinear response. Such evidence is based on studies of cellular communication from radiation-damaged cells—chemical communication that transfers damage to an undamaged cell, multiplying the deleterious effect of the original radiation (the bystander effect).[21] Other evidence comes from studies of genomic instability, a phenomenon in which radiation damage doesn't show up until several cell generations have passed (Morgan and Sowa, 2009; see also, Hill, 2012, in this issue of the *Bulletin*).

In a 2012 study on atomic-bomb survivor mortality data (Ozasa et al., 2012), low-dose analysis revealed unexpectedly

strong evidence for the applicability of the supralinear theory. From 1950 to 2003, more than 80,000 people studied revealed high risks per unit dose in the low-dose range, from 0.01 to 0.1 Sv. The study's authors, themselves, did not go so far as to suggest a supralinear response, saying only that the results were difficult to interpret. However, advocates for supralinear response are likely to see a simple explanation, namely supralinearity. Note that such effects do not show up in studies of cancer *incidence* in the atomic-bomb studies.

Zero response

In contrast to theories of supralinear responses, some industry stakeholders argue that the response might be zero for doses up to a threshold, below 0.1 Sv. A completely zero response is unlikely, given the heterogeneity of human populations, including differing immune and repair systems among people. However, a quasi-threshold, with a dose response below 0.1 Sv, is a standard theoretical possibility and a hypothesis that some researchers strongly believe will be vindicated one day, thereby confounding the conventional view of an LNT dose response.

In 2007, the latest cancer-incidence results were released on atomic-bomb survivors from 1950 to 1998; in this update, there was a mathematical fit to a threshold at 0.04 Sv, as well as a fit to the LNT model.[22] However, these findings were not reiterated in the 2012 update on cancer mortality, which reported a response that appeared to rise above the LNT prediction at low doses.

The French National Academy and Institute of Medicine put out their own short report advocating for a quasi-threshold based largely on cellular data (Aurengo et al., 2005) and criticizing those who think otherwise. In turn, the French study has been criticized, not just on the merits, but also for lack of objectivity.[23,24] For LNT dissenters, the French Academy's study has been their counterpoint when the authority of the US BEIR report is invoked. Thus, any layperson wishing to engage in the discussion must reach a decision on which of these reports is likely to contain the most credible scientific judgments.

Hormesis theory

Demonstration of a quasi-threshold would be unlikely to assuage those who abhor radiation-producing technology on existential grounds, but it might eventually affect regulations and overall opinion. The radiation hormesis theory—that some radiation is beneficial—would provide more comfort, if it could be demonstrated. The best evidence for this concept in humans can be found in national data on home radon measurements and lung cancer rates at the county level. However, the reliance on cancer data aggregated to the county level has been roundly criticized by epidemiologists (Lubin, 2002). Results from more sophisticated epidemiologic studies of the same association do show the expected dose response when individual cancers are matched to dose (Darby et al., 2005; Krewski et al., 2006).

Though it still is a pet topic of enterprising journalists, the radiation hormesis theory is no longer of much interest to researchers. The BEIR VII report, published in 2006, discounted

the concept; the French Academy of Sciences took it more seriously, while discounting other evidence that suggests the response might be supralinear at low doses.

Given the increase in radiation from medical diagnostics and the interest in protracted exposure, the possible existence of a threshold or hormetic effect for public policy appears to be a moot issue for developed countries when it comes to future exposures. Even if the level of medical diagnostic exposures does not increase in the future, over the course of 40 years most people in developed countries will receive an average of 0.1 Sv from medical procedures, alone. With this in mind as a dose starting point for millions of people, it is fair to say that any exposure to radioactive elements from a nuclear accident or a dirty bomb would definitely contribute to their delayed cancer risk.

Adaptive response

Of more current interest than hormesis is the concept of adaptive response, where low doses of radiation can prime cells to withstand later, higher doses of radiation (see Hill, 2012, in this issue of the *Bulletin*). The idea is that very low doses, like a vaccination, teach the body how to recognize and repair or remove radiation-damaged cells. Thus, subsequent chronic doses would be less dangerous. Under some theories, this effect can lead to a sublinear response at doses below 0.1 Sv (Morgan and Sowa, 2009). In other words, the excess risk at low doses could be less than predicted by the LNT. The range of doses for which this effect might be applicable is not known; nor is it known whether it might compensate for deleterious bystander effects and genomic instability.

LNT as matter of convenience

It should be noted that all of these cellular effects—including bystander effect, genomic instability, and adaptive response, some of which are thought to have effects working in opposite directions—could already be incorporated into the linear human dose-response curve (Morgan and Sowa, 2009), making the debate much ado about nothing.

Many professional risk analysts, especially those with calm temperaments, do not fret much about the debate over dose response below 0.1 Sv. They simply handle it as a standard problem in uncertainty management, much as they handle many other parts of risk assessment calculations: They take the LNT as the midrange, add uncertainty bounds around it, and possibly use subjective-likelihood distributions to accommodate alternative scientific hypotheses. This is essentially the approach that has been followed in calculations supporting compensation of weapons-test veterans and workers in the weapons complex (Kocher et al., 2008), although the possibility of a threshold or hormesis has not been included in this work. If non-linear, dose-response models are included—for example, threshold or hormesis models—consistency would be necessary and dose terms would need to be added for medical technology and, possibly, background radiation.

Dealing with the uncertainty components from gaps in knowledge about low-level radiation effects is essential (Hoffman et al., 2011). According to these risk analysts, by quantifying uncertainty,

the most important debates over low-level radiation exposures can proceed with less distraction (e.g., planning for accident response and weighing benefits and risks of technologies). However, this approach does not satisfy critics of the LNT, because the average risks usually come quite close to the LNT predictions, even though the uncertainty bounds on the resulting predictions may include their views.

Conclusion

The public, legislators, and journalists are often at a loss to deal with the charges and counter charges that surface in the debate over low-level radiation exposures. It does not help to listen to industry leaders, nuclear activists, or individual researchers, who, one after another, propound their competing images of the underlying truth. Given the complexities, the only alternative for most people is to rely on scientific committees, like the BEIR committee and UNSCEAR, recognizing that the scientific jigsaw puzzle is incomplete. Not all pieces fit correctly, but a reasonable idea of the true situation emerges from the recognizable image visible from the pieces already assembled.

It is now reasonably clear that protracted exposure does not protect against radiation-induced cancer. Rather, it is the cumulative radiation exposure from all sources that must be examined. In developed countries, the average accumulated dose from medical procedures is now so high that a significant percentage of the population in these countries will be above 0.1 Sv. Therefore, this population will be primed for radiation-induced, delayed cancers from releases from nuclear reactors or dirty bombs, even using the hypothetical dose-response models of the LNT dissenters. There is no longer a convenient excuse to avoid using the LNT to estimate consequences from real or projected releases of radioactive materials, even when the dose of concern is below 0.1 Sv.

Particularly when it comes to cost–benefit decisions on retrofitting reactors or planning for spent-fuel pools, regulations that depend on estimates of cancer risks are using LNT slope coefficients that are decades out of date (see Brock and Sherbini, 2012, in this issue of the *Bulletin*). Thus, pressure to update regulations may build, as awareness grows of the five-to-tenfold disparity between the risk estimates per unit dose recommended by scientists today and the older values still used by regulators in cost–benefit calculations for determining allowable doses.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Notes

1. There had been hints in some earlier, smaller, occupational studies, e.g., Wing et al. (1991).
2. When exposures are only to gamma and beta rays, they are usually measured in units of grays (Gy). But when other types of radiation are involved in a dose calculation—for example, neutrons and alpha particles—the comparable unit is either a "weighted gray" or a sievert. These latter units weigh different types of radiation by their estimated effectiveness in increasing delayed cancer rates; therefore, doses and health risks can be compared among epidemiologic studies that involve different mixtures of radiation types.

3. Some analysts add a quadratic term to account for any curvature in the dose-response curve. However, at low doses, this linear-quadratic model becomes a linear model.
4. Weighted colon dose multiplies the neutron dose component by an effectiveness factor of 10 (Chomentowski et al., 2000).
5. No model is assumed, which means the fit is nonparametric. Instead, the data are smoothed and used to define straight-line segments. The circles indicate the excess relative risk at the mean dose in each of the 22 specific dose categories.
6. An ERR of 0.1 means that the cancer rate has increased by 10 percent. To get an absolute risk, one multiplies the ERR by the baseline cancer rate.
7. Some critics also argue, incorrectly, that the atomic-bomb data have no control groups. In fact, it has the best types of control groups epidemiologic methods can offer. When a study can present excess health effects as a function of dose, it has internal controls for comparison. Subjects in each dose category serve as controls for each other, all the way down to zero dose.
8. The 1980 Biologic Effects of Ionizing Radiation (BEIR) report found that the slope of the response was 10 times lower than the value in the 2006 BEIR report; the 1995 BEIR report found it was twice as low (Marshall, 1990; National Research Council, 2006; Reissland, 1981). Interestingly, as the slope of the birth-defect response decreased considerably over time, so, too, did public interest in the matter; perhaps the direction of change in these slopes defines, in part, public concern.
9. Some caveats: First of all, unexpected results are always a possibility and could very well appear in the next study. Second, molecular analysis of future tumors may one day lead to identification of subgroups with dose-responses that are much higher than the population average. Also, new cancer cases will emerge in the future for those exposed at young ages; possibly, these rates will be dramatically different in old age than current projections expect. As a result, lifetime risks for those exposed at young ages could conceivably change significantly.
10. At the time, this theory was supported by the interpretation of experiments on cells showing that, for the same total dose, cellular damage increased the faster the dose was delivered. Consequently, there was strong support for scaling down the risks determined from the bomb data, when it came to predicting cancer from chronic, protracted exposures. These experiments did not involve human cancer, in which development is a more complex process than can be inferred from experiments on isolated cells. Furthermore, the dose response measured in these experiments was for the total cellular damage, not the damage restricted to those components that affect cancer development, which could have their own, distinct dose response.
11. Cardis's critics do not accept that the Canada results simply reflect the highest data point among a set with wide variance; they have spent extensive energy focusing on the weaknesses of only this study, while overlooking or ignoring weaknesses in other studies with lower ERR/Sv results (Ashmore et al., 2010; Boice, 2010). If Canada, the study with the highest ERR/Sv, is removed from the study, as the critics wish, the overall results will no longer be statistically significant. Blind reliance on 95 percent confidence limits is no longer the practice in epidemiology, but it remains a widespread practice among stakeholders—when they will benefit from discounting data. Studies are assessed as a group, for instance, in the context of the other studies discussed in this article.
12. The findings were not greatly influenced by data from any one country: Formal statistical tests provided no evidence for differences in risk between countries. Thus, there was no statistical basis for removing the highest data point. Analyses excluding one country at a time produced excess relative risks per Sv ranging from 0.58 (excluding Canada) to 1.25 (excluding the United Kingdom). Only by excluding Canada did the results lose statistical significance.
13. To date, none of the epidemiology studies dealing with protracted exposures have

explicitly accounted for the effect of uncertainty in dose estimation. Paying attention to uncertainty in dose estimation is perhaps most important with the Techa River data and some of the studies of background radiation discussed later in the text, because mathematical models are used in part to reconstruct individual exposures, filling in gaps in direct measurements. Accounting for measurement uncertainty strengthened the findings of an association with radiation in studies of thyroid disease following nuclear weapons tests (Lyon et al., 2006).

14. Two epidemiologic studies, one in India (Nair et al., 2009) and one in China (Tao et al., 2012), are notable because they include individualized doses, which typically would mean they rely on internal controls by dose category, like the analysis of the atomic-bomb survivors. However, the individualized dose method is weakened in these studies, because the authors mixed together distinct geographic regions, some with low doses and some with high. No separate analyses were given in the studies to account for different baseline cancer rates in each region; nor was there stratification by region. Had there been, it is likely that the confidence intervals would have increased. As it was, the confidence intervals around their slightly negative slopes were quite wide, limiting their usefulness in potentially contradicting other studies, as EPRI maintains they do. Early markers of cancer risk, namely dose-related chromosomal aberrations (China) and mitochondrial DNA mutations (India) have been found in these high-background regions, casting some doubt on the null epidemiologic findings in these studies. Both studies exclude persons under 30, the age period when radiation-induced leukemia is extremely high according to atomic-bomb results. In the Chinese mortality study the authors note the difficulty in diagnosing liver cancer mortality. When liver cancer is removed from the analysis, the ERR/Sv is positive and the upper confidence interval for the ERR/Sv is much greater than that for the other studies mentioned in this article, including the 15-country study and the Techa River cohort study. Thus, from this perspective, the study of high background radiation in China is not at all inconsistent with studies showing risks of protracted exposure greater than predicted by analysis of the atomic-bomb data. The study in India did not provide an analysis with liver cancer removed, so a comparison cannot be made. For a more positive view of these types of studies, see Boice et al. (2010). For a discussion of other studies in high-background-radiation regions, see Hendry et al. (2009).
15. The weights here correspond to different times spent near the riverbank (Standring et al., 2009).
16. To obtain this curve, no model was assumed, which means the fit is called nonparametric: Instead of fitting to a model (e.g., a linear model), a running average of the data was used to define the curve.
17. The next BEIR report is not yet in the planning.
18. Because many more cancers are expected in the atomic-bomb cohort in the next 20 years, more information can be expected to emerge on the low-dose range in the future. Given the 50 years it has taken for the atomic-bomb analyses to produce powerful results, we cannot expect Fukushima data to contribute much for a great many decades, particularly because the average dose is likely to be lower. However, the ability to perform genetic sequencing of removed tumors offers a new opportunity to expand the power of epidemiologic studies.
19. Presentations to the BEIR committee are open to the public. The biographies of the committee members appear in the report. So, too, are the names of the numerous outside reviewers listed in the final report. Both of these procedures allow outsiders to assess whether or not the committee is balanced.
20. It is perhaps out of the same concern to avoid social amplification of risk that the UNSCEAR authors have declined to use the LNT to predict the total number of excess cancers that will result over time as a result of the Chernobyl accident.

Such a number would be very small compared with the number of cancers that would have appeared without the accident. One of the biggest paradoxes in the low-level radiation debate is that an individual risk can be a minor concern, while the societal risk (total delayed cancers in an exposed population) can be of major concern.

21. Some argue that bystander effects could also be protective, signaling the body to increase repair efforts.
22. The use of a pure threshold in the fit was a mathematical convenience; a quasi-threshold would have fit just as well.
23. According to the criticism, too many members had strong prior views tied to their relationships with the French nuclear industry or their medical practice in radiation medicine. In contrast to the policy followed in preparation of the BEIR reports, no biographies of the authors were provided in the report of the French Academies, deepening suspicion that something was being hidden.
24. Furthermore, the French study did not undergo the intensive peer-review process used with the BEIR committee reports. Of course, the BEIR report process is not perfect, either, as history shows. In its 1980 report, for example, the committee muffed the slope of the LNT (Marshall, 1990). However, the BEIR committees do follow processes established by the US National Academies of Sciences and the US Institute of Medicine, which require assembling a group of scientists with a broad range of perspectives. Attempts are made to balance biased views, which are inevitable in any sizeable committee of active scientists or medical professionals.

Author biography

Guest editor of the *Bulletin*'s special issue on low-dose radiation risks, **Jan Beyea** is a nuclear physicist, who, for 40 years, has listened to, and sometimes participated in, the debate over risks from low-level radiation exposure. He is a co-author of papers on environmental epidemiology, including a study of the Three Mile Island accident. Beyea has been a member and reviewer of numerous studies for the National Research Council, most recently serving as a committee member for the completed study *America's Energy Future*, and the ongoing study, *The Feasibility of Inertial Fusion Energy*. He currently is a member of the World Trade Center Health Registry Scientific Advisory Committee. He advises plaintiff law firms on litigation strategy in large, toxic tort cases, where he has watched some of the most prominent researchers in the world go head to head, debating the risks of low-level radiation. He is chief scientist at Consulting in the Public Interest.

Exhibit B : Comment by Drs. Lennart Hardell, Fredrik Soderqvist, PhD and Michael Carlberg, MSc.

Section 3.5.1.1 Epidemiological Studies, RF fields epidemiology, Pages 57-68

We have read the SCENIHR 2013 Preliminary opinion on Potential health effects of exposure to electromagnetic fields (EMF), especially relating to epidemiological studies on neoplastic diseases. It is concluded at page 4 in the abstract that "*Based on the most recent cohort and incidence time trend studies, it appears that the evidence for glioma became weaker while the possibility of an association with acoustic neuroma remains open*".

This statement is not based on facts but on selective inclusion of studies with omission of the most recent publications, e.g. from our research group (the Hardell group). Our studies were well known to the Expert group since Dr Kjell Hansson Mild was one of these experts and also a co-author in most of the Hardell group studies. In fact he communicated our studies to the SCENIHR expert group obviously without response. If these studies had been included it would be apparent that the final conclusions on brain tumour risk in SCENIHR are not based on scientific facts. In contrast the evidence for glioma and acoustic neuroma would become stronger if recent publications had been included.

In the Terms of Reference (page 16) it is stated that the Committee is requested e.g.:

1. To update its opinions of 2009 in the light of newly available information
2. To give particular attention to issues affected by important gaps in knowledge in the previous opinions, especially:
    - The potential adverse effects of EMF on the nervous system, including neurobehavioral disorders, and on the risk of neo-plastic diseases;

It seems as if the Committee has been anxious to include 'newly available information' at least regarding some studies, e.g. **Benson VS, Pirie K, Schüz J, Reeves GK, Beral V, Green J. Int J Epidemiol 2013, Sep 27**, see page 64, not included in reference list. On the contrary our studies were excluded. In the following a summary is given.

Background:

The carcinogenic effect of RF-EMF on humans was evaluated at a meeting during 24 – 31 May 2011 at the International Agency for Research on Cancer (IARC) at WHO in Lyon, France. The Working Group consisted of 30 scientists representing four areas: 'animal cancer studies', 'epidemiology', 'exposure' and 'mechanistic and other relevant data' (http://monographs.iarc.fr/ENG/Meetings/vol102-participants.pdf). One of us, LH, was invited as an expert in the epidemiology group. On 31 May 2011 IARC categorised RF-EMFs from mobile phones, and from other devices that emit similar non-ionising electromagnetic fields, as a Group 2B, i.e. a 'possible', human carcinogen. The decision was almost unanimous.

The IARC decision on mobile phones was based mainly on two sets of case-control human studies on brain tumour risk; our studies from Sweden (the Hardell group) and the IARC Interphone study. Both provided complementary and supportive results on positive associations between two types of brain tumours; glioma and acoustic neuroma, and exposure to RF-EMF from mobile phones. No consistent evidence was found for meningioma, a benign type of brain tumour. After the IARC meeting we have published further studies with new data, both overview of studies with meta-analysis (number 1 below) and our case-control study including brain

tumour cases diagnosed during 2007-2009 (number 2-4 below). Furthermore we applied the Hill viewpoints on the risk for brain tumours associated with use of mobile and cordless phones (number 5 below). These criteria were developed in the 1960's during the height of the tobacco and lung cancer controversy.

Recent studies from the Hardell group not included in SCENIHR 2013:

1. **Hardell L, Carlberg M, Hansson Mild K. Use of mobile phones and cordless phones is associated with increased risk for glioma and acoustic neuroma. *Pathophysiology* 2013;20:85-110. Epub 2012 Dec 21.**

Abstract
The International Agency for Research on Cancer (IARC) at WHO evaluation of the carcinogenic effect of RF-EMF on humans took place during a 24-31 May 2011 meeting at Lyon in France. The Working Group consisted of 30 scientists and categorised the radiofrequency electromagnetic fields from mobile phones, and from other devices that emit similar non-ionising electromagnetic fields (RF-EMF), as Group 2B, i.e., a 'possible', human carcinogen. The decision on mobile phones was based mainly on the Hardell group of studies from Sweden and the IARC Interphone study. We give an overview of current epidemiological evidence for an increased risk for brain tumours including a meta-analysis of the Hardell group and Interphone results for mobile phone use. Results for cordless phones are lacking in Interphone. *The meta-analysis gave for glioma in the most exposed part of the brain, the temporal lobe, odds ratio (OR)=1.71, 95% confidence interval (CI)=1.04-2.81 in the ≥10 years (>10 years in the Hardell group) latency group. Ipsilateral mobile phone use ≥1640h in total gave OR=2.29, 95% CI=1.56-3.37. The results for meningioma were OR=1.25, 95% CI=0.31-4.98 and OR=1.35, 95% CI=0.81-2.23, respectively. Regarding acoustic neuroma ipsilateral mobile phone use in the latency group ≥10 years gave OR=1.81, 95% CI=0.73-4.45. For ipsilateral cumulative use ≥1640h OR=2.55, 95% CI=1.50-4.40 was obtained.* Also use of cordless phones increased the risk for glioma and acoustic neuroma in the Hardell group studies. Survival of patients with glioma was analysed in the Hardell group studies yielding in the >10 years latency period hazard ratio (HR)=1.2, 95% CI=1.002-1.5 for use of wireless phones. This increased HR was based on results for astrocytoma WHO grade IV (glioblastoma multiforme). Decreased HR was found for low-grade astrocytoma, WHO grades I-II, which might be caused by RF-EMF exposure leading to tumour-associated symptoms and earlier detection and surgery with better prognosis. *Some studies show increasing incidence of brain tumours whereas other studies do not. It is concluded that one should be careful using incidence data to dismiss results in analytical epidemiology.* The IARC carcinogenic classification does not seem to have had any significant impact on governments' perceptions of their responsibilities to protect public health from this widespread source of radiation.

2. **Carlberg M, Söderqvist F, Hansson Mild K, Hardell L. Meningioma patients diagnosed 2007-2009 and the association with use of mobile and cordless phones, *Environ. Health* 2013;12:60, doi:10.1186/1476-069X-12-60. Epub Jul 19, 2013**

Abstract
BACKGROUND: To study the association between use of wireless phones and meningioma.
METHODS: We performed a case--control study on brain tumour cases of both genders aged 18--75 years and diagnosed during 2007--2009. One population-based control matched on gender and age was used to each case. Here we report on meningioma cases including all available controls. Exposures were assessed by a questionnaire. Unconditional logistic regression analysis was performed.
RESULTS: In total 709 meningioma cases and 1,368 control subjects answered the questionnaire. *Mobile phone use in total produced odds ratio (OR) = 1.0, 95% confidence interval (CI) = 0.7-1.4 and cordless phone use gave OR = 1.1, 95% CI = 0.8-1.5.* The risk increased statistically significant per 100 h of cumulative use and highest OR was found in the fourth quartile (>2,376 hours) of cumulative use for all studied phone types. There was no statistically significant increased risk for ipsilateral mobile or cordless phone use, for meningioma in the temporal lobe or per year of latency. Tumour volume was not related to latency or cumulative use in hours of wireless phones.
CONCLUSIONS: *No conclusive evidence of an association between use of mobile and cordless phones and meningioma was found.* An indication of increased risk was seen in the group with highest cumulative use but was not supported by statistically significant increasing risk with latency. Results for even longer latency periods of wireless phone use than in this study are desirable.

Abstract
We previously conducted a case-control study of acoustic neuroma. Subjects of both genders aged 20-80 years, diagnosed during 1997-2003 in parts of Sweden, were included, and the results were published. We have since made a further study for the time period 2007-2009 including both men and women aged 18-75 years selected from throughout the country. These new results for acoustic neuroma have not been published to date. Similar methods were used for both study periods. In each, one population-based control, matched on gender and age (within five years), was identified from the Swedish Population Registry. Exposures were assessed by a self-administered questionnaire supplemented by a phone interview. Since the number of acoustic neuroma cases in the new study was low we now present pooled results from both study periods based on 316 participating cases and 3,530 controls. Unconditional logistic regression analysis was performed, adjusting for age, gender, year of diagnosis and socio-economic index (SEI). Use of mobile phones of the analogue type gave odds ratio (OR) = 2.9, 95% confidence interval (CI) = 2.0-4.3, increasing with >20 years latency (time since first exposure) to OR = 7.7, 95% CI = 2.8-21. Digital 2G mobile phone use gave OR = 1.5, 95% CI = 1.1-2.1, increasing with latency >15 years to an OR = 1.8, 95% CI = 0.8-4.2. The results for cordless phone use were OR = 1.5, 95% CI = 1.1-2.1, and, for latency of >20 years, OR = 6.5, 95% CI = 1.7-26. Digital type wireless phones (2G and 3G mobile phones and cordless phones) gave OR = 1.5, 95% CI = 1.1-2.0 increasing to OR = 8.1, 95% CI = 2.0-32 with latency >20 years. *For total wireless phone use, the highest risk was calculated for the longest latency time >20 years: OR = 4.4, 95% CI = 2.2-9.0.* Several of the calculations in the long latency category were based on low numbers of exposed cases. Ipsilateral use resulted in a higher risk than contralateral for both mobile and cordless phones. OR increased per 100 h cumulative use and per year of latency for mobile phones and cordless phones, though the increase was not statistically significant for cordless phones. *The percentage tumour volume increased per year of latency and per 100 h of cumulative use, statistically significant for analogue phones. This study confirmed previous results demonstrating an association between mobile and cordless phone use and acoustic neuroma.*

4. **Hardell L, Carlberg M, Söderqvist F, Hansson Mild K. Case-control study of the association between malignant brain tumors diagnosed 2007-2009 and mobile and cordless phone use.** ***Int J Oncol.*** **2013;43:1833-1845. Epub 2013 Sep 24**

Abstract
Previous studies have shown a consistent association between long-term use of mobile and cordless phones and glioma and acoustic neuroma, but not for meningioma. When used these phones emit radiofrequency electromagnetic fields (RF-EMFs) and the brain is the main target organ for the handheld phone. The International Agency for Research on Cancer (IARC) classified in May, 2011 RF-EMF as a group 2B, i.e. a 'possible' human carcinogen. The aim of this study was to further explore the relationship between especially long-term (>10 years) use of wireless phones and the development of malignant brain tumours. We conducted a new case-control study of brain tumour cases of both genders aged 18-75 years and diagnosed during 2007-2009. One population-based control matched on gender and age (within 5 years) was used to each case. Here, we report on malignant cases including all available controls. Exposures on e.g. use of mobile phones and cordless phones were assessed by a self-administered questionnaire. Unconditional logistic regression analysis was performed, adjusting for age, gender, year of diagnosis and socio-economic index using the whole control sample. Of the cases with a malignant brain tumour, 87% (n=593) participated, and 85% (n=1,368) of controls in the whole study answered the questionnaire. *The odds ratio (OR) for mobile phone use of the analogue type was 1.8, 95% confidence interval (CI)=1.04-3.3, increasing with >25 years of latency (time since first exposure) to an OR=3.3, 95% CI=1.6-6.9. Digital 2G mobile phone use rendered an OR=1.6, 95% CI=0.996-2.7, increasing with latency >15-20 years to an OR=2.1, 95% CI=1.2-3.6. The results for cordless phone use were OR=1.7, 95% CI=1.1-2.9, and, for latency of 15-20 years, the OR=2.1, 95% CI=1.2-3.8. Few participants had used a cordless phone for >20-25 years.* Digital type of wireless phones (2G and 3G mobile phones, cordless phones) gave increased risk with latency >1-5 years, then a lower risk in the following latency groups, but again increasing risk with latency >15-20 years. Ipsilateral use resulted in a higher risk than contralateral mobile and cordless phone use. Higher ORs were calculated for tumours in the temporal and overlapping lobes. Using the meningioma cases in the same study as reference entity gave somewhat higher ORs indicating that the results were unlikely to be explained by recall or observational bias. This study confirmed previous results of an association between mobile and cordless phone use and malignant brain tumours. These findings provide support for the hypothesis that RF-EMFs play a role both in the initiation and promotion stages of carcinogenesis.

5. **Hardell L, Carlberg M. Using the Hill viewpoints from 1965 for evaluating strengths of evidence of the risk for brain tumors associated with use of mobile and cordless phones.** ***Rev Environ Health*** **2013;38:97-106. doi: 10.1515/reveh-2013-0006.**

Abstract
BACKGROUND: Wireless phones, i.e., mobile phones and cordless phones, emit radiofrequency electromagnetic fields (RF-EMF) when used. An increased risk of brain tumors is a major concern. The International Agency for Research on Cancer (IARC) at the World Health Organization (WHO) evaluated the carcinogenic effect to humans

from RF-EMF in May 2011. It was concluded that RF-EMF is a group 2B, i.e., a "possible", human carcinogen. Bradford Hill gave a presidential address at the British Royal Society of Medicine in 1965 on the association or causation that provides a helpful framework for evaluation of the brain tumor risk from RF-EMF.
METHODS: All nine issues on causation according to Hill were evaluated. Regarding wireless phones, only studies with long-term use were included. In addition, laboratory studies and data on the incidence of brain tumors were considered.
RESULTS: *The criteria on strength, consistency, specificity, temporality, and biologic gradient for evidence of increased risk for glioma and acoustic neuroma were fulfilled. Additional evidence came from plausibility and analogy based on laboratory studies. Regarding coherence, several studies show increasing incidence of brain tumors, especially in the most exposed area. Support for the experiment came from antioxidants that can alleviate the generation of reactive oxygen species involved in biologic effects, although a direct mechanism for brain tumor carcinogenesis has not been shown. In addition, the finding of no increased risk for brain tumors in subjects using the mobile phone only in a car with an external antenna is supportive evidence. Hill did not consider all the needed nine viewpoints to be essential requirements.*
CONCLUSION: Based on the Hill criteria*, glioma and acoustic neuroma should be considered to be caused by RF-EMF emissions from wireless phones and regarded as carcinogenic to humans,* classifying it as group 1 according to the IARC classification. Current guidelines for exposure need to be urgently revised.

SUMMARY

During 2013 our research group has published results from further studies on brain tumour risk associated with use of mobile and/or cordless desktop phones. We published data on tumour risk for use of these devices during 20 years or more. Clearly we find again an increased risk for malignant brain tumours including the most common type glioma (‘brain cancer’). We find also increased risk of acoustic neuroma, a benign tumour of the hearing nerve (number VIII). These tumours usually lead to hearing problems (deafness), tinnitus and dizziness although rarely lethal. Still we find no clear increased risk for meningioma, even after 20 years use of the mobile phone.

Especially worrying is that we find highest risk for glioma and acoustic neuroma in subjects who started use of the wireless phone before the age of 20 years. We have also found that the prognosis of glioma (astrocytoma grade IV) is worse the longer time one has used the wireless phone. That means that long-term use shortens the survival.

Further research has thus strengthened the evidence in support of an increased risk of malignant brain tumours and acoustic neuroma associated with use of mobile phones. Based on the latest findings and using the so called Hill viewpoints from the 1960’s exposure to RF-EMF from mobile phones may now be classified as a human cancer causing agent, Group 1, according to the definitions used by IARC.

It is unfortunate that SCENIHR has disregarded these findings and instead relies heavily on the much criticised Danish cohort study on mobile phone users with poor exposure data. We have discussed the many shortcomings in that study, see **Söderqvist F, Carlberg M, Hardell L. Review of four publications on the Danish cohort study on mobile phone subscribers and risk of brain tumors. *Reviews Environmental Health*. 2012; 27: 51-58.** SCENIHR lacks reference to our publication and accordingly also critical comments on the Danish cohort study. The same lack of critical review applies to the study by Benson et al, included in SCENIHR, but without acknowledge of the limitations in that study.

The CEFALO study on brain tumour risk in children is included in SCENIHR, however without a critical review of the study. For example use of cordless phones was assessed only during the 3 first years of use, a most peculiar definition. Our review of that study is omitted from SCENIHR, see **Söderqvist F, Carlberg M, Hansson Mild K, Hardell L. Childhood brain tumour risk and its association with wireless phones: a commentary. *Environmental Health*. 2011; 10: 106.**

In addition to the Danish cohort study and the UK study by Benson et al SCENIHR relies heavily on time trend analyses. However the conclusion by IARC in the 2011 evaluation was that: "*Time-trend analyses did not show an increased rate of brain tumours after the increase in mobile phone use. However, these studies have substantial limitations because most of the analyses examined trends until the early 2000s only. Such analyses are uninformative if excess risk only manifests more than a decade after phone use begins, or if phone use only affects a small proportion of cases—eg, the most heavily exposed, or a subset of brain tumours*." See **Baan R, Grosse Y, Lauby-Secretan B, *et al*. Carcinogenicity of radiofrequency electromagnetic fields. *Lancet Oncology*. 2011; 12: 624-626.**

In our publication number 4 above, we presented restricted cubic spline plot of the relationship between latency of wireless phone use and malignant brain tumours, see figure below. The solid line indicates the OR estimate and the broken lines represent the 95% CI. Adjustment was made for age at diagnosis, gender, SEI-code and year of diagnosis. Obviously the latency is 20+ years for malignant brain tumours according to these results. Thus, it confirms the conclusion by IARC on incidence data that "*Such analyses are uninformative if excess risk only manifests more than a decade after phone use begins";* in fact it may even be two decades based on our data. Our results are also in agreement with de Vocht et al "*According to these ecological results the latency period is at least 11-12 years, but probably more than 20 years."* See **de Vocht F, Hannam K, Buchan I. Environmental risk factors for cancers of the brain and nervous system: the use of ecological data to generate hypotheses. *Occup Environ Med* 2013; 70: 349-356.**

In summary, the preliminary SCENIHR conclusion that glioma risk is weaker now is not scientifically justified. The only way that conclusion could be reached by SCENIHR is to exclude critical studies that present evidence to the contrary, i.e. studies that report the risk of glioma (and acoustic neuroma) is stronger now than in 2009. Including our studies would give different conclusions supported by critical review of the limitations in cohort studies and incidence data. The Preliminary Opinion should be sent back to the Committee for new evaluation of the scientific data, and should integrate the results of these published data.

Electromagnetic pollution from phone masts. Effects on wildlife

Alfonso Balmori

Direccion General del Medio Natural, Consejería de Medio Ambiente, Junta de Castilla y Leon, C/Rigoberto Cortejoso, 14, 47014 Valladolid, Spain

Received 10 August 2008; received in revised form 28 August 2008; accepted 30 January 2009

Abstract

A review on the impact of radiofrequency radiation from wireless telecommunications on wildlife is presented. Electromagnetic radiation is a form of environmental pollution which may hurt wildlife. Phone masts located in their living areas are irradiating continuously some species that could suffer long-term effects, like reduction of their natural defenses, deterioration of their health, problems in reproduction and reduction of their useful territory through habitat deterioration. Electromagnetic radiation can exert an aversive behavioral response in rats, bats and birds such as sparrows. Therefore microwave and radiofrequency pollution constitutes a potential cause for the decline of animal populations and deterioration of health of plants living near phone masts. To measure these effects urgent specific studies are necessary.

Keywords: Effects on wildlife; Effects on birds; Electromagnetic radiation; Mammals; Microwaves; Mobile telecommunications; Non-thermal effects; Phone masts; Radiofrequencies

1. Introduction

Life has evolved under the influence of two omnipresent forces: gravity and electromagnetism. It should be expected that both play important roles in the functional activities of organisms [1]. Before the 1990's radiofrequencies were mainly from a few radio and television transmitters, located in remote areas and/or very high places. Since the introduction of wireless telecommunication in the 1990's the rollout of phone networks has caused a massive increase in electromagnetic pollution in cities and the countryside [2,3].

Multiple sources of mobile communication result in chronic exposure of a significant part of the wildlife (and man) to microwaves at non-thermal levels [4]. In recent years, wildlife has been chronically exposed to microwaves and RFR (Radiofrequency radiation) signals from various sources, including GSM and UMTS/3G wireless phones and base stations, WLAN (Wireless Local Area Networks), WPAN (Wireless Personal Area Networks such as Bluetooth), and DECT (Digital Enhanced (former European) Cordless Telecommunications) that are erected indiscriminately without studies of environmental impact measuring long-term effects. These exposures are characterized by low intensities, varieties of signals, and long-term durations. The greater portion of this exposure is from mobile telecommunications (geometric mean in Vienna: 73% [5]). In Germany the GSM cellular phone tower radiation is the dominating high frequency source in residential areas [6]. Also GSM is the dominating high frequency source in the wilderness of Spain (personal observation).

Numerous experimental data have provided strong evidence of athermal microwave effects and have also indicated several regularities in these effects: dependence of frequency within specific frequency windows of "resonance-type"; dependence on modulation and polarization; dependence on intensity within specific intensity windows, including super-low power density comparable with intensities from base stations/masts [4,7–9]. Some studies have demonstrated different microwave effects depending on wavelength in the range of mm, cm or m [10,11]. Duration of exposure may be as important as power density. Biological effects resulting from electromagnetic field radiation might depend on dose, which indicates long-term accumulative effects [3,9,12]. Modulated and pulsed radiofrequencies seem to be more effective in producing effects [4,9]. Pulsed waves (in blasts), as well as certain low frequency modulations exert greater

doi:10.1016/j.pathophys.2009.01.007

biological activity [11,13–15]. This observation is important because cell phone radiation is pulsed microwave radiation modulated at low frequencies [8,9].

Most of the attention on possible biological effects of electromagnetic radiation from phone masts has been focused on human health [5,16–21]. The effects of electromagnetic pollution on wildlife, have scarcely been studied [22–25].

The objective of this review is to detail advances in knowledge of radiofrequencies and microwave effects on wildlife. Future research may help provide a better understanding of electromagnetic field (EMF) effects on wildlife and plants and their conservation.

2. Effects on exposed wildlife

2.1. Effects on birds

2.1.1. Effects of phone mast microwaves on white stork

In monitoring a white stork (*Ciconia ciconia*) population in Valladolid (Spain) in vicinity of Cellular Phone Base Stations, the total productivity in nests located within 200 m of antennae, was 0.86 ± 0.16. For those located further than 300 m, the result was practically doubled, with an average of 1.6 ± 0.14. Very significant differences among total productivity were found ($U = 240$; $P = 0.001$, Mann–Whitney test). Twelve nests (40%) located within 200 m of antennae never had chicks, while only one (3.3%) located further than 300 m had no chicks. The electric field intensity was higher on nests within 200 m (2.36 ± 0.82 V/m) than nests further than 300 m (0.53 ± 0.82 V/m). In nesting sites located within 100 m of one or several cellsite antennae with the main beam of radiation impacting directly (Electric field intensity >2 V/m) many young died from unknown causes. Couples frequently fought over nest construction sticks and failed to advance the construction of the nests. Some nests were never completed and the storks remained passively in front of cellsite antennae. These results indicate the possibility that microwaves are interfering with the reproduction of white stork [23]. (Fig. 1)

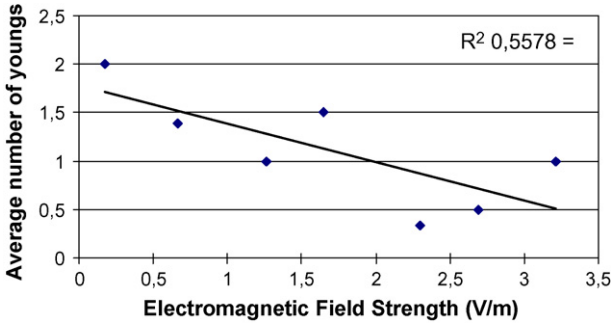

Fig. 1. Average number of youngs and electric field intensity (V/m) in 60 nests of white storks (*Ciconia ciconia*) (Hallberg, Ö with data of Balmori, 2005 [23]).

2.1.2. Effects of phone mast microwaves on house sparrows

A possible effect of long-term exposure to low-intensity electromagnetic radiation from mobile phone (GSM) base stations on the number of house sparrows during the breeding season was studied in Belgium. The study was carried out sampling 150 point locations within six areas to examine small-scale geographic variation in the number of house sparrow males and the strength of electromagnetic radiation from base stations. Spatial variation in the number of house sparrow males was negative and highly significantly related to the strength of electric fields from both the 900 and 1800 MHz downlink frequency bands and from the sum of these bands (Chi-square-tests and AIC-criteria, $P < 0.001$). This negative relationship was highly similar within each of the six study areas, despite differences among areas in both the number of birds and radiation levels. Fewer house sparrow males were seen at locations with relatively high electric field strength values of GSM base stations and therefore support the notion that long-term exposure to higher levels of radiation negatively affects the abundance or behavior of house sparrows in the wild [24].

In another study with point transect sampling performed at 30 points visited 40 times in Valladolid (Spain) between 2002 and 2006, counting the sparrows and measuring the mean electric field strength (radiofrequencies and microwaves: 1 MHz to 3 GHz range). Significant declines ($P = 0.0037$) were observed in mean bird density over time, and significantly low bird density was observed in areas with high electric field strength. The logarithmic regression of the mean bird density vs. field strength groups (considering field strength in 0.1 V/m increments) was $R = -0.87$; $P = 0.0001$ According to this calculation, no sparrows would be expected to be found in an area with field strength >4 V/m [25]. (Fig. 2)

In the United Kingdom a decline of several species of urban birds, especially sparrows, has recently happened [26]. The sparrow population in England has decreased in the last 30 years from 24 million to less than 14. The more abrupt decline, with 75% descent has taken place from 1994 to 2002. In 2002, the house sparrow was added to the Red List of U.K. endangered species [27]. This coincides with the rollout of mobile telephony and the

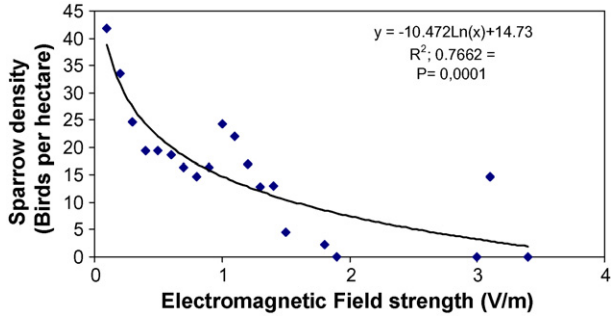

Fig. 2. Mean sparrow density as a function of electric field strength grouped in 0.1 V/m. (Balmori and Hallberg, 2007 [25]).

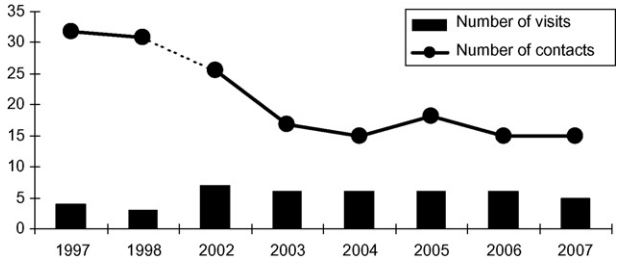

Fig. 3. Annual number of contacts (Mean) for 14 species studied in "Campo Grande" urban park (lack the information of the years 1999–2001).

possible relationship of both circumstances should be investigated.

In Brussels, many sparrows have disappeared recently [28]; similar declines have been reported in Dublin [29]. Van der Poel (cited in Ref. [27]) suggested that sparrows might be declining in Dutch urban centres also.

2.1.3. *Effects on the bird community at an urban park*

Microwaves may be affecting bird populations in places with high electromagnetic pollution. Since several antennas were installed in proximities of "Campo Grande" urban park (Valladolid, Spain) the bird population has decreased and a reduction of the species and breeding couples has occurred. Between 1997 and 2007, of 14 species, 3 species have disappeared, 4 are in decline and 7 stay stable (Balmori, unpublished data) (Fig. 3). In this time the air pollution (SO2, NO2, CO and Benzene) has diminished.

During the research some areas called "silence areas" contaminated with high microwave radiation (>2 V/m), where previously different couples usually bred and later disappeared, have been found. Several anomalies in magpies (*Pica pica*) were detected: plumage deterioration, locomotive problems (limps and deformations in the paws), partial albinism and melanism, especially in flanks [30]. Recently cities have increased cases of partial albinism and melanism in birds (*Passer domesticus*, *Turdus merula* and *P. pica*) (personal observation).

2.1.4. *Possible physiological mechanisms of the effects found in birds*

Current scientific evidence indicates that prolonged exposure to EMFs, at levels that can be encountered in the environment, may affect immune system function by affecting biological processes [3,31,32]. A stressed immune system may increase the susceptibility of a bird to infectious diseases, bacteria, viruses, and parasites [33].

The plumage of the birds exposed to microwaves looked, in general, discolorated and lack of shine. This not only occurred in ornamental birds; such as peacocks, but also in wild birds; such as, tits, great tits, house sparrows, etc (personal observation). We must mention that plumage deterioration is the first sign of weakening or illnesses in birds since damaged feathers are a sure sign of stress.

Physiological conditions during exposure minimize microwave effects. Radical scavengers/antioxidants might be involved in effects of microwaves [4].

Microwaves used in cellphones produce an athermal response in several types of neurons of the birds nervous system [34]. Several studies addressed behavior and teratology in young birds exposed to electromagnetic fields [23,25,35–37]. Most studies indicate that electromagnetic field exposure of birds generally changes, but not always consistently in effect or in direction, their behavior, reproductive success, growth and development, physiology and endocrinology, and oxidative stress [37]. These results can be explained by electromagnetic fields affecting the birds' response to the photoperiod as indicated by altered melatonin levels [38].

Prolonged mobile phone exposure may have negative effects on sperm motility characteristics and male fertility as has been demonstrated in many studies made in man and rats [39–46]. EMF and microwaves can affect reproductive success in birds [23,25,35,36,47]. EMF exposure affected reproductive success of kestrels (*Falco sparverius*), increasing fertility, egg size, embryonic development and fledging success but reducing hatching success [35,36].

The radiofrequency and microwaves from mobile telephony can cause genotoxic effects [48–55]. Increases in cytological abnormalities imply long-term detrimental effects since chromosomal damage is a mechanism relevant to causation of birth defects and cancer [55].

Long-term continuous, or daily repeated EMF exposure can induce cellular stress responses at non-thermal power levels that lead to an accumulation of DNA errors and to inhibition of cell apoptosis and cause increased permeability of blood–brain barrier due to stabilization of endothelial cell stress fibers. Repeated occurrence of these events over a long period of time (years) could become a health hazard due to a possible accumulation of brain tissue damage. These findings have important implications with regards to potential dangers from prolonged and repeated exposure to non-ionizing radiation [56,57].

Pulsed magnetic fields can have a significant influence on the development and incidence of abnormalities in chicken embryos. In five of six laboratories, exposed embryos exhibited more structural anomalies than controls. If the data from all six laboratories are pooled, the difference for the incidence of abnormalities in exposed embryos and controls is highly significant [58]. Malformations in the nervous system and heart, and delayed embryo growth are observed. The embryo is most sensitive to exposure in the first 24 h of incubation [58]. An increase in the mortality [59] and appearance of morphological abnormalities, especially of the neural tube [13,60,61] has been recorded in chicken embryos exposed to pulsed magnetic fields, with different susceptibility among individuals probably for genetic reasons. A statistically significant high mortality rate of chicken embryos subjected to radiation from a cellphone, compared to the control group exists [62,63]. In another study eggs exposed to a magnetic

field intensity of 0.07 T showed embryonic mortality during their incubation was higher. The negative effect of the magnetic field was manifested also by a lower weight of the hatched chicken [64]. Bioelectric fields have long been suspected to play a causal role in embryonic development. Alteration of the electrical field may disrupt the chemical gradient and signals received by embryo cells. It appears that in some manner, cells sense their position in an electrical field and respond appropriately. The disruption of this field alters their response. Endogenous current patterns are often correlated with specific morphogenetic events [65].

Available data suggests dependencies of genotype, gender, physiological and individual factors on athermal microwave effects [4,9]. Genomic differences can influence cellular responses to GSM Microwaves. Data analysis has highlighted a wide inter-individual variability in response, which was replicated in further experiments [4]. It is possible that each species and each individual, show different susceptibility to radiation, since vulnerability depends on genetic tendency, and physiologic and neurological state of the irradiated organism [15,35–37,61,66–68]. Different susceptibility of each species has also been proven in wild birds exposed to electromagnetic fields from high-voltage power lines [47].

2.2. Effects on mammals

2.2.1. Alarm and aversion behavior

Rats spent more time in the halves of shuttle boxes that were shielded from 1.2 GHz. Microwaves irradiation. The average power density was about 0.6 mW/cm^2. Data revealed that rats avoided the pulsed energy, but not the continuous energy, and less than 0.4 mW/cm^2 average power density was needed to produce aversion [69]. Navakatikian & Tomashevskaya [70] described a complex series of experiments in which they observed disruption of rat behavior (active avoidance) from radiofrequency radiation. Behavioral disruption was observed at a power density as low as 0.1 mW/cm^2 (0.027 W/kg). Mice in an experimental group exposed to microwave radiation expressed visible individual panic reaction, disorientation and a greater degree of anxiety. In the sham exposed group these deviations of behavior were not seen and all animals show collective defense reaction [71]. Microwave radiation at 1.5 GHz pulsing 16 ms. At 0.3 mW/cm^2 power density, in sessions of 30 min/day over one month produced anxiety and alarm in rabbits [72].

Electromagnetic radiation can exert an aversive behavioral response in bats. Bat activity is significantly reduced in habitats exposed to an electromagnetic field strength greater than 2 V/m [73]. During a study in a free-tailed bat colony (*Tadarida teniotis*) the number of bats decreased when several phone masts were placed 80 m from the colony [74].

2.2.2. Deterioration of health

Animals exposed to electromagnetic fields can suffer a deterioration of health and changes in behavior [75,76].

There was proof of frequent death in domestic animals; such as, hamsters and guinea pigs, living near mobile telecommunication base stations (personal observation).

The mice in an experimental group exposed to microwave radiation showed less weight gain compared to control, after two months. The amount of food used was similar in both groups [71]. A link between electromagnetic field exposure and higher levels of oxidative stress appears to be a major contributor to aging, neurodegenerative diseases, immune system disorders, and cancer in mammals [33].

The effects from GSM base transceiver station (BTS) frequency of 945 MHz on oxidative stress in rats were investigated. When EMF at a power density of 3.67 W/m^2, below current exposure limits, were applied, MDA (malondialdehyde) level was found to increase and GSH (reduced glutathione) concentration was found to decrease significantly ($P < 0.0001$). Additionally, there was a less significant ($P = 0.0190$) increase in SOD (superoxide dismutase) activity under EM exposure [77].

2.2.3. Problems in reproduction

In the town of Casavieja (Ávila, Spain) a telephony antenna was installed that had been in operation for about 5 years. Then some farmers began blaming the antenna for miscarriages in many pigs, 50–100 m from the antenna (on the outskirts of the town). Finally the topic became so bad that the town council decided to disassemble the antenna. It was removed in the spring 2005. From this moment onwards the problems stopped (C. Lumbreras personal communication).

A Greek study reports a progressive drop in the number of rodent births exposed to radiofrequencies. The mice exposed to 0.168 μW/cm^2 become sterile after five generations, while those exposed to 1.053 μW/cm^2 became sterile after only three generations [22].

In pregnant rats exposed to 27.12 MHz continuous waves at 100 μW/cm^2 during different periods of pregnancy, half the pregnancies miscarried before the twentieth day of gestation, compared to only a 6% miscarriage rate in unexposed controls, and 38% of the viable foetuses had incomplete cranial ossification, compared to less than 6% of the controls. Findings included a considerable increase in the percentage of total reabsorptions (post-implantation losses consequent to RF radiation exposure in the first post-implantation stage). Reduced body weight in the exposed dams reflected a negative influence on their health. It seems that the irradiation time plays an important role in inducing specific effects consequent to radiofrequency radiation exposure [78]. There was also a change in the sex ratio, with more males born to rats that had been irradiated from the time of conception [2]. Moorhouse and Macdonald [79] find a substantial decline in female Water Vole numbers in the radio-collared population, apparently resulting from a male skew in the sex ratios of offspring born to this population. Recruits to the *radio-tracked* population were skewed heavily in favour of males (43:13). This suggests that radio-collaring of females caused male-skewed sex ratios.

Mobile phone exposure may have negative effects on sperm motility characteristics and male fertility in rats [46]. Other studies find a decrease of fertility, increase of deaths after birth and dystrophic changes in their reproductive organs [11]. Intermittent exposure showed a stronger effect than continuous exposure [4]. Brief, intermittent exposure to low-frequency EM fields during the critical prenatal period for neurobehavioral sex differentiation can demasculinize male scent marking behavior and increase accessory sex organ weights in adulthood [80].

In humans, magnetic field exposures above 2.0 mG were positively associated with miscarriage risk [81]. Exposure of pregnant women to mobile phone significantly increased foetal and neonatal heart rate, and significantly decreased the cardiac output [82].

2.2.4. Nervous system

Microwaves may affect the blood brain barrier which lets toxic substances pass through from the blood to the brain [83]. Adang et al. [84] examined the effect of microwave exposure to a GSM-like frequency of 970 MHz pulsed waves on the memory in rats by means of an object recognition task. The rats that have been exposed for 2 months show normal exploratory behavior. The animals that have been exposed for 15 months show derogatory behavior. They do not make the distinction between a familiar and an unfamiliar object. In the area that received radiation directly from "Location Skrunda Radio Station" (Latvia), exposed children had less developed memory and attention, their reaction time was slower and neuromuscular apparatus endurance was decreased [85]. Exposure to cell phones prenatally and, to a lesser degree, postnatally was associated with behavioral difficulties such as emotional and hyperactivity problems around 7 years of age [86]. Electromagnetic radiation caused modification of sleep and alteration of cerebral electric response (EEG) [87–89]. Microwave radiation from phone masts may cause aggressiveness in people and animals (personal observation).

2.3. Effects on amphibians

Disappearance of amphibians and other organisms is part of the global biodiversity crisis. An associated phenomenon is the appearance of large numbers of deformed amphibians. The problem has become more prevalent, with deformity rates up to 25% in some populations, which is significantly higher than previous decades [90]. Balmori [91] proposed that electromagnetic pollution (in the microwave and radiofrequency range) is a possible cause for deformations and decline of some wild amphibian populations.

Two species of amphibians were exposed to magnetic fields at various stages of development. A brief treatment of early amphibian embryos produced several types of abnormalities [92]. Exposure to a pulsed electromagnetic field produced abnormal limb regeneration in adult Newts [93]. Frog tadpoles (*Rana temporaria*) developed under electromagnetic field (50 Hz, 260 A/m) have increased mortality. Exposed tadpoles developed more slowly and less synchronously than control tadpoles and remain at the early stages for longer. Tadpoles developed allergies and EMF caused changes in blood counts [94].

In a current study exposing eggs and tadpoles ($n = 70$) of common frog (*R. temporaria*) for two months, from the phase of eggs until an advanced phase of tadpole, to four telephone base stations located 140 m away: with GSM system 948.0–959.8 MHz; DCS system: 1830.2–1854.8; 1855.2–1879.8 MHz. and UMTS system: 1905–1910; 1950–1965; 2140–2155 MHz. (electric field intensity: 1.847–2.254 V/m). A low coordination of movements, an asynchronous growth, with big and small tadpoles, and a high mortality (90%) was observed. The control group ($n = 70$), under the same conditions but inside a Faraday cage (metallic shielding component: EMC-reinforcement fabrics 97442 Marburg Technic), the coordination of movements was normal, the development was synchronously and the mortality rate was only 4.2% [95].

2.4. Effects on insects

The microwaves may affect the insects. Insects are the basis and key species of ecosystems and they are especially sensitive to electromagnetic radiation that poses a threat to nature [96].

Carpenter and Livstone [97] irradiated pupae of Tenebrio molitor with 10 GHz microwaves at 80 mW for 20–30 min and 20 mW for 120 min obtained a rise in the proportion of insects with abnormalities or dead. In another study exposing fruit flies (*Drosophila melanogaster*) to mobile phone radiation, elevated stress protein levels (Hsp70) was obtained, which usually means that cells are exposed to adverse environmental conditions ('non-thermal shock') [98]. Panagopoulos et al. [99] exposed fruit flies (*D. melanogaster*) to radiation from a mobile phone (900 MHz) during the 2–5 first days of adulthood. The reproductive capacity of the species reduced by 50–60% in modulated radiation conditions (emission while talking on the phone) and 15–20% with radiation nomodulated (with the phone silent). The results of this study indicate that this radiation affects the gonadal development of insects in an athermal way. The authors concluded that radio frequencies, specifically GSM, are highly bioactive and provoke significant changes in physiological functions of living organisms. Panagopoulos et al. [100] compare the biological activity between the two systems GSM 900 MHz and DCS 1800 MHz in the reproductive capacity of fruit flies. Both types of radiation were found to decrease significantly and non-thermally the insect's reproductive capacity, but GSM 900 MHz seems to be even more bioactive than DCS 1800 MHz. The difference seems to be dependent mostly on field intensity and less on carrier frequency.

A study in South Africa finds a strong correlation between decrease in ant and beetle diversity with the

electromagnetic radiation exposure (D. MacFadyen, personal communication.). A decrease of insects and arachnids near base stations was detected and corroborated by engineers and antenna's maintenance staff [101]. In houses near antennas an absence of flies, even in summer, was found.

In a recent study carried out with bees in Germany, only a few bees irradiated with DECT radiation returned to the beehive and they needed more time. The honeycomb weight was lower in irradiated bees [102]. In recent years a "colony collapse disorder" is occurring that some authors relate with pesticides and with increasing electromagnetic pollution [96].

The disappearance of insects could have an influence on bird's weakening caused by a lack of food, especially at the first stages in a young bird's life.

2.5. *Effects on trees and plants*

The microwaves may affect vegetables. In the area that received radiation directly from "Location Skrunda Radio Station" (Latvia), pines (*Pinus sylvestris*) experienced a lower growth radio. This did not occur beyond the area of impact of electromagnetic waves. A statistically significant negative correlation between increase tree growth and intensity of electromagnetic field was found, and was confirmed that the beginning of this growth decline coincided in time with the start of radar emissions. Authors evaluated other possible environmental factors which might have intervened, but none had noticeable effects [103]. In another study investigating cell ultrastructure of pine needles irradiated by the same radar, there was an increase of resin production, and was interpreted as an effect of stress caused by radiation, which would explain the aging and declining growth and viability of trees subjected to pulsed microwaves. They also found a low germination of seeds of pine trees more exposed [104]. The effects of Latvian radar was also felt by aquatic plants. *Spirodela polyrrhiza* exposed to a power density between 0.1 and 1.8 $\mu W/cm^2$ had lower longevity, problems in reproduction and morphological and developmental abnormalities compared with a control group who grew up far from the radar [105].

Chlorophylls were quantitatively studied in leaves of black locust (*Robinia pseudoacacia* L.) seedlings exposed to high frequency electromagnetic fields of 400 MHz. It was revealed that the ratio of the two main types of chlorophyll was decreasing logarithmically to the increase of daily exposure time [106].

Exposed tomato plants (*Lycopersicon esculentum*) to low level (900 MHz, 5 V/m) electromagnetic fields for a short period (10 min) measured changes in abundance of three specific mRNA after exposure, strongly suggesting that they are the direct consequence of application of radio-frequency fields and their similarities to wound responses suggests that this radiation is perceived by plants as an injurious stimulus [107]. Non-thermal exposure to radiofrequency fields induced oxidative stress in duckweed (*Lemna minor*) as well as unespecific stress responses, especially of antioxidative enzymes [108].

For some years progressive deterioration of trees near phone masts have been observed in Valladolid (Spain). Trees located inside the main lobe (beam), look sad and feeble, possibly slow growth and a high susceptibility to illnesses and plagues. In places we have measured higher electric field intensity levels of radiation (>2 V/m) the trees show a more notable deterioration [109]. The tops of trees are dried up where the main beams are directed to, and they seem to be most vulnerable if they have their roots close to water. The trees don't grow above the height of the other ones and, those that stand out far above, have dried tops (Hargreaves, personal communication and personal observation). White and black poplars (*Populus sp*.) and willows (*Salix sp*.) are more sensitive. There may be a special sensitivity of this family exists or it could be due to their ecological characteristics forcing them to live near water, and thus electric conductivity. Other species as *Platanus sp*. and *Lygustrum japonicum,* are more resistant (personal observation). Schorpp [110] presents abundant pictures and explanations of what happens to irradiated trees.

3. Conclusions

This literature review shows that pulsed telephony microwave radiation can produce effects especially on nervous, cardiovascular, immune and reproductive systems [111]:

- Damage to the nervous system by altering electroencephalogram, changes in neural response or changes of the blood–brain barrier.
- Disruption of circadian rhythms (sleep–wake) by interfering with the pineal gland and hormonal imbalances.
- Changes in heart rate and blood pressure.
- Impairment of health and immunity towards pathogens, weakness, exhaustion, deterioration of plumage and growth problems.
- Problems in building the nest or impaired fertility, number of eggs, embryonic development, hatching percentage and survival of chickens.
- Genetic and developmental problems: problems of locomotion, partial albinism and melanism or promotion of tumors.

In the light of current knowledge there is enough evidence of serious effects from this technology to wildlife. For this reason precautionary measures should be developed, alongside environmental impact assessments prior to installation, and a ban on installation of phone masts in protected natural areas and in places where endangered species are present. Surveys should take place to objectively assess the severity of effects.

Raytheon Microwave Gun Recalled Amidst Controversy **Ethical and operational cases against the pain gun**

John Hudson Jul 19, 2010

A controversial microwave weapon called the Active Denial System has been recalled from Afghanistan, according to an Air Force spokesperson. The pain gun generates a targeted burning sensation in humans using millimeter waves. The device was plagued by a series of technical and safety issues. On top of that, a number of public commentators opposed it on humanitarian grounds. There's no official explanation for the recall, but here's what critics have said about it in recent weeks:

- **What Is the Active Denial System?** Sharon Weinberger at AOL News describes it as a "controversial nonlethal weapon that uses microwave energy to create intense pain...The weapon is designed to shoot an invisible beam of energy at people, creating an intense burning sensation that forces them to flee. The Air Force has called it the 'goodbye effect.'"

- **It's Very Effective,** writes the Wall Street Journal's Nathan Hodge, who felt the effects of it firsthand: "I dutifully took my turn. Even though I was standing several hundred meters downrange, I could immediately feel the heat when the operator fired. It wasn't that bad, at first: It was a miserably cold morning, and pain ray gave a nice blast of heat, like someone had opened an oven door right in front of me. But it quickly became unbearable. Instinctively, I stepped away."

- **Will This Really Help the War Effort?** wonders Noah Shachtman at Wired: "I'm sure they're telling themselves that the generally non-lethal microwave weapon is a better, safer crowd control alternative than an M-16. But those ray-gun advocates better think long and hard about the Taliban's propaganda bonanza when news leaks of the Americans zapping Afghans until they feel roasted alive."

- **This Tactic Is Unconscionable,** writes Digby at Hullabaloo: "Setting aside the fact that using a 'pain ray' in general is a horrible idea, how much more horrible is it to use in a country that already sees itself invaded by men who look like robot insects and where unmanned planes kill targets from a distance? It's hard not to see that as a weapons laboratory on a people who have no means to protest."

- **A Disturbing Trend,** writes Ando Arike at Harper's: "Although 'first-generation' weapons like rubber bullets and pepper spray have gained a certain acceptance, despite their many drawbacks, exotic technologies like the Active Denial System invariably cause public alarm. Nevertheless,The trend is now away from chemical and 'kinetic' weapons that rely on physical trauma and toward post-kinetic weapons that, as researchers put it, 'induce behavioral modification' more discreetly. One indication that the public may come to accept these new weapons has been the successful introduction of the Taser—apparently, even the taboo on electroshock can be overcome given the proper political climate."

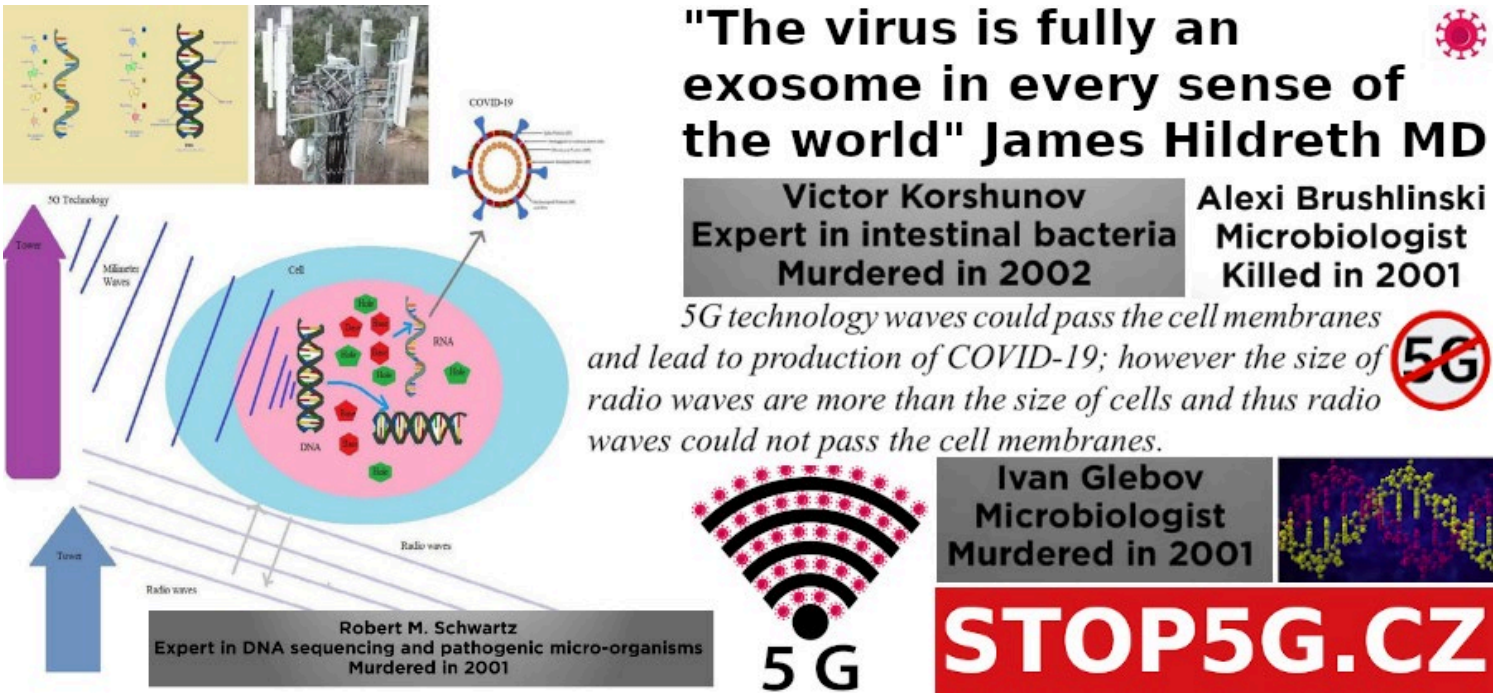
How Everyone Will Test Positive For COVID-19 – PCR Tests – 5G Technology and induction of coronavirus in skin cells



If you want to find the secrets of the universe, think in terms of energy, frequency and vibration.

Nicola Tesla

We know that the prescribed PCR tests are not detecting Covid-19 genome. According CDC's own literature (CDC 2019 – Novel Coronavirus 2019-nCoC – Real-time RT-PCR Diagnostic Panel) **Positive results are**

indicative of active infection with 2019-nCoV but do not rule out bacterial infection or co-infection with other viruses. They are detecting all varieties of Coronavirus, including the common cold and counted it as Covid-19.

How Everyone Will Test Positive For COVID-19

A positive test result shows you may have antibodies from an infection with the virus that causes COVID-19. However, there is a chance a positive result means that you have antibodies from an infection with a virus from the same family of viruses called coronaviruses, such as one that causes the common cold.

Having antibodies to the virus that causes COVID-19 may provide protection from getting infected with the virus again.

It has been pointed out for months, that geographical location experiencing the most cases of covid also seem to have active 5g technology. 5G Launches In Wuhan Weeks Before Coronavirus Outbreak After video went viral in which David Icke suggested that 5G somehow responsible for positive cases of Covid-19 YouTube deleted and begin to deleting all videos on the subject.

5G Technology and induction of coronavirus in skin cells

Received May 13, 2020 – Accepted June 9, 2020

This paper gives scientific explanation of relationship between 5G technology and Coronavirus.

In this research, we show that 5G millimeter waves could be absorbed by dermatologic cells acting like antennas, transferred to other cells and play the main role in producing Coronaviruses in biological cells. DNA is built from charged electrons and atoms and has an inductor-like structure. This structure could be divided into linear, toroid and round inductors. Inductors interact with external electromagnetic waves, move and produce some extra waves within the cells. The shapes of these waves are similar to shapes of hexagonal and pentagonal bases of their DNA source. These waves produce some holes in liquids within the nucleus. To fill these holes, some extra hexagonal and pentagonal bases are produced. These bases could join to each other and form virus-like structures such as Coronavirus. To produce these viruses within a cell, it is necessary that the wavelength of external waves be shorter than the size of the cell. Thus 5G millimeter waves could be good candidates for applying in constructing virus-like structures such as Coronaviruses (COVID-19) within cells.

[SPACEX – 5G – Earth in Microwave Oven – Satellites – Frequencies from 10.7 GHz to 86 GHz – Directed Energy Weapons – Palpitations – Abnormality of the Heartbeat]

ON MAY 26, SPACEX FILED an application with the Federal Communications Commission for 30,000 "next-generation" ("Gen2") satellites. They should orbit at between 328 km (203 miles) and 614 km (380 miles) in altitude. They should use frequencies from 10.7 GHz to 86 GHz. They should aim focused beams that can cover the Earth in a mosaic of overlapping cells, each cell being about 8 kilometers in diameter (5G Apocalypse – The Extinction Event). Wake up people!

The databases filed with the FCC by SpaceX indicate that 40,700 1-MHz channels are available to each satellite, and that a minimum of 7.8125 MHz of spectrum is needed for each user, if it's counted them correctly. Which means the Gen2 Starlink satellites could be capable of serving up to 150 million Internet users at the same time. (Project BlueBeam – Directed Energy Weapons, Holograms in the Sky, 5G Satellites, LRAD – Medusa)

This is not a good thing

Arthur Firstenberg requested to hear from people who have been having heart palpitations since April 22. With its launch of 60 more satellites on April 22, SpaceX brought the number of its "first generation" ("Gen1") satellites up to 420, which is the number it had previously announced it needed for "minor" coverage of the mid-latitudes to about 56 degrees north and south. The responses to my request have come from far and wide, and I find them extremely disturbing. Here are some of them: ***"I had a horrible bout of palpitations one evening while upstairs,"*** wrote Julie from Bulgaria. "I keep a journal and had recorded it, as I felt as though I was going to pass out or worse! The date? The 23rd of April."

"I checked my calendar back on April 22," wrote Crystal from California. "Yes indeed, I was a MESS that day with heart palpitations. I was also extremely dizzy, fatigued, confused, irritable and bloated. I was such a mess."

"Not only have I been having heart palpitations for three weeks now," wrote Elena from France on May 20, "I am having breathing difficulties. I am only 33 and in perfect health otherwise, doing a lot of sport and eating well. There have been a couple of nights when I thought I would have a heart attack, I was suffocating, could not breathe and my heart was beating so hard and fast, you could hear it from another room."

"In April about the 22nd I awakened with double vision," wrote John from Alabama. "I went to the ER and a CT scan was done and I was referred to a neurologist. He said that I had a stroke."

"I love earthing – just walking barefoot on the earth," wrote Suzy from England. "I have noticed these last days that when I put my feet on the earth I feel like there is a jagged vibration instead of the peace that I usually experience."

"For the last month or so I have been getting the most heavy and intense heart palpitations I have ever experienced," wrote Ivan from British Columbia, Canada on May 20. "Also in this last month my ability to get a good night's sleep has deteriorated significantly for no apparent reason."

"I have been having heart palpitations," wrote Rebecca from the state of Washington on May 21, "and my nine-year-old daughter has been complaining of feeling heartbeat in her head and even her legs. This began a few weeks ago."

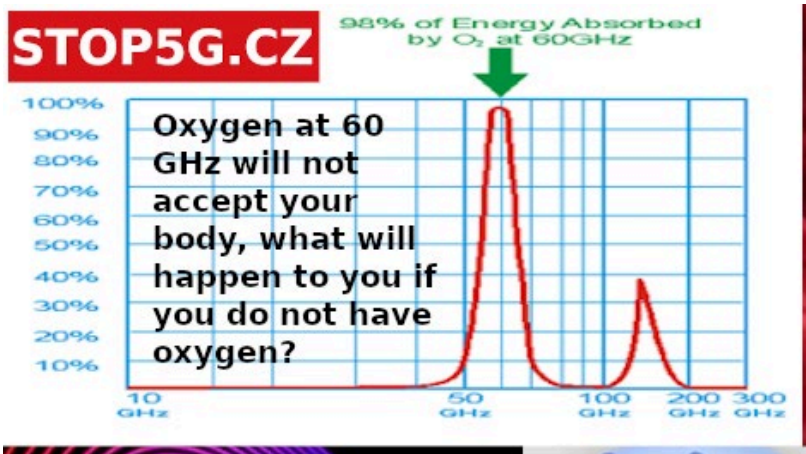
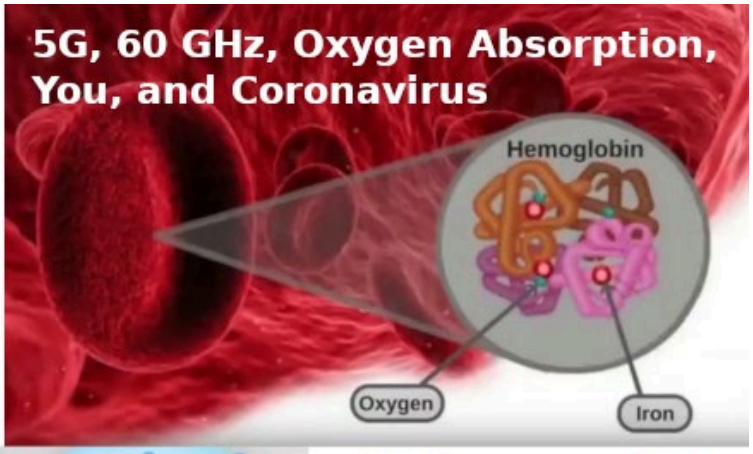
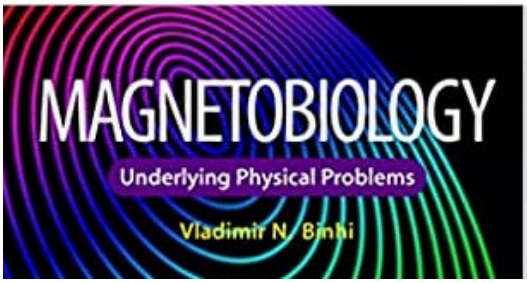
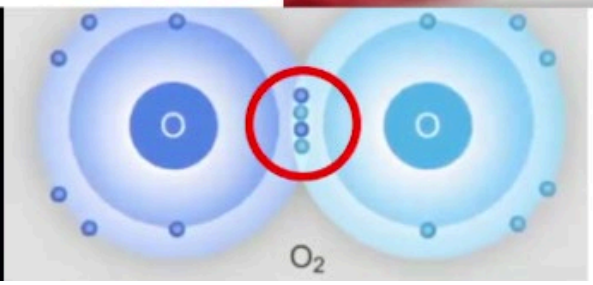
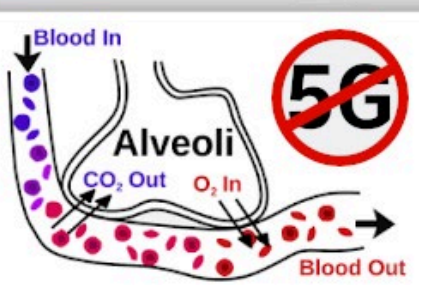
5G – 60GHz Wireless Network – Oxygen Absorption – Unable to Breath











Oxygen the atom is O. Oxygen the molecule is 0^2. Two atoms together. These two atoms form the oxygen molecule and share some electrons. 60 GHz causes electrons surrounding oxygen molecules to spin, akin to how high-powered microwaves running on 2.4 impact molecules in food such as water. They're heating, in part, by

impacting those molecules to rotate or oscillate with each wave. The movement energy from the rotation of these super tiny water molecules helps heat the rest of the food.

In a similar way that 2.4 causes H^20 to oscillate, 5G/60 GHz even at low power causes electrons on oxygen molecules to spin; changes to the spin frequencies on oxygen electrons impact human biology.

The *impact of oxygen molecules spinning the electrons is that it makes the hemoglobin unable to uptake the oxygen and get it to the rest of your body.*

60GHz Wireless Network

60GHz V-band wireless has many technical advantages as High speed links or lack of interference. The 57-64 GHz band is located in the millimeter-wave portion of the electromagnetic spectrum, where the wavelength varies from ten millimeters (30 GHz) down to one millimeter (300 GHz).

Exposure to Extremely Low-Frequency Electromagnetic Fields Modulates Na^+ Currents in Rat Cerebellar Granule Cells through Increase of AA/PGE_2 and EP Receptor-Mediated cAMP/PKA Pathway

Yan-Lin He[☯], Dong-Dong Liu[☯], Yan-Jia Fang, Xiao-Qin Zhan, Jin-Jing Yao, Yan-Ai Mei*

Institutes of Brain Science, School of Life Sciences and State Key Laboratory of Medical Neurobiology, Fudan University, Shanghai, China

Abstract

Although the modulation of Ca^{2+} channel activity by extremely low-frequency electromagnetic fields (ELF-EMF) has been studied previously, few reports have addressed the effects of such fields on the activity of voltage-activated Na^+ channels (Na_v). Here, we investigated the effects of ELF-EMF on Na_v activity in rat cerebellar granule cells (GCs). Our results reveal that exposing cerebellar GCs to ELF-EMF for 10–60 min significantly increased Na_v currents (I_{Na}) by 30–125% in a time- and intensity-dependent manner. The Na_v channel steady-state activation curve, but not the steady-state inactivation curve, was significantly shifted (by 5.2 mV) towards hyperpolarization by ELF-EMF stimulation. This phenomenon is similar to the effect of intracellular application of arachidonic acid (AA) and prostaglandin E_2 (PGE_2) on I_{Na} in cerebellar GCs. Increases in intracellular AA, PGE_2 and phosphorylated PKA levels in cerebellar GCs were observed following ELF-EMF exposure. Western blottings indicated that the Na_V 1.2 protein on the cerebellar GCs membrane was increased, the total expression levels of Na_V 1.2 protein were not affected after exposure to ELF-EMF. Cyclooxygenase inhibitors and PGE_2 receptor (EP) antagonists were able to eliminate this ELF-EMF-induced increase in phosphorylated PKA and I_{Na}. In addition, ELF-EMF exposure significantly enhanced the activity of PLA_2 in cerebellar GCs but did not affect COX-1 or COX-2 activity. Together, these data demonstrate for the first time that neuronal I_{Na} is significantly increased by ELF-EMF exposure *via* a cPLA2 AA PGE_2 EP receptors PKA signaling pathway.

Introduction

A number of studies have noted that exposure to extremely low-frequency electromagnetic fields (ELF-EMF) alter animal behaviors and modulate biological effects, including changes in gene expression, regulation of cell survival and promotion of cell differentiation [1–3]. In addition, exposure to ELF-EMF induces changes in cerebral blood flow in old Alzheimer's mice. Enzyme activity in the cytosol or at the membrane and subsequent alternations in intracellular signaling are found in lymphoma B cells and Chinese hamster lung (CHL) cells upon exposure to ELF-EMF [4–6]. ELF-EMF can also modify the biophysical properties of cell membranes, such as changes in the membrane permeability of carbonic anhydrase [7], stimulation of the activity of Ca^{2+}-activated potassium channels via increases in Ca^{2+} concentration [3,8] and increased the expression level of Ca^{2+} channel protein [9]. However, very few studies have investigated the effects of EMF on sodium channels, in particular, the voltage-gated sodium (Na_v) channels which are highly expressed in neurons.

Voltage-gated sodium channels (Na_V) are one of the primary classes of ion channels responsible for driving neuronal excitability in both the central and peripheral nervous system. Na_V are clinically important because they play an important role in the generation of neuronal activity and alterations in Na_V are key factors in a number of pathologies [10]. Recent studies have revealed that Na_V channels participate in the rising phase of the neuronal action potential and contribute to many cellular functions including apoptosis, motility and secretory membrane activity [11–13]. Moreover, the EMF exposure was recently reported to modulate neuronal excitation and neurogenesis, which may be related to Na_V channel activity [8,14,15]. Thus, a thorough investigation of the influence of ELF-EMF on Na_V channels and the corresponding mechanism of action could help to uncover the effects of ELF-EMF-induced biological effects on brain physiology, pathogenesis and neural development.

Cerebellar granule cells (GCs) occupy a key position in the cerebellar–cortical circuitry by forming the input layer of the major cerebellar afferent system. Cerebellar GCs grown in primary culture express tetrodotoxin (TTX)-sensitive Na_V channels which are responsible for action potentials (APs) and for the code relay in the cerebellar circuitry [16,17]. Cerebellar GCs are widely used as a model for neuronal cell development and apoptosis [18–20]. We have previously shown that the I_{Na} densities of cerebellar GCs are modulated by the lipid products ceramide and arachidonic acid (AA). Ceramide reduces the I_{Na} of

cerebellar GCs by increasing calcium release through the ryanodine-sensitive Ca^{2+} receptor [21] while elevation in intracellular AA levels increases the I_{Na} of cerebellar GCs through the PGE_2-mediated activation of the cAMP/PKA pathway [22]. The present study was conducted to determine whether exposure to ELF-EMF influences the Na^+ channels of cerebellar GCs and, if so, whether this effect is mediated by changes in ceramide and/or arachidonic acid. The data presented in this report demonstrate that the activity of neuronal Na^+ channels is significantly increased by ELF-EMF stimulation. Notably, the effect of ELF-EMF is mediated by an increase in $cPLA_2$ activity and subsequent changes in intracellular concentration of arachidonic acid (AA) and EP receptor-mediated activation of the cAMP/PKA signaling pathway are involved.

Results

First, we investigated the actions of extremely low frequency electromagnetic fields (ELF-EMF) on the I_{Na} of cerebellar GCs. An I_{Na} was elicited by a depolarization step to −20 mV from the holding potential of −100 mV. When cerebellar GCs were exposed to ELF-EMF (1 mT) for 10 min, the amplitude of the I_{Na} was increased by approximately 51.8% ±3.8% ($n = 12$, $P<0.05$) compared to cells that were not exposed to ELF-EMF ($n = 8$, Fig. 1A). However, the mean capacitance of recorded cells for the control group (13.05±0.40 pF, $n = 7$) and for the ELF-EMF treatment group (12.45±0.77pF, $n = 6$) showed no significant difference ($P = 0.48$). The similar in capacitance indicated that the increased current density upon ELF-EMF exposure was not due to different in abnormal cell morphology. In addition, the increase in I_{Na} density induced by ELF-EMF exposure was time dependent. When cerebellar GCs were exposed to ELF-EMF for 30 min, 60 min or 90 min, the density of the I_{Na} increased by 67.1% ±4.38% ($n = 8$, $P<0.05$), 125.6% ±8.26% ($n = 16$, $P<0.05$), 102.4% ±4.1% ($n = 9$, $P<0.05$), respectively, compared to controls (Fig. 1B). We also tested the effects of low-density ELF-EMF (0.4 mT) on I_{Na}. The results shown in Fig. 1C indicated that, when cerebellar GCs were exposed to 0.4 mT ELF-EMF, a longer exposure time was needed to induce an increase in I_{Na} density. The density of I_{Na} was only increased by 3.62% ±2.38% ($n = 6$) when cerebellar GCs were exposed to ELF-EMF (0.4 mT) for 6 h. Upon an increase in the length of cell exposure to ELF-EMF (0.4 mT) to 12 h, the I_{Na} density increased by 31.6% ±3.38% ($n = 8$, $P<0.05$, Fig. 1D). Because a previous study indicated that when cells are exposed to ELF-EMF over a long term, their levels of protein expression may be affected [5], which will be difficult to further identify the primary factor involved in the ELF-EMF-induced I_{Na} increase. Thus, we chose to focus on the mechanism by which a relatively short-term exposure to a 1 mT ELF-EMF induces an I_{Na} increase.

Next, we investigated the effects of ELF-EMF on the voltage-gating properties of I_{Na} channels. The activation properties of I_{Na} in cerebellar GCs following exposure to ELF-EMF were studied using the appropriate voltage protocols. I_{Na} were evoked by a 20 ms depolarizing pulse from a holding potential of −100 mV to potentials between −70 and 20 mV, with 5 mV steps 5 s intervals (Fig. 2A). Fig. 2B illustrated a voltage-current curve in which the maximum activation potential was changed from −27.3±0.9 mV to −32.5±2.5 mV when cerebellar GCs were exposed to ELF-EMF for 60 min ($n = 13$ for control and $n = 12$ for ELF-EMF exposure, $P<0.05$). A value for steady-state activation of I_{Na} was then obtained by normalizing the conductance as a function of the command potential; conductance was calculated as $G_{Na} = I_{Na}/(Vm1/2–Vrev)$. The data points were fitted to the Boltzmann function $G_{Na}/G_{Na}\text{-max} = 1/\{1+\exp[(Vm1/2–Vm)/k]\}$. As shown in Fig. 2C, after cerebellar GCs were exposed to ELF-EMF for 60 min, the half-activation potentials changed from −40.93±0.67 mV to −46.87±1.3 5 mV ($n = 10$, $P<0.05$), with slope factors of 3.7±0.1 mV and 4.6±1.0 mV ($n = 10$). These data indicate that ELF-EMF exposure significantly shifts the voltage dependence of the steady-state activation of I_{Na} of cerebellar GCs.

Next, we studied the effects of ELF-EMF exposure on the voltage dependence of the steady-state inactivation of I_{Na} channels. I_{Na} were elicited using 1-s conditioning pre-pulses ranging from −100 to −40 mV in steps of 5 mV prior to a −10 mV test pulse (Fig. 2D). The steady-state inactivation curve was then fitted using the Boltzmann equation $I_{Na}/I_{Namax} = 1/\{1+\exp[(V_m–V_{m1/2})/k]\} + A$. In the 11 cells studied, the $V_{m\ 1/2}$ values were −72.7±0.74 mV ($n = 6$) and −68.2±0.75 mV ($n = 5$) for cells with or without ELF-EMF exposure, respectively (Fig. 2E). These data indicate that the steady-state inactivation curve of I_{Na} in cerebellar GCs did not significantly shift upon exposure to ELF-EMF.

Our previous study showed that elevation in arachidonic acid (AA) concentration increased I_{Na} through prostaglandin E_2 (PGE_2)-mediated activation of the cAMP/PKA pathway [22]. In the present study, the effect of ELF-EMF exposure on I_{Na} and the I_{Na} steady-state activation curve was similar to the effect of AA on I_{Na}. We therefore tested whether cAMP/PKA activation was involved in the increase in I_{Na} in cerebellar GCs subjected to ELF-EMF exposure. The results in Fig. 3A showed that H-89, a selective PKA antagonist, significantly attenuated the increase in I_{Na} elicited by ELF-EMF exposure. Incubating cerebellar GCs with 10 μM H-89 for 60 minutes decreased the evoked I_{Na} by 42.7% ±4.0% ($n = 9$, $P<0.05$). There was, however, only 12.4% ±6.4% (n = 14) in I_{Na} after exposure to ELF-EMF in the presence of H89. Hence, H89 suppressed the induction of the I_{Na} activity after ELF-EMF exposure. Similarly, administration of 10 μM dibutyryl cAMP (db-cAMP, a embrane-permeable cAMP analog) produced a significant increase of I_{Na} by 47.2±6.6% ($n = 7$, $P<0.05$). Notably, exposure to ELF-EMF did not further potentiate the effect of db-cAMP on I_{Na} (54.8±8.9%, $n = 20$). Hence, these data support our conclusion that cAMP/PKA pathway is involved in the effect of ELF-EMFs on I_{Na}.

In addition, we determined the intracellular levels of phosphorylated PKA (pPKA) by immunoblot assays and found significant increase in phospho-PKA after ELF-EMF exposure. These data indicate that when the cells were exposed to ELF-EMF, the intracellular levels of pPKA were increased by 38.6% ±3.76% ($n = 4$, $P<0.05$), 42.4% ±4.32% ($n = 4$, $P<0.05$),30.4% ±1.5% ($n = 4$, $P<0.05$) and 17.8±2.14% ($n = 4$, $P<0.05$), respectively (Fig. 3C). These data suggest that PKA activation is associated with the ELF-EMF-induced increase in I_{Na} in cerebellar GCs.

Previous study indicated that Na_V activities can be modulated by the cAMP/PKA pathways upon phosphorylation of the α-subunits of Na_V channels [23]. Besides increases in the modification of steady-state activation propriety, exposure to ELF-EMF might also elicit insertion of additional Na_V channels into the membrane, which might then further account for the ELF-EMF-induced up-regulation of I_{Na}. To investigate whether ELF-EMF induced insertion of new Nav channels on the membrane, we first ascertained that Na_V 1.2 α-subunits plays a significant role in Na_V channel of cerebellar GCs as reported previously [17]. As shown in Fig. 4A, the expression of Na_V 1.2 was significantly reduced by siRNA. Similarly, the current amplitude of I_{Na} was also significantly reduced. The current amplitude of I_{Na} recorded from

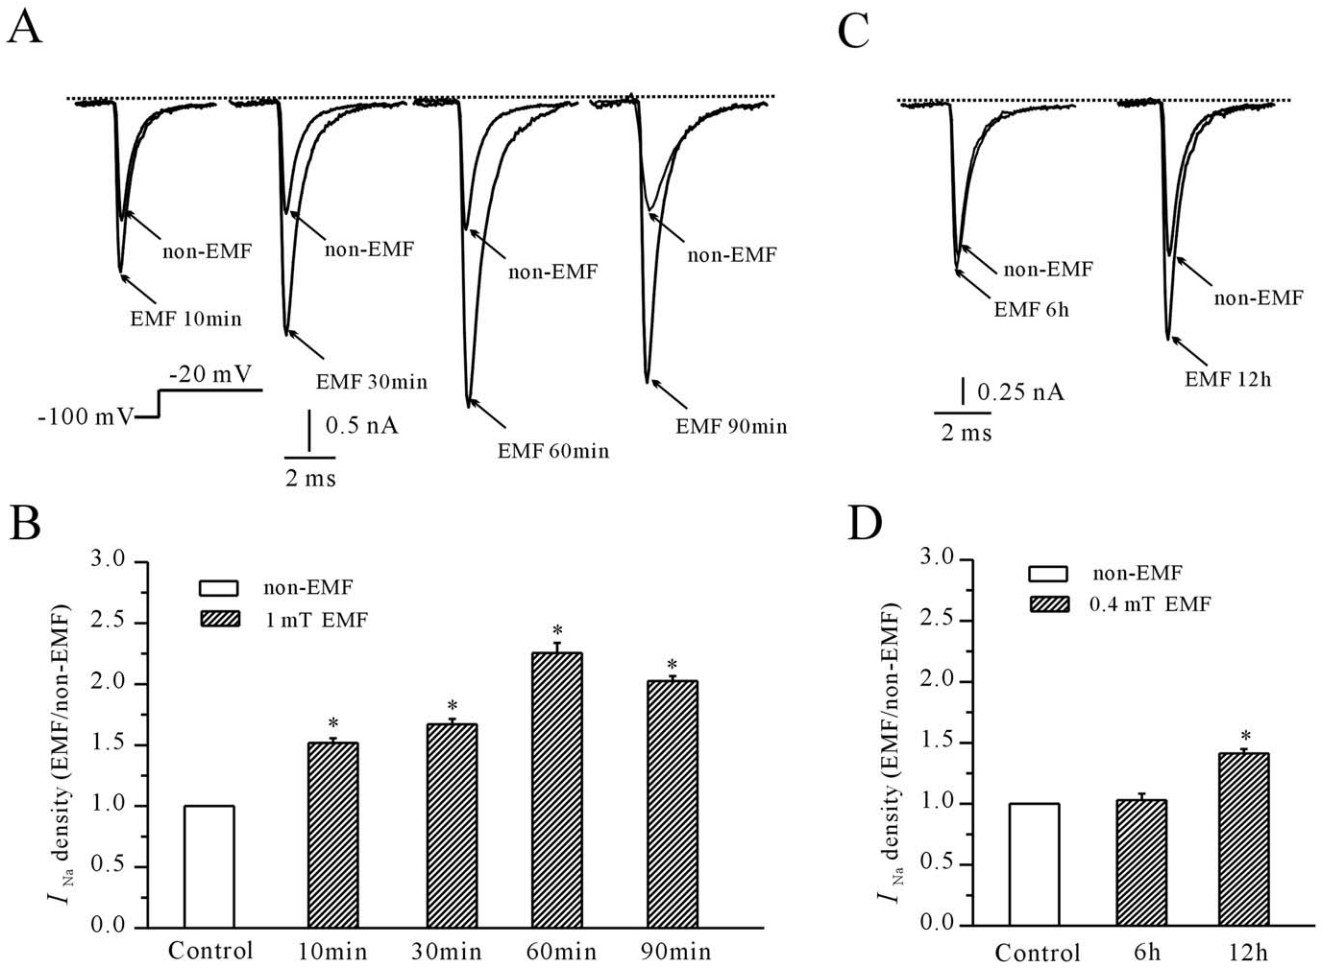

Figure 1. Time-dependent increase in I_{Na} in cerebellar GCs following exposure to ELF-EMF (1 mT or 0.4 mT). Superimposed I_{Na} evoked by a 20 ms depolarizing pulse from a holding potential from −100 to −20 mV. Current traces were obtained from cerebellar GCs exposed to ELF-EMF (1 mT) for lengths of time ranging from 10 min to 90 min. (B) Statistical analysis of the activating effects of ELF-EMF (1 mT) exposure at various times on the density of I_{Na}. The data are reported as the mean ± S.E.M. from 8–16 cells. *, $P<0.05$ compared to control using a one-way ANOVA test. (C) I_{Na} traces obtained from cerebellar cells exposed to ELF-EMF (0.4 mT) for 6 h and 12 h. (D) Statistical analysis of the activating effects of ELF-EMF (0.4 mT) exposure for 6 h and 12 h on the density of I_{Na}. The data are reported as the mean ± S.E.M. from 8–10 cells. *, $P<0.05$ compared to control using Student's *t*-test.

the control group was −1400.32±162.15 pA ($n=7$), and it was reduced to −207.89±95.55 pA ($n=5$, $P<0.05$) after knocking down the Na_V 1.2 gene (Fig. 4B).

Next, we determined the levels of Na_V 1.2 protein on membrane surface using biotinylation assay. The data obtained from four independent experiments showed that the Na_V 1.2 protein on the cerebellar GCs membrane (Na_V 1.2 M) was increased by 21.8% ±3.3% after exposed to ELF-EMF for 60 min (Fig. 4C). The total expression levels of Na_V 1.2 protein (Na_V 1.2 T), however, was not affected after exposure to ELF-EMF (Fig. 4D). These data indicate that exposure to ELF-EMF activates PKA, which then modulates I_{Na}, in part, by insertion of new Na_V channels into the membrane.

It is well known that the cellular effects of PGE_2 are mediated through a family of G-protein-coupled receptors designated EP1, EP2, EP3 and EP4 [24,25]. Of these, EP2 and EP4 are involved in activation of the cAMP/PKA pathway [26]. Our previous study demonstrated that all four types of EP receptors mRNA are found in cerebellar GCs [22]. Because EP2 and EP4 can activate the PKA pathway, we used EP2 and EP4 receptor antagonists (AH6809 and AH23848, respectively) to investigate whether EP receptors played a role in the activation of PKA after exposure to ELF-EMF. As shown in Fig. 5A and 5B, in the presence of 20 μM AH6809 or 20 μM AH23848, 60 minutes of ELF-EMF exposure only increased I_{Na} by 9.54% ±4.7% ($n=6$) and 5.52±4.71% ($n=5$), respectively. In the absence of the EP receptor antagonists, exposure to ELF-EMF increased I_{Na} to 125.6% ±8.26% ($n=16$, $P<0.05$). Similarly, blocking EP2 and EP4 receptors using AH6809 or AH23848 significantly reduced the ELF-EMF exposure-induced increase in pPKA levels. The results in Fig. 5C showed that in the presence of 20 μM AH6809 or 20 μM AH23848, 60 min of ELF-EMF exposure only increased intracellular levels of pPKA by 7.25% ±1.67% or 6.5% ±2.8% ($n=4$), respectively.

Because EP receptors, which stimulate the cAMP/PKA signaling pathway, are activated by PGE_2, we next studied the release of PGE_2 from cerebellar GCs following exposure to ELF-EMF using a direct rat PGE_2 ELISA kit. As shown in Fig. 6A, the amount of PGE_2 released from control cerebellar GCs was 64.36±1.88 pmol. Following exposure to ELF-EMF

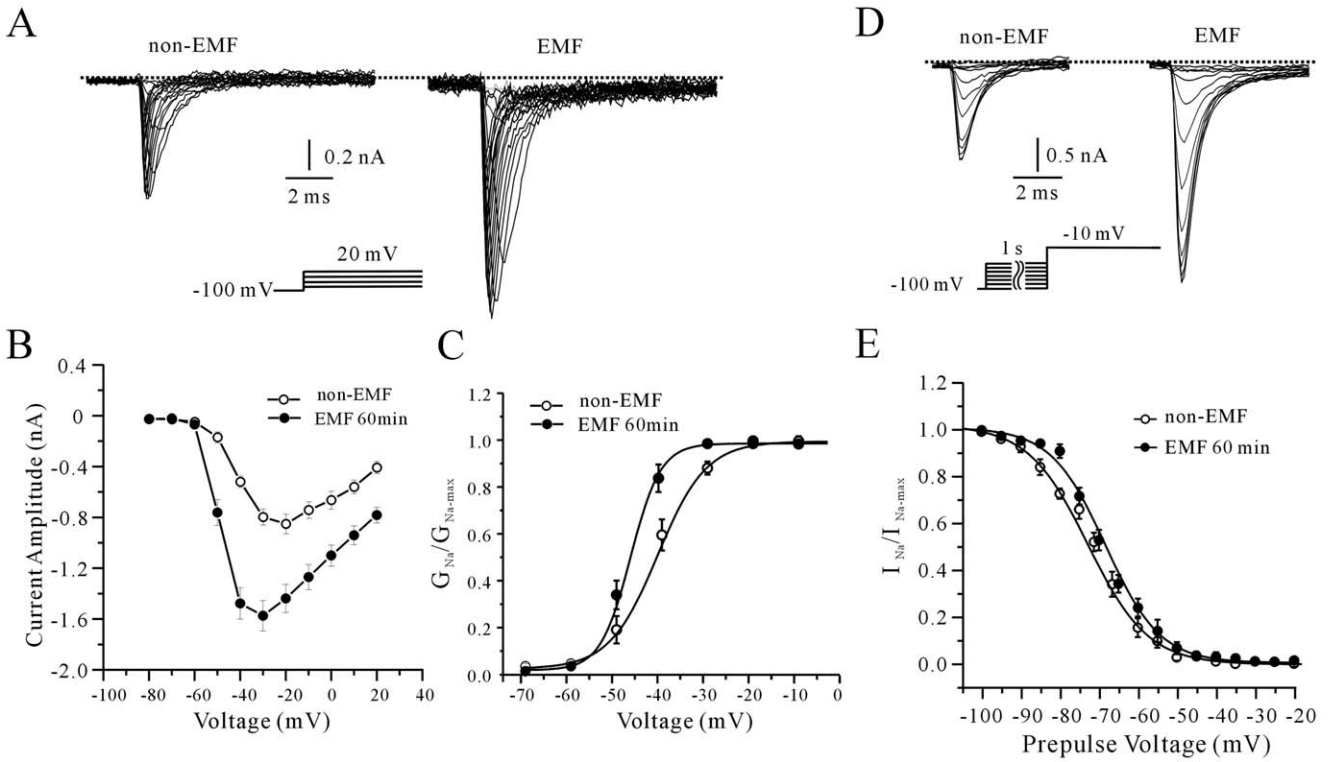

Figure 2. The effects of 1 mT ELF-EMF exposure on the steady-state activation and inactivation of I_{Na}. (A) The effects of 60 minutes of ELF-EMF exposure on the steady-state activation of I_{Na}. The cells were held at −100 mV and depolarized in 5 mV steps from −70 to 20 mV with intervals of 5 s. (B) The voltage-dependent activation curve of I_{Na} in control cells and cells exposed to ELF-EMF. The data are from 13 (control) or 12 (ELF-EMF-exposed) cells and are expressed as means ± SEM. (C) Comparison of the plot of the normalized conductance of I_{Na} as a function of the command potential in control and ELF-EMF-exposed cells. (D) The effects of 60 minutes of ELF-EMF exposure on the steady-state inactivation of I_{Na}. The voltage protocol is shown below the current record. (E) Steady-state inactivation curves of I_{Na} for control and ELF-EMF-exposed cells. The data are from 6 (control) and 5 cells (ELF-EMF-exposed) and are expressed as means ± S.E.M.
